**Abstract.** Different sea-ice models apply unique approaches in the computation of nutrient diffusion between the ocean and the ice bottom, which are generally decoupled from the calculation of turbulent heat flux. Often, a simple molecular diffusion formulation is used. We argue that nutrient transfer from the ocean to sea ice should be as consistent as possible with heat transfer, since all these fluxes respond to varying forcing in a similar fashion. We hypothesize that biogeochemical models which do not consider such turbulent nutrient exchanges between the ocean and the sea-ice, despite considering brine drainage and bulk exchanges through ice freezing/melting, may underestimate bottom-ice algal production. The Los Alamos Sea Ice Model (CICE + Icepack) was used to test this hypothesis by comparing simulations without and with diffusion of nutrients across sea-ice bottom dependent on velocity-shear, implemented in a way that is consistent with turbulent heat exchanges. Simulation results support the hypothesis, showing a significant enhancement of ice algal production and biomass when nutrient limitation was relieved by bottom-ice turbulent exchange. Our results emphasize the potentially critical role of turbulent exchanges to sea ice algal blooms, and the importance of thus properly representing them in biogeochemical models. The relevance of this becomes even more apparent considering ongoing trends in the Arctic Ocean, with a predictable shift from light to nutrient limited growth of ice algae earlier in the spring, as the sea ice becomes more fractured and thinner with a larger fraction of young ice with thin snow cover.

## 1 Introduction

Momentum, heat and mass fluxes between the ocean and the sea-ice are of utmost importance to predict sea-ice motion, thermodynamics, and biogeochemistry. However, when we look at models released over the last decades, we find not only inter-model differences in the physical concepts used to describe the processes responsible for some of the above fluxes, but also intra-model differences in the approaches used in calculating, for example, heat and mass fluxes. In this work we will focus on the differences related with the vertical diffusion of tracers between the water column and the bottom-ice and attempt to explore their consequences on nutrient limitation for sea-ice algal growth.

31 We may divide the ocean-ice exchange processes into those related to: (i) entrapment during freezing; (ii) flushing and release  
32 during melting;(iii) brine gravity drainage, driven by density instability, parameterized as either a diffusive or a convective  
33 process; (iv) molecular diffusion; and (v) turbulent diffusion at the interface between the ocean and the ice induced by velocity  
34 shear – the latter process being the focus of this study (e.g. Arrigo et al., 1993 and references therein; Jin et al., 2006; McPhee,  
35 2008; Notz and Worster, 2009; Turner et al., 2013; Tedesco and Vichi, 2010, 2019; Jeffery et al., 2011; Vancoppenolle et al.,  
36 2013).

37 These processes are considered in several sea ice models. Arrigo et al. (1993) distinguished nutrient exchanges resulting from  
38 gravity drainage in brine channels, from brine convection in the skeletal layer, dependent on the ice growth rate. These brine  
39 fluxes were used to calculate nutrient exchanges as a diffusive process. Lavoie et al. (2005) also calculated nutrient exchanges  
40 as a diffusive process. Jin et al. (2006; 2008) computed nutrient fluxes across the bottom layer as an advection process  
41 dependent on ice growth rate and based on Wakatsuchi and Ono (1983). Molecular diffusion was also considered. More  
42 recently, other authors have integrated formulations of “enhanced diffusion” (Vancoppenolle et al., 2010; Jeffery et al., 2011)  
43 or convection (Turner et al., 2013), based on hydrostatic instability of brine density profiles, to compute brine gravity drainage  
44 and tracer exchange within the ice and between the ice and the sea water. Comparisons between salt dynamics in growing sea  
45 ice with salinity measurements showed that convective Rayleigh number-based parameterizations (e.g. Wells et al., 2011),  
46 such as the one by Turner et al. (2013), outperform diffusive and simple convective formulations (Thomas et al., 2020).

