**Abstract.** Changes in anthropogenic activity during public holidays influence air pollutant concentrations. The objective of this study is to quantify the public holiday's effect on air quality and to analyse the added value of accounting for the holidays in AQ modelling and forecasting. Spatial and temporal distributions of atmospheric concentrations of the major air pollutants (main attention put to  
10 NO<sub>2</sub>, but also included O<sub>3</sub>, CO, PM<sub>2.5</sub>, SO<sub>2</sub>) were considered at the European scale for all public holidays of 2018. Particular attention was given to the events with the most-pronounced continental or regional impact: Christmas and New Year, Easter, May vacations and last days of Ramadan. The simulations were performed with the Eulerian chemistry transport model SILAM v.5.7. Three model runs were performed: the baseline with no treatment of holidays, the run considering holidays as  
15 Sundays, and the run forcing 80% reduction of emissions during holidays, for the week-day sensitive sectors. The emission scaling was applied on a country basis. The model predictions were compared with in-situ observations collected by the European Environment Agency. The experiment showed that even conservative treatment of official holidays has a large positive impact on NO<sub>x</sub> (up to 30% of bias reduction in the holiday days) and also improves the CO, PM<sub>2.5</sub> and O<sub>3</sub> predictions. In many cases, the  
20 sensitivity study suggested deeper emission reduction than the level of Sundays. An individual consideration of the holiday events in different countries may further improve their representation in the models: specific diurnal pattern of emissions, additional emission due to fireworks, different driving patterns, etc.

25 **Keywords:** holiday emissions of air pollutants, AQ modelling, SILAM model, AQ model sensitivity

## 1. Introduction

Air quality (AQ) and its temporal and spatial changes are determined by human activities via the release of various aerosols and gases (Derwent and Hjellbrekke, 2012; Fu et al., 2020; Hassan et al., 2013; Karl et al., 2019; Kukkonen et al., 2020; Lehtomäki et al., 2018; Shi et al., 2019), and modulated by  
30 meteorological conditions (Jacob and Winner, 2009; Jhun et al., 2015; Singh et al., 2013; Sofiev et al., 2020).

The ability of atmospheric composition models to follow the temporal variability of air pollution critically depends on representation of the emission temporal behavior by the inventories used by the

models. Arguably the most-difficult task is to catch the variations originating from rare events. Changes  
35 in the human behavior during non-working days of various type (Beirle et al., 2003; de Foy et al., 2020,  
2016; Elansky, 2020; Gour et al., 2013; Hassan et al., 2013; Xu et al., 2017; Zou et al., 2019; Rozbicka  
and Rozbicki, 2016), including some religious ceremonies (Dasari et al., 2020), cultural practices  
(Khezri et al., 2015; Nodehi et al., 2018; Ye et al., 2016), celebratory events and festivities (Hoyos et  
al., 2020; Jiang et al., 2015; Lai and Brimblecombe, 2017; Retama et al., 2019), etc cause large  
40 variations of emission of air pollutants, which are hard to quantify because of their specificity.  
However, the weekend and (some) holiday effects have certain similarities, which might allow drawing  
an analogy between weekday vs. weekend and holiday vs. non-holiday pollution levels.

Majority of currently available emission inventories are built as gridded yearly or monthly totals for the  
key primary pollutants (Frost et al., 2013; Granier et al., 2019, 2011), (<https://eccad.aeris-data.fr/>, access  
45 5.2.2021). Temporal variations at shorter time scales received less attention but their impact on AQ  
itself and the model's ability to reproduce the concentration has been considered in several studies as  
well (Fu et al., 2013; Gioli et al., 2015; Guevara et al., 2017, 2021; Iriti et al., 2020; McGraw et al.,  
2010). Several studies have demonstrated the crucial role of spatial and temporal resolution of emission  
inventories in environmental science, air quality modeling, and air pollution policy making (Frost et al.,  
50 2013; Gioli et al., 2015; Zhao et al., 2015; Zhou et al., 2020).

A number of observations-based studies focused on effects of the weekends and, sometimes, specific  
holidays on pollutants concentrations (Chen et al., 2019; Forster and Solomon, 2003). Lonati et al.  
(2006) examined the weekend effect for particulate matter (PM<sub>10</sub> and PM<sub>2.5</sub>) emissions from traffic  
sources in the city of Milan. The research indicated that concentrations of these compounds in the urban  
55 area were lower than the levels during the weekdays. Gour et al. (2013) considered differences in the  
pollution levels during weekends and weekdays in Delhi and showed that pollution variation follows the  
pattern of working activities on weekends and weekdays. Parra and Franco (2016), pointed out that the  
concentration of NO<sub>2</sub>, NO<sub>x</sub>, CO, and PM<sub>2.5</sub> in working days is higher than that at the weekend, but the  
concentration of O<sub>3</sub> in working days is lower than that of the weekend, due to ozone titration. In (2017),  
60 Ding et al. reported that during the Chinese New Year the NO<sub>x</sub> emissions are usually lower by about  
10% reflecting the lower business and industrial activities.. In a recent study, Hua et al. (2021)  
estimated the holiday effect of PM<sub>2.5</sub> and NO<sub>2</sub> by a Generalized Additive Model (GAM) with regard to  
time and meteorological parameters at 34 air quality monitoring stations during the five heating seasons  
from 2014 to 2019 in Beijing. According to their results, the holiday effect was much stronger than the  
65 weekend effects with increasing PM<sub>2.5</sub> by 2% to 30% and decreasing NO<sub>2</sub> in contrast.

Khalil et al. (2016) analysed hourly measurements of nitrogen oxide (NO<sub>x</sub>), non-methane hydrocarbons  
(NMHCs), ozone (O<sub>3</sub>), sulphur dioxide (SO<sub>2</sub>), PM<sub>2.5</sub>, and PM<sub>10</sub> collected at the coastal town of Yanbu,  
Saudi Arabia during weekends, Eids, Ramadan, and the Hajj periods and demonstrated that the ozone  
concentrations stay practically the same over these holiday days but the precursor levels are

70 significantly lower. They reported a substantial increase in night-time emissions during Ramadhan due to the reversal of diurnal activities (day to night).

The fireworks and bonfires during Christmas and New Year of 2013 and 2014 were recognized as the main sources of PM<sub>2.5</sub> in Mexico city by Retama et al. (2019). Singh et al. (2019) considered the effect of fireworks on air quality, visibility, and human health and reported significant changes in pollutant  
75 concentrations and a decrease in visibility. Yao et al. (2019) studied air quality trends and fireworks impact in Shanghai during spring festivals from 2013 to 2017 by monitoring hourly PM<sub>2.5</sub> and gaseous pollutants at an urban and a suburban sites. A decreasing trend of PM<sub>2.5</sub> in this study revealed the positive effect of firework regulation on air quality.

Recently, various methods based on observed data and models were applied to measure the impact of  
80 COVID-19 lockdown on air pollution. These studies investigated the role of transport and industry sectors (as the main sources of air pollution) on pollutants concentrations during the lockdown (Fan et al., 2020; Grivas et al., 2020; Huang et al., 2020; Menut et al., 2020; Sharma et al., 2020; Wang and Su, 2020).

The above works showed that the effects of isolated events, such as public holidays, can be substantial.  
85 Yet its systematic analysis at large scales (e.g., a continent and a full year) is missing and a systematic approach to their incorporation into AQ models is yet to be developed.

The goal of the current paper is to address this gap and to make the first step towards incorporation of the public holidays into the regular atmospheric composition and air quality modelling in Europe. We quantified the added value of a comparatively primitive and conservative inclusion of official holidays  
90 into temporal profiles of emission of air pollutants. Secondly, a sensitivity study was performed demonstrating the extent of the necessary adjustments and potential benefits of a more detailed analysis of each specific holiday event.

The paper is organised as follows. The next section presents the methodology of the study: information on the European holidays, ways of their incorporation in the emission temporal profiles, the  
95 atmospheric composition model SILAM v.5.7 and its setup, as well as the statistical measures of the model performance. The Results section presents the outcome of the annual SILAM computations for 2018 and the impact of the holiday information on the model skills. The Discussion section compares the outcome with other studies and demonstrates the sensitivity of the results to the changes in the holiday emission representation.

## 100 **2. Materials and methods**

### **2.1. European Holidays**

We collected a list of official holidays in Europe from the Calendarific global holidays API (<https://calendarific.com/api-documentation?v=2>, access 10.01.2021) for the full year of 2018. We

consider the events marked with “National holiday”, “Local holiday” or “Common local holiday” as  
 105 holidays (see examples for some European countries in Table 1 - Table 3). Since the Sunday emission  
 was applied country-wise, the “local” or “common local” holidays might sometimes cover wider  
 territories than they should. However, higher level of details was technically not possible to  
 accommodate and between missing some local/regional holidays and covering wider areas. Since  
 “religious” and “observance” holidays were not considered we preferred to include the others. The  
 110 maximum possible error does not exceed 10% because in 2018 National holidays counted to ~800  
 whereas Common Local and Local were ~60 and ~80, respectively.

The model computations included all holidays in 2018 but, for the sake of brevity, the analysis below  
 will concentrate on the Christmas and New Year weeks, Easter (analysed at the European scale), May  
 Day, and the Festival of Breaking the Feast at last days of Ramadan (Eid al-Fitr, analysed for Turkey).

## 2.2. Atmospheric composition model SILAM

120 SILAM (System for Integrated modeLling of Atmospheric coMposition, <http://silam.fmi.fi/>, access:  
17.01.2021) is an offline 3D chemical transport model (Sofiev et al., 2015a), also used for emergency  
decision support (Sofiev et al., 2006) and inverse atmospheric composition problems (Sofiev, 2019;  
Vira and Sofiev, 2012). The model incorporates Eulerian and Lagrangian dispersion frameworks and a  
variety of chemical / physical transformation modules covering the troposphere and the stratosphere  
125 (Carslaw et al., 1995; Damski et al., 2007; Gery et al., 1989; Kouznetsov and Sofiev, 2012; Sofiev,  
2002, 2000; Sofiev et al., 2010; Yarwood et al., 2005). SILAM features a mass-conservative positive-  
definite advection scheme based on principles laid down by M.Galperin (Galperin et al., 1996). The  
model can be run at a range of resolutions and coverage starting from a kilometre scale over a limited  
area and up to the whole globe (Brasseur et al., 2019; Kouznetsov et al., 2020; Petersen et al., 2019;  
130 Sofiev et al., 2020, 2015b; Xian et al., 2019). The vertical structure of the modelling domain consists of  
stacked layers starting from the surface. The layers can be defined either in z- or hybrid sigma-pressure  
coordinates. The model can be driven with a variety of numerical weather prediction or climate models.

## 2.3. Simulation setup

The simulations were performed for the whole year of 2018 for the European domain with the setup  
135 following the operational configuration of SILAM in the Copernicus Atmospheric Monitoring Service  
(CAMS) regional air quality forecasts, as of November 2020 (<https://atmosphere.copernicus.eu>, access  
20.02.2021). The only exception was a twice coarser grid resolution to reduce the computational costs  
(Table 4).

Table 4. SILAM setup.

Domain and resolution	25W-45E, 30N-72N, 350 × 210 cells of 0.2° × 0.2° size
Vertical structure	10 stacked layers with upper boundaries at 25, 75, 175, 375, 775, 1500, 2700, 4700, 6700 and 8700m above surface
Boundary conditions	First-day operational C-IFS (Integrated Forecasting System of European Centre for Medium-Range Weather Forecasting ECMWF with online-coupled chemistry) forecasts at 0.4° resolution
Meteorological driver	First-day operational IFS forecasts interpolated to 0.2° × 0.2° regular

	lon-lat grid
Anthropogenic emissions	CAMS_REG_AP v4.2/2017 with GNFR temporal and vertical profiles ( <a href="https://eccad.aeris-data.fr/">https://eccad.aeris-data.fr/</a> , access 5.2.2021)
Natural emissions	SILAM sea-salt (Sofiev et al., 2011), dynamic biogenic emissions based upon Poupkou et al. (2010), mineral dust
Chemical and aerosol transformations	Modified CBM-5 gas-phase transformation, SO <sub>4</sub> , NO <sub>3</sub> , NH <sub>4</sub> ion chemistry, SO <sub>2</sub> oxidation, nitrate formation, Volatility-basis set for secondary organics
Deposition	Dry: Resistance approach (Wesely, 1989) for gases, (Kouznetsov and Sofiev, 2012) for aerosols, Wet: SILAM v2018 wet deposition scheme

140

The anthropogenic emissions in CAMS\_REG\_AP v4.2 inventory are given as maps of annual totals separately for each country and 16 GNFR sectors (Gridded Nomenclature For Reporting) European Environment Agency., 2013). To get the hourly emissions, the annual means are scaled with three temporal profiles, defined separately for each sector, corresponding to month-of-year (MOY), day-of-week (DOW), and hour-of-day (HOD) profiles (Granier et al., 2019). In the CAMS-regional operational setup, the anthropogenic emissions are used without accounting for public holidays.