47 Interestingly, heat exchange is often calculated differently from salinity in models. In the case of the former, typically, a  
48 transfer mechanism (turbulent or not) at the interface between the ocean and the sea ice is not dependent on any type of brine  
49 exchange. In the case of salinity, such a mechanism is not considered (e.g. Vancoppenolle et al., 2007; Turner et al., 2013).  
50 Presumably, such differences result from the relative importance of various physical processes for different tracers. Heat  
51 transfer between the ice and the water is a fundamental mechanism in explaining sea-ice thermodynamics, irrespective of brine  
52 exchanges. On the other hand, ice desalination depends mostly on brine gravity drainage and flushing during melting (Notz  
53 and Worster, 2009).

54 Vertical convective mixing of nutrients under the sea ice may result from brine rejection and/or drainage from the sea ice (Lake  
55 and Lewis, 1970; Niedrauer and Martin, 1979; Reeburgh, 1984) and from turbulence due to shear instabilities generated by  
56 drag at the interface between the ocean and the sea ice (Gosselin et al., 1985; Cota et al., 1987; Carmack, 1986), internal waves  
57 and topographical features (Ingram et al., 1989; Dalman et al., 2019). Gosselin et al. (1985) and Cota et al. (1987) stressed the  
58 significance of tidally induced mixing in supplying nutrients to sympagic algae. Biological demand for silicic acid (hereafter  
59 abbreviated as silicate) and nitrate is limited by the physical supply (Cota and Horne, 1989; Cota and Sullivan, 1990).

60 The analysis of several models published over the last decades and their approaches to calculate tracer diffusion across the ice-  
61 ocean interface shows that some models do not consider this process or limit it to molecular diffusion. Other models consider  
62 turbulent exchanges parameterized as a function of the Rayleigh number, calculated from brine vertical density gradients. Only  
63 one-two of the sampled models (Lavoie et al., 2005 and Mortenson et al., 2017) uses a-parameterizations based on friction  
64 velocity. The former uses eddy diffusion to simulate the vertical supply of nutrients to the molecular sublayer, where nutrient

65 fluxes and their supply to the bottom ice are limited by molecular diffusion. The latter uses a coupled ocean-sea ice model but,  
66 ultimately, molecular diffusion is the controlling process. Both authors use the same approach to compute the thickness of the  
67 molecular sublayer, based on friction velocity.

68 In the absence of ice growth and when brine gravity drainage is limited, diffusive nutrient exchanges between the ocean and  
69 the ice have the capacity to limit primary production. This limitation will be alleviated in the presence of a turbulent exchange  
70 mechanism. We argue that nutrient transfer at the interface between the ocean and the sea ice should be as consistent as possible  
71 with heat transfer since all these fluxes are closely linked. We hypothesize that models which do not consider the role of current  
72 velocity shear on turbulent nutrient exchanges between the ocean and the sea-ice may underestimate bottom-ice algal  
73 production.

74 To test the above hypothesis, we use a 1D vertically resolved model implemented with CICE+Icepack and contrast results  
75 using the default diffusion parameterization and a “turbulent” parameterization analogous to that of heat and salt transfer, at  
76 the interface between the ocean and the sea ice, based on McPhee (2008). This implementation of the turbulent  
77 parameterization is specific for the software used and it may be different in other models.

## 78 **2 Methods**

### 79 **2.1 Concepts**

80 Turbulent exchanges may be parameterized through the flux of a quantity at the interface between the ocean and the sea ice,  
81 calculated as the product of a scale velocity and the change in the quantity from the boundary to some reference level (McPhee,  
82 2008):

$$83 \langle w'S' \rangle = \alpha_s u^* (S_w - S_0) \quad (1)$$

84 Where,  $\langle w'S' \rangle$  represents the averaged co-variance of the turbulent fluctuations of interface vertical velocity ( $\text{m s}^{-1}$ ) and  
85 salinity, respectively,  $\alpha_s$  is an interface salt/nutrient exchange coefficient (dimensionless);  $u^*$  is the friction velocity ( $\text{m s}^{-1}$ );  $S_0$   
86 and  $S_w$  are interface and far-field salinities, respectively.