145

To assess the sensitivity of air concentrations of pollutants to holidays, three SILAM runs were made: the baseline (hereinafter, the BL case), with the holiday days considered as Sundays (the HS case), asensitivity run with holidays getting 80% of emission reduction for the sectors affected by the DOW profile (the R3 case). The R3 case was constructed for the Discussion section as a definite low boundary of the possible effect with no realistic scenario behind. Technically, the emissions were adjusted by altering the DOW scaling coefficients for dates and countries where the holidays occur. For the HS case the coefficients were set to their Sunday values, and for the R3 case they were forced to 0.2× of the weekday value. The DOW coefficients for the affected sectors are shown in Figure 1. Other sectors (D\_Fugitives, G\_Shipping, H\_Aviation, I\_OffRoad, J\_Waste, K\_AgriculturalLivestock, and L\_AgriculturalOther) have unity DOW coefficients for all three cases.

150

155

Figure 1. Day-of-week coefficients for the affected sectors. HPlus is the value forced for national holidays for the R3 case.

### 3. Evaluation scores

For evaluation of the simulations we used the hourly data of the AQ monitoring stations downloaded from the European Environmental Agency portal (EEA, <http://discomap.eea.europa.eu/map/fme/AirQualityExport.htm>, visited 10.01.2021). Since we focus on regional-scale effects, a subset of representative stations was selected, namely, the stations classified from 1 to 7 according to Joly and Peuch (2012) classification. This dataset is also used for the operational CAMS-regional evaluation (751 stations over the European domain).

The effect of holidays was considered for the main pollutants observed by the EEA network: PM<sub>2.5</sub>, SO<sub>2</sub>, CO, NO<sub>2</sub>, NO<sub>x</sub>, and O<sub>3</sub>. Five statistics were considered following the CAMS evaluation standards: bias, fractional bias (FracB), Pearson correlation coefficient (corr), RMSE, and fractional gross error (FGerr). Primary attention was given to the temporal correlation coefficient as the most-sensitive parameter to the temporal emission resolution.

We considered the effect of holidays at two temporal scales. The short-term impact was analysed for the one-week period centred around each holiday day. For each day of this period, the spatial statistics were computed across the observational stations, and evolution of these statistics from day to day was compared between the SILAM runs. The long-term longitudinal effect was analysed at annual level for the whole 2018 and attention was given to the temporal statistics computed for the stations time series.

Since the diurnal profile of emission during holidays is unknown, albeit probably specific for each event and country, the current study mainly used daily averaging of both observational and model data for computations of the statistics.

In the below examples, we used a set of randomly picked stations in the Netherlands where SILAM shows good skills (see <https://regional.atmosphere.copernicus.eu>, visited 03.07.2021 and illustrations in

180 the Discussion section, Figure 8 and Figure 9, which give a full overview of the model performance in Europe). The initially good model performance was important since it allowed interpreting the discrepancies and sensitivities in terms of emission rather than model errors.

## 4. Results

### 4.1. Short-term impact of public holidays

185 The impact of holidays on the SILAM spatial skills was the largest for the Christmas week (Figure 2a). As expected, the Christmas period is characterised by lower emissions, which resulted in a high bias of the BL model run and almost 50% growth of the RMSE compared to surrounding days. The reduction of emission in the HS run improved the performance but did not eliminate the problem completely. Comparison of daily-mean concentrations showed reduction of the model bias for the HS run by  $\sim 4.5$   
 190  $\mu\text{g m}^{-3}$  of  $\text{NO}_2$ . Consequently, the RMSE was also lower, by  $\sim 14 \mu\text{g m}^{-3}$ . These improvements constitute about 26% of the baseline statistics (see Figs. S1-S6 in the Supplementary section for other species). Examples of the time series of the modelled and observed  $\text{NO}_2$  concentrations at individual stations (Figure 2b, c) show that the HS run, being a step in the right direction, incorporated only a fraction of the actual emission reduction.

195

Figure 2. (a): SILAM daily-mean spatial scores for Christmas (whole Europe), (b, c): Time series of the modelled and observed concentrations for two stations in the Netherlands (locations: NL00738 (5.71E, 52.11N), NL00247 (5.39E, 51.41N)).

The New Year holidays have substantial impact on the first two days in January (Figure 3a). The HS run showed  $\sim 10\%$  lower RMSE and about  $1 \mu\text{g m}^{-3}$  reduction of bias. However, similar to the Christmas

200 case, the Sunday emission level may be a too conservative reduction for this event, which is well visible in Figure 3b, c.

Comparing the HS and BL runs for Easter (Figure 4), one can see a substantial improvement of the scores for the days of the event. Similarly to the winter holiday week, Easter emission reduction seems to be deeper than that of Sundays (see results for other species in the Supplementary Materials, Figs. 205 S7- S12).