87  
88 We calculate salt or nutrient exchanges using a similar approach:

$$89 F_N = -\alpha_s u^* (N_w - N_0) \quad (32)$$

90 In fact, ~~†~~ This is an extension of the concept used for heat and salt by McPhee (2008) (see page 112, Fig. 6.3). The minus sign  
91 used in (32) and (4) is for compatibility with the CiCE + Icepack convention that upward fluxes are negative (e.g. Hunke et  
92 al., 2015).  $\alpha_s$  varies between  $8.6 \cdot 10^{-5}$ , during the melting season, and 0.006, during winter (McPhee et al., 2008).

Where,  $\langle w'S \rangle$  represents the averaged co-variance of the turbulent fluctuations of interface vertical velocity ( $\text{m s}^{-1}$ ) and salinity, respectively,  $\alpha_s$  is an interface salt/nutrient exchange coefficient (dimensionless);  $u^*$  is the friction velocity ( $\text{m s}^{-1}$ );  $S_o$  and  $S_w$  are interface and far-field salinities, respectively.

Hereafter we will assume that salt turbulent exchanges are similar to nutrient exchanges and governed by the same principles and parameters. The main difference between turbulent heat and salt/nutrient exchanges is due to the exchange coefficients that may be higher for heat. The heat exchange coefficient ( $\alpha_h$ ) is around 0.006. The ratio ( $R$ ) between  $\alpha_h$  and  $\alpha_s$  may vary from unity to a range between 35 and 70 during ice melting and because of double diffusion, leading to a range in  $\alpha_s$  between  $8.6 \cdot 10^{-5}$  and 0.006 (McPhee et al., 2008).

The net downward heat flux from the ice to the ocean in the Los Alamos Sea Ice Model (CICE + Icepack) is given by (Hunke et al., 2015) and it is computed according to McPhee et al. (2008) [Eq. (2)]:

$$F_{\text{bot}} = -\rho_w c_w \alpha_h u^* (T_w - T_f) \quad (2)$$

Where,  $\rho_w$  is the density of seawater ( $\text{kg m}^{-3}$ );  $c_w$  is the specific heat of seawater ( $\text{J kg}^{-1} \text{K}^{-1}$ );  $\alpha_h$  is the heat transfer coefficient (dimensionless);  $T_w$  is the water temperature (K);  $T_f$  is the freezing temperature (K).

We calculate salt or nutrient exchanges using a similar approach:

$$F_N = -\alpha_s u^* (N_w - N_0) \quad (3)$$

In fact, this is an extension of the concept used for heat and salt by McPhee (2008) (see page 112, Fig. 6.3). The minus sign used in (3) and (4) is for compatibility with the CICE + Icepack convention that upward fluxes are negative (e.g. Hunke et al., 2015).

Before explaining how 3 was implemented in the CICE+Icepack we describe the model vertical biogeochemical grid (biogrid), the tracer equation and the bottom boundary conditions. The biogrid is the non-dimensional grid used for discretizing the vertical transport equations of biogeochemical tracers, defined between the brine height ( $h$ ), which takes the value zero, and the ice-ocean interface, which takes the value one (Jeffery et al., 2016). The Icepack tracer equation (without biogeochemical reaction terms for the sake of simplicity) may be written as [for more details, refer Jeffery et al. (2011; 2016)]:

$$\varphi \frac{\partial N}{\partial t} = \left\{ \frac{(x-1)}{h} \frac{\partial z_t}{\partial t} - \frac{x}{h} \frac{\partial z_b}{\partial t} \right\} \frac{\partial}{\partial x} (\varphi N) + \frac{1}{h} \frac{\partial}{\partial x} (w_f N) + \frac{\partial}{\partial x} \left( \frac{D_{MLD} + \varphi D_m}{h^2} \frac{\partial N}{\partial x} \right) \quad (3)$$