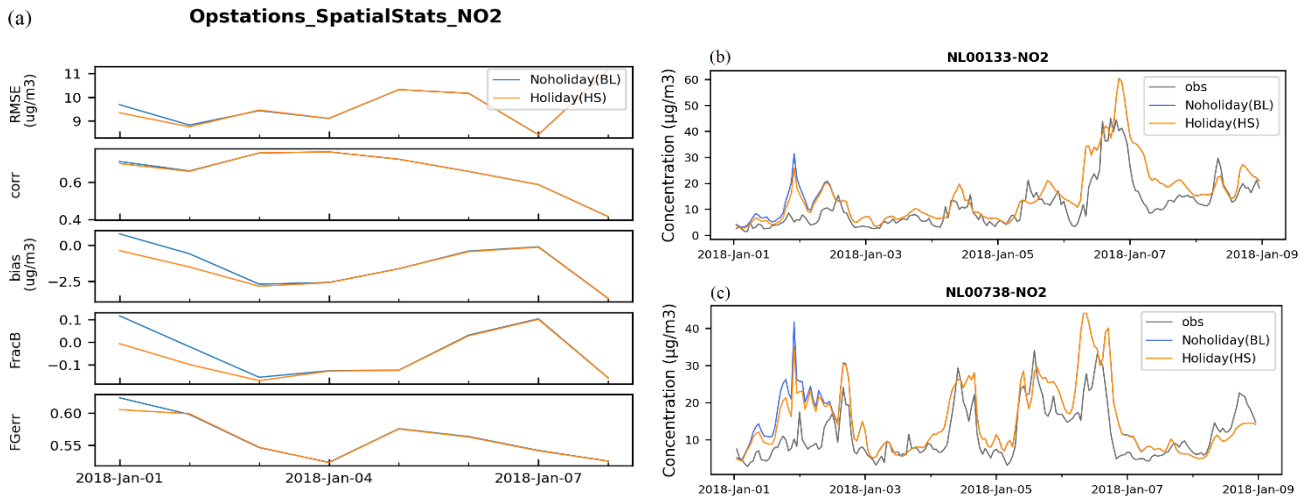

Figure 3. (a): SILAM daily-mean spatial scores for New Year holiday (whole Europe), (b, c): Time series of the modelled and observed concentrations for two stations in the Netherlands (locations: NL00133 (5.88E, 50.9N), NL00738 (5.71E, 52.11N)).

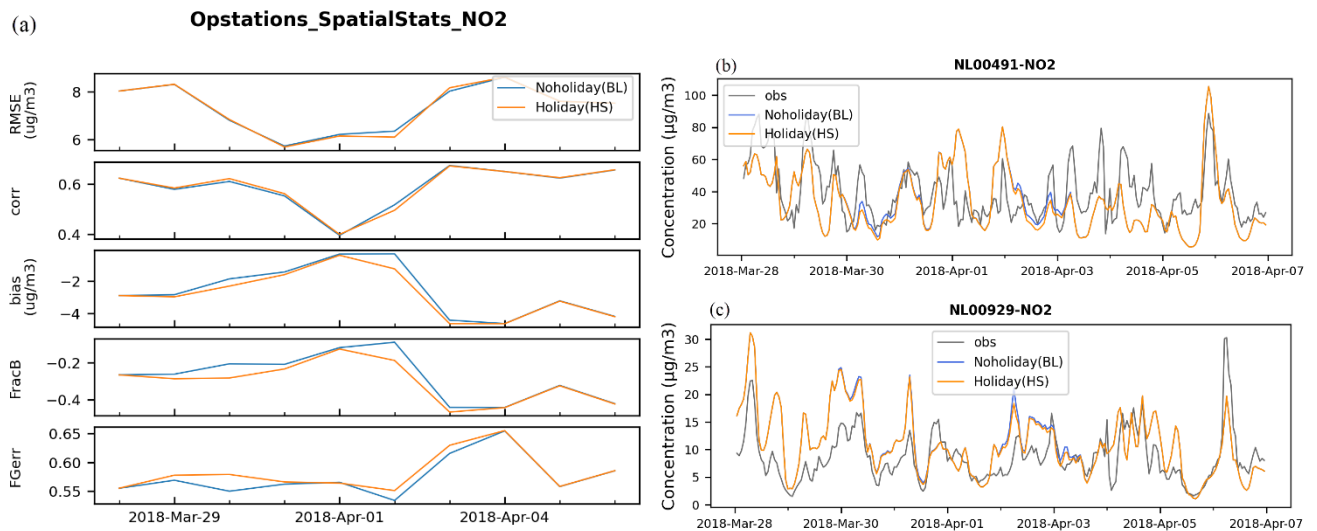

Figure 4. (a): SILAM daily-mean spatial scores for Easter (whole Europe), (b, c): Time series of the modelled and observed concentrations for two stations in the Netherlands (locations: NL00491 (4.43E, 51.94N), NL00929 (6.93E, 52.88N)).

The first 10 days of May were considered as an example of late-spring / summer vacations (there are no whole-Europe holidays during summer itself). The HS run showed slightly lower values for RMSE but, similar to Easter, initially negative bias increased further. Nevertheless, the bias time series became smoother comparing to the BL one, which is an indication of improvement: the systematic emission under-estimation should be handled separately. Reduction of NO<sub>x</sub> resulted in a substantial improvement of the ozone scores (Supplementary Material, Figs. S13- S18). This connection was the strongest among all holidays throughout the year, owing to the active chemistry and photolysis in May.

215

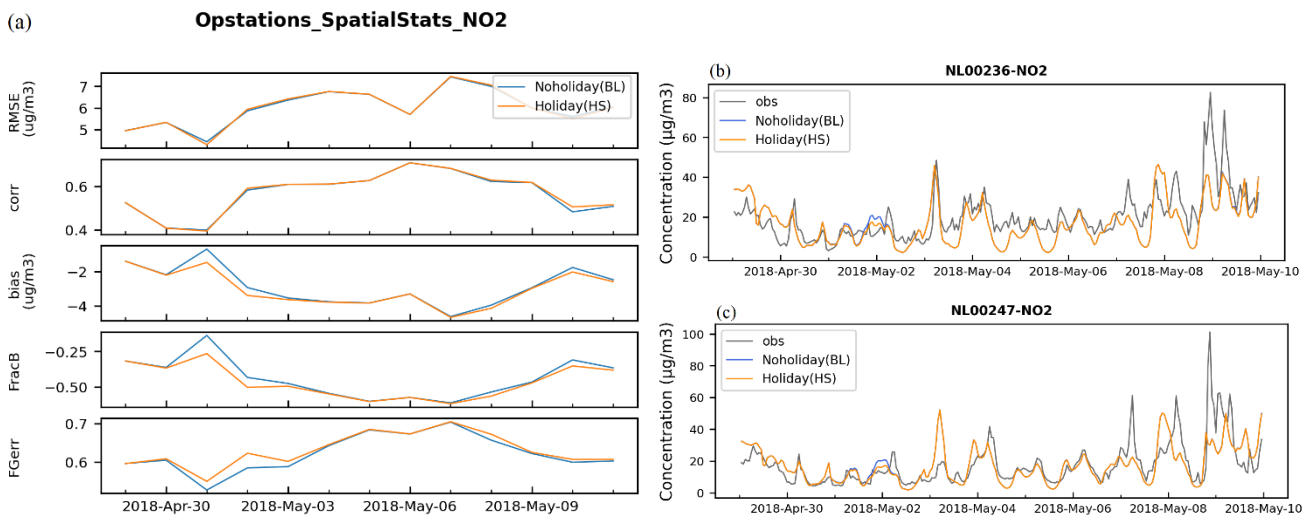

Figure 5. (a): SILAM daily-mean spatial scores for May vacations (whole Europe), (b, c): Time series of the modelled and observed concentrations for two stations in the Netherlands (locations: NL00236 (5.47E, 51.47N), NL00247 (5.39E, 51.41N)).

220 In the Muslim countries (Turkey, Albania), the Ramadan month is not a public holiday as a whole, just working hours are reduced, which is not reflected in the HS run. Only the last three days of Ramadan - the Ramadan Feast – are the public holidays in Turkey (Table 3, Figure 6 for NO<sub>2</sub>, Supplementary material for other species, Figs. S19- S24). For these days, there are distinct differences between the BL and HS model runs. However, similar to Easter and the May day, the model is generally low biased for NO<sub>2</sub> in Turkey during this period, therefore the additional reduction of the concentrations is, formally speaking, not an improvement: the negative bias increases. Nevertheless, it is a step in the right direction, as seen from the reduced variations of the model skills of the HS run: handling a flat systematic bias is easier than a scatter. The NO<sub>2</sub> under-estimation in Turkey probably originates from the understated emissions, which update would resolve the issue. Due to this under-estimation, it is difficult to estimate how conservative the Sunday-level emission reduction is for these holidays (Figure 6 b, c).

225

230

Unlike the Christmas and Easter holidays, which exist in most European countries, especially those with the highest density of the observational network and the strongest emission, the Ramadan Feast days have a substantial effect only for the Turkish stations. At the European scale, the effect is negligible.

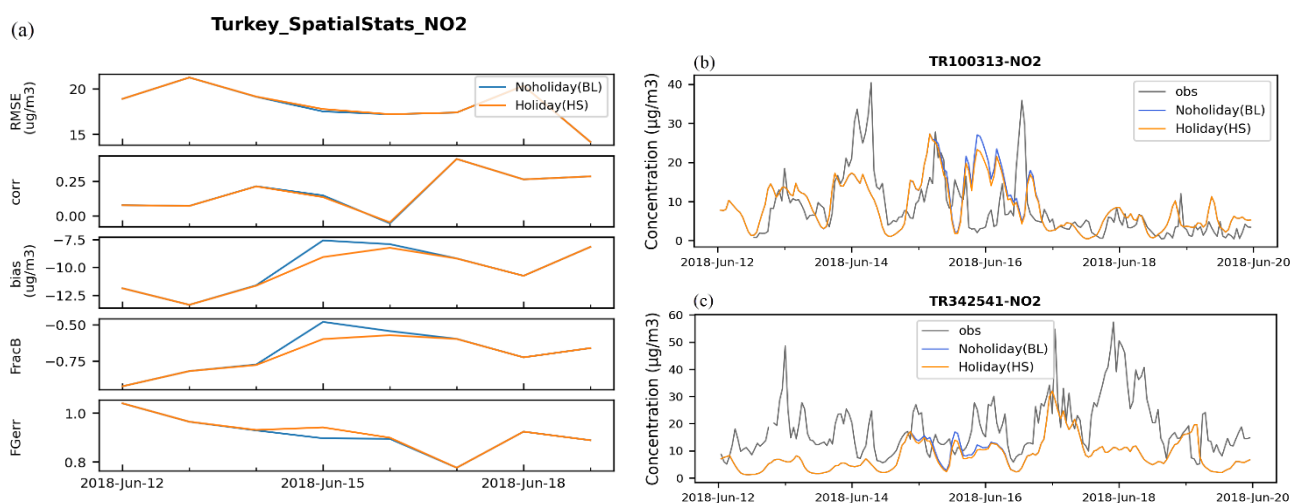

Figure 6. (a): SILAM daily-mean spatial scores for Ramadan (only stations in Turkey), (b, c): Time series of the modelled and observed concentrations for two Turkish stations (locations: TR100313 (27.98E, 40.49N), TR342541 (29.16E, 41.01N)).

235

## 4.2. Long-term statistics

At the annual scale, the impacts of holidays on the model performance is limited. The reduction affects only the days with changed emissions and practically do not influence already the next day. The most-significant impact was for Christmas and New Year weeks but even for them the effect faded out by the next day. According to the annual statistics, the HS run performed slightly better than the BL: the model bias and RMSE in HS run are lower and correlation is higher than in the BL run. Quantitatively, at annual level the overall effect for NO<sub>2</sub> for the whole Europe was less than 1%, which reflects the typical number of holiday days in a year (< 3%) and up to ~30% improvement during these days. Impact on other species was lower than that for NO<sub>2</sub>.

## 245 5. Discussion

### 5.1. Holiday effect on model skills: episodically significant, noticeable at annual level

The simulations presented in the previous section confirmed that the official holidays substantially affect air quality, as also shown in the studies outlined in the Introduction. The holiday incorporation into the simulations as Sundays, being very simple technically, brings noticeable improvement of the model skills for the days with the modified emission. Since the number of such days in each year is <

250

3%, the overall improvement of the annual skills is expectedly within 1%, which is quite significant at such level of aggregation.