Where  $0 \leq x \leq 1$  is the relative depth of the vertical domain of the biogrid,  $z_t$  and  $z_b$  are vertical positions of the ice top and bottom (m), respectively,  $\varphi$  is sea ice porosity,  $w_f$  is the Darcy velocity due to the sea ice flushing of tracers ( $\text{m s}^{-1}$ ), Where  $D_m$  is the molecular diffusion coefficient and  $D_{MLD}$  is the mixed length diffusion coefficient ( $\text{m}^2 \text{s}^{-1}$ ) (Jeffery et al., 2011).  $D_{MLD}$  is detailed in Jeffery et al. (2011) and it is zero when the brine vertical density gradient is stable, otherwise (when density increases towards the ice top) it is calculated as:

$$D_{MLD} = \frac{gk}{\mu} \Delta \rho_e l \quad (4)$$

Where  $g$  is the acceleration of gravity ( $9.8 \text{ m s}^{-2}$ ),  $k$  is sea ice permeability,  $\mu$  is dynamic viscosity ( $2.2 \text{ kg m}^{-1} \text{s}^{-1}$ ),  $\rho_e$  is the equilibrium brine density and  $l$  is a length scale (7 m). The values shown here are the default ones in CICE+Icepack.

Formatted: Font: Italic

125 The bottom boundary condition of 3 is based on values of  $N$  at the sea ice bottom interface ( $N_0$  at  $x=I$ ) and in the ocean ( $N_w$ )  
 126 (Jeffery et al., 2011). Therefore, the last term of equation 3 at the bottom boundary may be written as:

$$127 \frac{D_{MLD} + \phi D_m}{h^2 \partial x} (N_0 - N_w) \quad (5)$$

128 With  $\phi=1$ .

129 In CICE+Icepack, diffusion time scales are calculated separately for later usage in 3 as:

$$130 \tau = \frac{D_m}{h^2} [s^{-1}] \quad (6)$$

131  
 132 And

$$133 \tau = \frac{D_{MLD}}{h^2} [s^{-1}] \quad (7)$$

134 A similar timescale for this turbulent process described by equation 3 may be calculated from:

135 Therefore, in the CICE model the implementation of turbulent diffusion nutrient exchanges at the ice-ocean interface in terms  
 136 consistent with heat exchanges is quite straightforward, depending on changing the timescales from Eq. (5) to (4). In other  
 137 models, other approaches may be required.

$$139 \tau = \frac{\alpha_s u^*}{zh} [s^{-1}] \quad (48)$$

140 Therefore, in the Los Alamos Sea Ice Model the implementation of turbulent diffusion nutrient exchanges at the ice-ocean  
 141 interface is quite straightforward. In other models, other approaches may be required.

142  
 143 Where  $z$  is a vertical distance (m) ( $h$  in the Los Alamos Sea Ice Model, see below). The above time scale is calculated for  
 144 consistency with CICE implementation of diffusion, where a comparable time scale is calculated as:

$$145 \tau = \frac{D_m}{h^2} [s^{-1}] \quad (5)$$

146 Or

$$147 \tau = \frac{D_{MLD}}{h^2} [s^{-1}] \quad (6)$$

148 The usage of  $h$  in these timescales implies merely the way they are normalized in the code before the actual diffusive fluxes  
 149 are calculated considering the distance between the points ( $h, \partial x$ , see above equation 3) where variables are calculated, along  
 150 the layers of the biogrid. The product  $h \cdot x$  corresponds to the actual distance of a given point from the top of the biogrid.

151 In the simulations using turbulent diffusion, we perform the same calculations, except that the molecular diffusion term  $\frac{\phi D_m}{h^2}$   
 152 is replaced with a turbulent diffusion term  $\frac{\alpha_s u^*}{h}$  at the interface between the last model layer and the ocean. This exchange  
 153 process takes place “outside” the sea ice where  $\phi=1$ , affecting directly only the tracer concentration at the ice-ocean interface.