The suggested simple approach should be considered as only the first step. Holidays are characterised by redistribution of emission due to changing traffic structure, shift of activities from office areas to suburbs, etc. Incorporation of these effects can further improve the model skills but will require quantitative information on such redistribution at the European level. Several approaches towards determining these profiles have been reported, e.g. (Guevara et al., 2021; Mues et al., 2014; Menut et al., 2012), but tests with SILAM showed no substantial improvement suggesting additional uncertainties in the proposed profiles. Some support can be found from traffic information, which is presently not available at continental scales (examples for two cities are provided below).

## 5.2. Sunday-based emission reduction for holidays is a conservative estimate

The simulations also suggested a comparatively simple way to achieve a more significant gain: the Sunday emission scaling (Figure 1) can be amplified. In a few cases, especially for the Christmas and New Year, the actual emission rates might be much lower, whereas for some events the emission of some species might increase. Thus, the New Year night celebration in many countries involves fireworks, which add substantial amount of PM. The second issue is that the Sunday diurnal profile of traffic (also other sources) is substantially different from that of the weekdays. In the present version of SILAM this difference is not accounted for, which evidently limits the model performance and the gain due to the holiday incorporation.

In order to estimate the actual emission reduction over the Christmas and New Year week, we performed a sensitivity simulation HolidayPlus (R3), for which the emission was reduced by 80% (see Methodology section for details). Being a clear overshoot, this run was deemed as the limit-from-below of the emission during the holidays. The corresponding observed and modelled time series of NO<sub>2</sub> concentrations at a station in the Netherlands are presented in Figure 7 for the Christmas week. The model scores at the station are generally very good, so we can attribute most of the appearing model-measurement discrepancies to the changing emission. As one can see, in the Netherlands the emission starts reducing already one day before the holiday – the 24<sup>th</sup> of December. The reduction during the 26<sup>th</sup> of December reaches a factor of a few times: the Sunday level (green line in Figure 7) is way too high whereas the 80% reduction is only slightly too low. Emission is low practically until the 30<sup>th</sup> of December when it shortly returns to the normal level before the next drop for the New Year celebration. This example shows the challenge of incorporation of such information into the model: formal public holidays tend to influence the emission several days around the event, especially if it appears close to the weekend or another holiday.

285

Figure 7. Time series of the modelled (BL and HS runs without and with accounting official holiday, respectively, and Holidaysplus (R3) run with 80% reduction of emission), and observed concentrations for the selected station. Location (6.04E, 51.12N).

The present findings are consistent the estimates of observations-based studies. Thus, with Hua et al (2021) also found that the holiday effect is much stronger than the weekend effects. They noticed the opposite signs for  $PM_{2.5}$  and  $NO_2$ : average increase of about 22% and average decrease of about 11%, respectively. Similarly, Retama et al., (2019) reported substantial effect of fireworks on PM at night and the following morning of Christmas Day and the New Year's day. Along the same lines, Rozbicka and Rozbicki (2016), demonstrated that daily mean ozone concentration and maximum ozone peaks are respectively 13% and 8% higher than those on weekdays, which also indicates a reduction in  $NO_2$  concentrations of about 20%. Conversely, Nodehi et al. (2018) study showed that the Norooz holidays (the Iranian New Year, or a spring festival), are characterised by a reduction of concentration of  $PM_{2.5}$  due to the reduction of the working activities and no massive fireworks. The reported reduction of  $PM_{2.5}$  concentration during the Ramadan Feast holidays is quite close to our estimates.

290

295

### 5.3. Regional specifics

The impact of holidays varies from country to country with substantial differences visible even at a sub-country level. The maps of the station-wise temporal correlation coefficients for hourly  $NO_2$ , CO,  $O_3$ , and  $PM_{2.5}$  concentrations (Figure 8, Figure 10) reveal a strong inhomogeneity of the effect for Christmas and New Year weeks. The effect can dramatically vary even within a single country – as seen from the comparison of maps of Figure 8 and country-median correlation coefficient of Figure 10.

In the case of  $NO_2$ , correlation increases, e.g., in Northern Germany, Italy, Poland and Eastern part of Finland for both HS and R3 runs. Conversely, there was no effect or even deterioration of skills in Southern Germany, Northern France, Madrid region, etc.

Other species showed qualitatively similar patterns but lower gains and losses. Significant changes are noticeable only for CO, which is also significantly affected by traffic. Minor changes for ozone were noticeable only in winter when  $NO_x$  emissions affect  $O_3$  concentrations due to titration. For PM, the

310 effect was not unequivocal: there is a small but coherent reduction of correlation in Eastern Europe in  
May but neutral response or an increase for Christmas. This once again refers to the regional habits of  
celebration of these holidays. One should also keep in mind the fireworks intensively used during New  
Year celebration in some countries (according to the current results, mainly in Western Europe).

Surprisingly, for the Christmas holidays, skills over most of France are generally worse for the HS run  
315 and much worse for R3 indicating a substantially different pattern of activities during holidays,  
compared to those of the neighboring countries. For May day the specificity did not show up:  
correlation has noticeably increased over most of the country, similar to its neighbors. Among the  
hypothetical reasons for such behavior, one could suggest more “active” habits for Christmas  
celebration in France than in the neighboring countries.

320 The R3 run, which was planned as an overshoot, showed strong improvement of temporal correlation in  
Eastern Europe, Central and Northern Italy and Northern Germany. Therefore, one can argue that even  
the 5-fold emission reduction in these countries / regions might be not that much of an exaggeration.

These issues deserve a more detailed analysis accounting for the varying traffic patterns and effects on  
days preceding to and following the official holidays.