Where  $D_m$  is the molecular diffusion coefficient and  $D_{MLD}$  is the mixed-length diffusion coefficient ( $m^2 s^{-1}$ ) (Jeffery et al., 2011). In the Los Alamos Sea Ice Model,  $h$  corresponds to the thickness of the biogeochemical grid (biogrid). This is the non-dimensional grid used for discretizing the vertical transport equations of biogeochemical tracers, defined between the brine height, which takes the value zero, and the ice-ocean interface, which takes the value one (Jeffery et al., 2016). The usage of  $h$  in these timescales implies merely the way they are normalized in the code before the actual diffusive fluxes are calculated considering the distance between the points ( $h \cdot \partial x$ , see below equation 7) where variables are calculated, along the layers of the biogrid. The product  $h \cdot x$  corresponds to the actual distance of a given point from the top of the biogrid. The time scales expressed in equations 5 and 6 are included in the Icepack transport equation, which may be written as [for more details, refer Jeffery et al. (2011; 2016)]:

$$\varphi \frac{\partial N}{\partial t} = \left( \frac{(x-1)}{h} \frac{\partial z_t}{\partial t} - \frac{x}{h} \frac{\partial z_b}{\partial t} \right) \frac{\partial}{\partial x} (\varphi N) + \frac{1}{h} \frac{\partial}{\partial x} (W_F N) + \frac{\partial}{\partial x} \left( \frac{D_{MLD} + \varphi D_m}{h^2} \frac{\partial N}{\partial x} \right) \quad (7)$$

Where  $0 \leq x \leq 1$  is the relative depth of the vertical domain of the biogrid,  $z_t$  and  $z_b$  are vertical positions of the ice top and bottom (m), respectively,  $\varphi$  is sea ice porosity,  $w_f$  is the Darcy velocity due to the sea ice flushing of tracers ( $m \cdot s^{-1}$ ),  $D_{MLD}$  is detailed in Jeffery et al. (2011) and it is zero when the brine vertical density gradient is stable, otherwise (when density increases towards the ice top) it is calculated as:

$$D_{MLD} = \frac{g k}{\mu} \Delta \rho_e l \quad (8)$$

Where  $g$  is the acceleration of gravity ( $9.8 \text{ m} \cdot \text{s}^{-2}$ ),  $k$  is sea ice permeability,  $\mu$  is dynamic viscosity ( $2.2 \text{ kg} \cdot \text{m}^{-1} \cdot \text{s}^{-1}$ ),  $\rho_e$  is the equilibrium brine density and  $l$  is a length scale (7 m). The values shown here are the default ones in Icepack.

The last term of equation 7 includes the contribution of molecular diffusion that is calculated at the interface of all layers of the biogrid and at the interface of the last layer and the ocean. In the simulations using turbulent diffusion, we perform the same calculations, except that the molecular diffusion term  $\frac{\varphi D_m}{h^2}$  is replaced with a turbulent diffusion term  $\frac{\alpha_z u_*^2}{h}$  at the interface between the last model layer and the ocean.

The transport equation is resolved along the biogrid, with a Flux Corrected, Positive Definite Transport Scheme, using the finite element Galerkin discretization (Jeffery et al., 2016). In the case of the bottom ice layer, tracer concentrations are calculated at the ice-ocean interface.

Therefore, in the CICE model the implementation of turbulent diffusion nutrient exchanges at the ice-ocean interface in terms consistent with heat exchanges is quite straightforward, depending on changing the timescales from Eq. (5) to (4). In other models, other approaches may be required.

From equations 4-6 - 6-8 it turns out that the product  $\alpha_z u$  by distance ( $z$ ) has the same dimensions of  $D_m$  or  $D_{MLD}$ , corresponding to a turbulent diffusion coefficient. Assuming  $z \approx 0.01 \text{ m}$ , turbulent diffusion induced by velocity shear, becomes comparable with molecular diffusion only for  $u^* < 0.0012 \text{ m} \cdot \text{s}^{-1}$ , considering the lower end of the  $\alpha_z$  range ( $8.6 \cdot 10^{-5}$ , see above) or  $u^* < 1.7 \cdot 10^{-5} \text{ m} \cdot \text{s}^{-1}$ , considering the upper end of the  $\alpha_z$  range (0.006). If we assume instead  $z \approx 0.00054 \text{ m}$  [the average thickness of the

187 ~~molecular sublayer reported in Lavoie et al. (2005)]0.001 m~~, the calculated  $u^*$  values increase by ~~one-two orders~~ ~~one-order~~ of  
188 magnitude (~~depending on  $\alpha_c$~~ ) but are still ~~very-low~~ (0.0004-0.03  $\text{m s}^{-1}$ ). In fact, such low friction velocities would require  
189 ~~extremely~~-low “stream” velocities - relative ice-ocean velocities. For an account of the relationship between “stream” and  
190 friction velocities under the sea ice see Supplementary information 3 of Olsen et al. (2019) and references therein. These  
191 authors show that “stream” velocities of only a few centimetres per second lead to friction velocities one order of magnitude  
192 lower but still in the order of 0.001  $\text{ms}^{-1}$ , i.e., ~~comparable-larger~~ only ~~to~~ ~~than~~ the highest  $u^*$  values estimated above. Considering  
193 current velocities relative to the sea ice observed during the N-ICE2015 cruise [Granskog et al., 2018; Figure 2d of Duarte  
194 et al. (2017)], with most values between 0.05 and  $> 0.2 \text{ m s}^{-1}$ , it is rather likely that friction velocities under the ice are frequently  
195 above the thresholds calculated above and that turbulent diffusion will dominate over molecular diffusion. Dalman et al. (2019)  
196 provided experimental evidence for such turbulent nutrient fluxes to the ice bottom, leading to increased chlorophyll  
197 concentrations at the bottom ice, in a strait with strong tidal currents. The mechanism treated here as turbulent diffusion seems  
198 analogous to “forced convection” in the lowermost parts of the brine network, which is driven by pressure differences caused  
199 by the shear under the sea ice (Neufeld, 2008; Vancoppenolle et al., 2013).

## 200 2.2 Implementation

201 We used the Los Alamos Sea Ice Model, which is managed by the CICE Consortium with an active forum  
202 (<https://bb.cgd.ucar.edu/cesm/forums/cice-consortium.146/>) and a git repository (<https://github.com/CICE-Consortium>). It  
203 includes two independent packages: CICE and Icepack. The former computes ice dynamic processes and the latter ice column  
204 physics and biogeochemistry. Their development is handled independently with respect to the GitHub repositories  
205 (<https://github.com/CICE-Consortium>). All the changes described below were implemented in two forks to the above  
206 repository, one for Icepack and another for CICE and they may be found in Duarte (2021a and b, respectively).

207 Our simulations may be run using only Icepack, since they are focused on ice column physics and biogeochemistry, without  
208 the need to consider ice dynamic processes. However, we used both CICE + Icepack together to allow for use of netCDF based  
209 input/output not included in Icepack. Therefore, we defined a 1D vertically resolved model with 1 snow layer and 15 ice layers  
210 and 5X5 horizontal cells. This is the minimum number of cells allowable in CICE due to the need to include halo cells (only  
211 the central “column” is simulated). Therefore, ice column physics and biogeochemistry were calculated by Icepack but CICE  
212 was the model driver. The input file (ice\_in) used in this study was included in our CICE fork and it lists all parameters used  
213 in the model and described in Hunke et al. (2016), Jeffery et al. (2016), Duarte et al. (2017) and in Tables S1 and S2. Any  
214 changes in “default” parameters or any other model settings will be specified.

215 We made several modifications in CICE to allow using forcing time series collected during the Norwegian young sea ice (N-  
216 ICE2015) expedition (Granskog et al., 2018) and described in Duarte et al. (2017) (see Fig. 2 of the cited authors). These  
217 modifications were meant to allow reading of forcing data at higher frequencies than possible with the standard input  
218 subroutines in the CICE file ice\_forcing.F90.

219 When the dynamical component of CICE is not used,  $u^*$  is set to a minimum value instead of being calculated as a function of  
220 ice-ocean shear stress (Hunke et al., 2015). Duarte et al. (2017) implemented shear calculations from surface current velocities  
221 (one of the models forcing functions) irrespective of the use of the CICE dynamics code. These modifications were also  
222 incorporated in the current model configuration so that shear can be used to calculate friction velocity and, thereafter, influence  
223 heat and tracer/nutrient exchanges, following Eqs. (31) and (48) and parameters described in McPhee et al. (2008). When the  
224 parameter `kdyn` is set to zero in `ice_in`, ice dynamics is not computed, but shear is calculated in the modified subroutine  
225 `icepack_step_therm1`, file `icepack_therm_vertical.F90`. If `kdyn` is not zero, these calculations are ignored since shear is already  
226 calculated in the dynamical part of the CICE code.