325

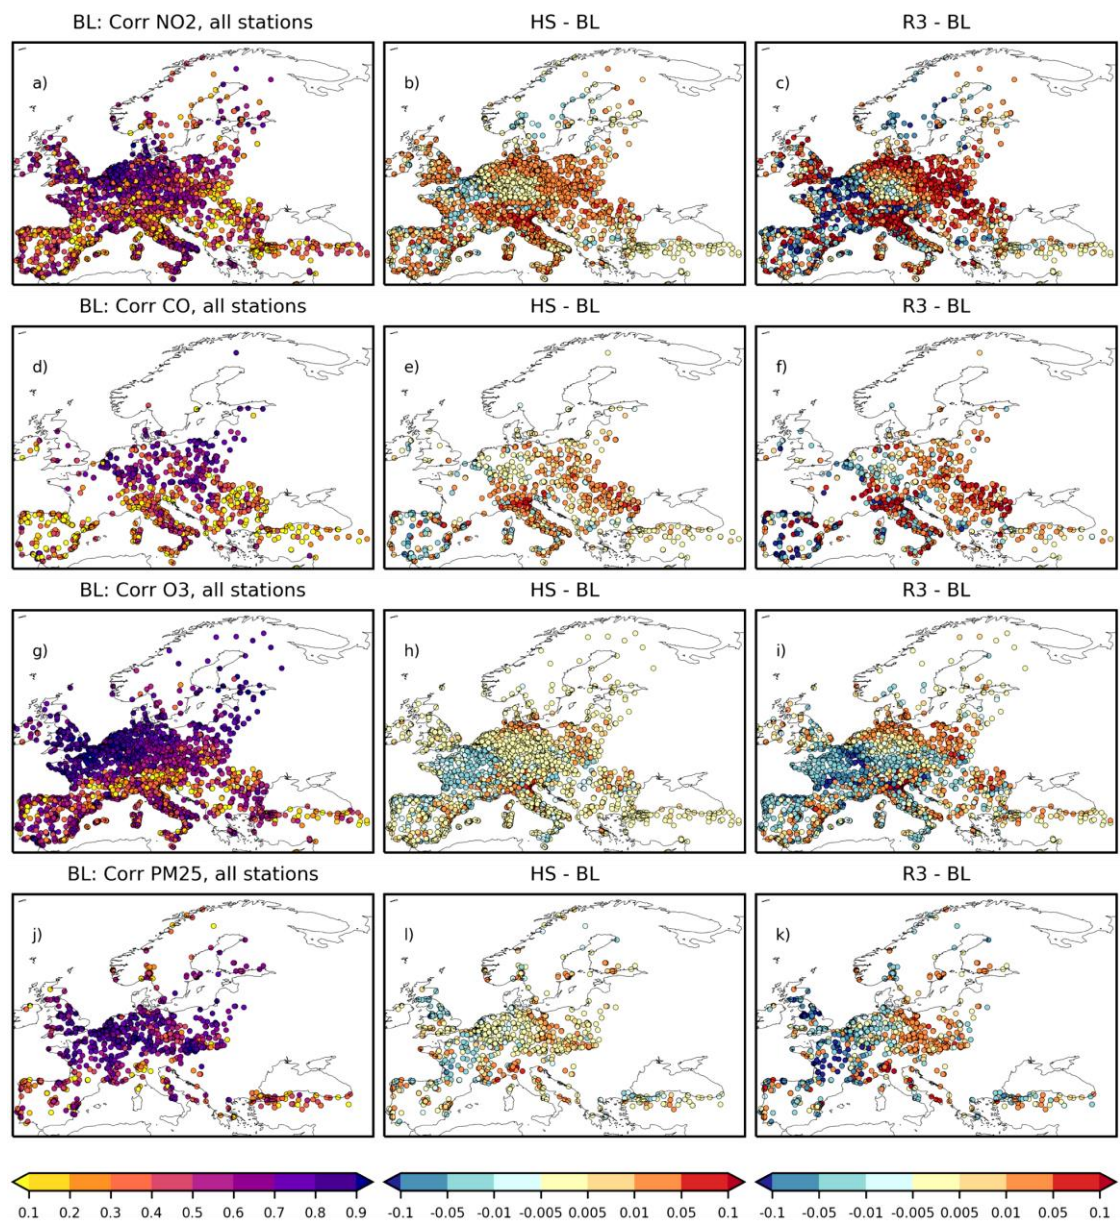

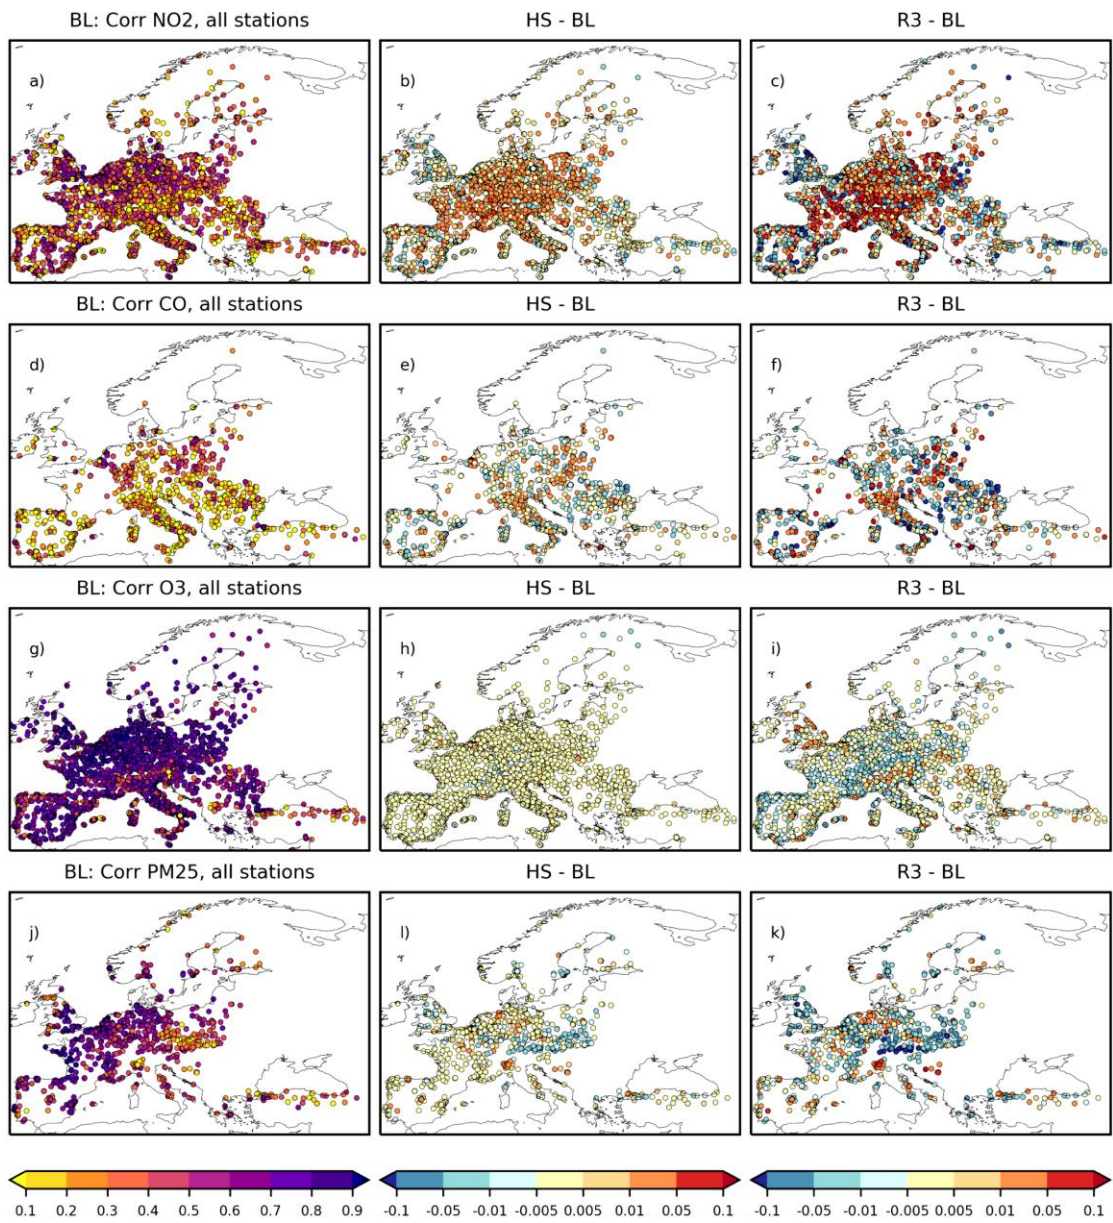

Figure 8. Maps of the temporal correlation coefficient of hourly NO<sub>2</sub>, CO, O<sub>3</sub>, and PM<sub>2.5</sub> concentrations for the EEA stations during the Christmas holidays (21-31 December 2018).

330

Figure 9. Maps of the temporal correlation coefficient of hourly NO<sub>2</sub>, CO, O<sub>3</sub>, and PM<sub>2.5</sub> concentrations for the EEA stations during the May day holidays (29 April – 11 May 2018).

Figure 10. Country-wise median change of temporal correlation coefficient during two weeks of Christmas holidays (21-31 December 2018). The numbers at the top of each panel shows the number of stations that reported data for the period.

335 **5.4. Local traffic counts illustrate the phenomenon**

As mentioned above, a lack of systematic continental-scale traffic counts data precludes their usage for determining or even verifying the assumptions of the current study. However, for a few cities the data

are available and can be used as illustration of the effect. Below we provide the time series for Helsinki and Dublin (Figure 11). The daily traffic counts over several years corroborate / illustrate the above discussion. Indeed, for Helsinki the May day traffic count almost perfectly meets the Sunday number of cars. The difference between the years illustrates the COVID-19 lockdown effects in 2020. For Dublin, two sequential Christmas – New Year holidays show that for this major event the traffic reduction is at least two times deeper than for ordinary Sunday: almost 4 times less cars were counted on 25-26 December than in ordinary day (approaching the 5-fold reduction of the extreme S3 run). The city also manifests about-twice lower traffic intensity during COVID-19 lockdowns. Finally, one can see that the traffic does not restore to normal intensity between Christmas and New Year, quite similar to what was indirectly noticed from the observations in the Netherlands.

340  
345  
350

Figure 11. Daily traffic count in Helsinki (upper panel) and Dublin (lower panel) during Christmas / New Year and May Day holidays. Stars mark the official holidays. Obs non-holiday day of 6 January in Dublin.

355 **6. Summary**

Incorporation of information on public holidays in emission of the affected anthropogenic sectors leads to substantial short-term improvements of the SILAM model scores, even if done conservatively. The