227 A Boolean parameter (`Bottom_turb_mix`) was added to the input file, which is set to “false” or “true” when the standard  
228 molecular diffusion approach or the new turbulent based diffusion approach is used, respectively. Another Boolean parameter  
229 (`Limiting_factors_file`) was added to the `ice_in` file. When set to “true” limiting factor values for light, temperature, nitrogen,  
230 and silicate are written to a text file every model timestep. These are calculated by Icepak biogeochemistry, according to  
231 Jeffery et al. (2016), but there is no writing-output option in the standard code.

### 232 **2.3 Model simulations**

233 Simulations were run for a refrozen lead (RL) without snow cover and for second-year sea ice (SYI) with ~40 cm snow cover  
234 monitored in April-June during the N-ICE2015 expedition (Granskog et al., 2018 and Fig. 1 of Duarte et al. 2017). Details on  
235 model forcing with atmospheric and oceanographic data collected during the N-ICE2015 expedition, including citations and  
236 links to the publicly available datasets are given in Fig. 2 and section 3 of Duarte et al. (2017) and in the Supporting information  
237 file. These data sets include wind speed, air temperature, precipitation, and specific humidity (Hudson et al., 2015); incident  
238 surface short and longwave radiation (Hudson et al., 2016); ice temperature and salinity (Gerland et al., 2017); sea surface  
239 current velocity, temperature, salinity and heat fluxes from a turbulence instrument cluster (TIC) (Peterson et al., 2016); sea  
240 surface nutrient concentrations (Assmy et al., 2016) and sea ice biogeochemistry (Assmy et al., 2017). Ocean forcing is based  
241 on measurements within the surface 2 meters which provide the boundary condition for the sea ice model. Model forcing files  
242 may be found in Duarte (2021c).

243 Refrozen lead simulations started with zero ice, whereas Second Year Ice Simulations started with initial conditions described  
244 in the Supporting information file (Table S3).

245 We ran simulations with the standard formulations for biogeochemical processes described in Jeffery et al. (2016) and settings  
246 described in Duarte et al. (2017), using mushy thermodynamics, vertically resolved biogeochemistry, and including: freezing,  
247 flushing, brine mixed length and molecular diffusion within the ice and at the interface between the ocean and the sea ice as  
248 nutrient exchange mechanisms (Jeffery et al., 2011, 2016). We contrasted the above simulations against others that replaced  
249 brine molecular and mixed length diffusion of nutrients at the interface between the ocean and the sea ice with diffusion driven  
250 by current velocity shear (Table 1), calculated similar to heat exchanges, and following the parameterization described in  
251 McPhee et al. (2008) and detailed above (equations 2 - 7). This contrast provides insight into the effects of velocity shear on

252 nutrient diffusion, ice algal production ( $\text{mg C m}^{-2} \text{d}^{-1}$ ), chlorophyll standing stocks ( $\text{mg Chl } a \text{ m}^{-2}$ ) and vertical distribution of  
253 chlorophyll concentration ( $\text{mg Chl } a \text{ m}^{-3}$ ) [note that CICE model output for algal biomass in  $\text{mmol N m}^{-3}$  was converted to  $\text{mg}$   
254  $\text{Chl } a \text{ m}^{-3}$  as in Duarte et al. (2017), using  $2.1 \text{ mg Chl } a \text{ mmol N}^{-1}$  and following Smith et al. (1993)]. However, due to the  
255 concurrent effects of algal biomass exchange between the ocean and ice, such a contrast is not enough to explicitly test our  
256 hypothesis and conclude about the effects of turbulent-driven nutrient supply on ice algal nutrient limitation. Therefore,  
257 simulations were also run contrasting the same model setups, as described above, but restarting from similar algal standing  
258 stocks and vertical distributions within the ice and, switching off algal inputs from the water to the ice. This was done by  
259 nullifying the variable `algalN`, defining the ocean surface background ice algal concentration, in file `icepack_zbgc.F90`,  
260 subroutine `icepack_init_ocean_bio` and in the restart files. In the case of the RL simulations that started with zero ice, first a  
261 simulation was run until the 12 May, and then the obtained ice conditions were used to restart new simulations without algal  
262 inputs from the ocean (`algalN = 0 \text{ mmol N m}^{-3}`). This way, when the simulations restarted, there was already an ice algal  
263 standing stock necessary for the modelling experiments developed herein. The SYI simulations were, by default, “restart  
264 simulations”, beginning with observed ice physical and biogeochemical variables. Therefore, there was already an algal  
265 standing stock in the ice from the onset (Text S1 and Table S3).