largest impact was found for NO<sub>x</sub>, which is controlled by the changes of the traffic intensity. Certain improvements were also found for PM<sub>2.5</sub> and ozone but the signal was weaker than that for NO<sub>x</sub>.

360 The effect of the emission reduction during holidays may look detrimental in case of a systematic under-estimation in some regions. However, in majority of such cases the bias became more homogeneous in time and thus easier to handle with, e.g., emission corrections via data assimilation or development of new emission inventories.

The sensitivity runs confirmed that the Sunday emission level, in many cases, is a too conservative proxy for the public-holiday emission. Thus, the reduction during Christmas and New Year holidays of 365 2018 was closer to a factor of 4 in Western Europe and possibly even stronger in Eastern Europe.

The current experiment used the prescribed sector-specific diurnal profiles of emission intensity, same for weekdays, weekends and holidays. Incorporation of specific profiles for weekends and holidays, when they become available, will further improve the quality of the model predictions.

370 The proposed method of handling emission reduction in AQ models, albeit very simple and with a room for improvement, gives noticeable gains in the model performance scores. The method is straightforward to implement in AQ models and can be considered as an easy way to significantly improve the model prediction skills for the periods of public holidays. An in-depth analysis of the specific holidays and related traditions in specific countries, such as fireworks in New Year night, 375 would, most probably, lead to further improvements of the AQ predictions.

## 7. Code and data availability

SILAM is an open-code system and can be obtained from the GitHub open repository (<https://github.com/fmidev/silam-model>, Kouznetsov and Delgado, 2021). The simulation results are 380 available on request from the authors of the paper.

## 8. Author contribution

The authors jointly devised the project and developed the paper concept. YF contributed to the implementation of the research and analysis of the results and drafted the paper. RK performed the SILAM computations and contributed to the analysis. MS contributed to the analysis, drafted the 385 Discussion and contributed to other sections of the paper. All authors edited the final text.

## 9. Acknowledgements

The study was performed within the scope of Academy of Finland project GLORIA (grant Nbr 310372). Financial support of Copernicus Atmospheric Monitoring Service (CAMS-50 and CAMS-61) for the SILAM development is kindly acknowledged.