266 McPhee et al. (2008) estimated different values for  $\alpha$ , depending on whether the sea ice is growing (highest value) or melting  
267 (lowest value) (Table 1). When running simulations for the RL, in some cases, we used only the minimum or the maximum  
268 values for  $\alpha$ , to allow for a more extreme contrast between molecular and turbulent diffusion parameterizations. This was done  
269 since the former value will tend to minimize differences, whereas the latter will tend to emphasize them. We also completed  
270 simulations for the RL and for SYI changing between the maximum and the minimum values of  $\alpha$ , when ice was growing or  
271 melting, respectively, and following McPhee et al. (2008) (see Table 1 for details). This parameterization with a variable  $\alpha$   
272 is likely the most realistic one, accounting for double diffusion during ice melting (McPhee et al., 2008).

273 Apart from contrasting the way bottom-ice exchanges of nutrients were calculated, some simulations contrasted different  
274 parameters related to silicate limitation (Table 1). This approach follows Duarte et al. (2017), where simulations were tuned  
275 by changing the Si:N ratio and the half saturation constant for silicate uptake because silicate limitation was leading to an  
276 underestimation of algal growth. From this exercise we were able to assess if such tuning was still necessary after implementing  
277 turbulent diffusion at the interface between the ocean and the sea ice, driven by velocity shear. Moreover, we repeated  
278 simulations with varying snow heights to further investigate the interplay between light and nutrient limitation under  
279 contrasting nutrient diffusion parameterizations (Table 1).

Table 1. Model simulations. Refrozen lead (RL) simulation RL\_Sim1 corresponds to RL\_Sim5 described in Duarte et al. (2017) - the simulation leading to a best fit to the observations in that study. The remaining RL simulations 2 – 5 differ from RL\_Sim1 in using turbulent diffusion at the interface between the ocean and the sea ice for nutrients in a comparable way as it is calculated for heat and driven by velocity shear. Moreover, RL\_Sim5 differs in the concentration of ice algae in the water column that colonize the sea ice bottom (algalN) and in silicate limitation related parameters. These changes were done iteratively to fit the model to the observations. In RL\_Sim2 and RL\_Sim3 the maximum ( $\alpha_s=0.006$ ) and the minimum ( $\alpha_s=0.006/70=8.6 \cdot 10^{-5}$ ) values recommended by McPhee et al. (2008), respectively, are used throughout the simulations, to provide extreme case scenarios for comparison with RL\_Sim1. In RL\_Sim4,  $\alpha_s=8.6 \cdot 10^{-5}$  when ice is not growing and 0.006 otherwise, as recommended by McPhee et al. (2008), to account for double diffusive processes during ice melting that slow down mass exchanges. The remaining RL simulations (RL\_Sim6-9) are like the previous ones (RL\_Sim1-4, respectively), except for algalN that was set to zero  $\text{mmol N m}^{-3}$ , and all simulations were restarted with the same values for all variables. Therefore, simulations 6 – 9 may differ only from 13 May 2015, when they were restarted. Second year ice simulation SYI\_Sim\_1 is based on Duarte et al. (2017) SYI\_Sim4 but without algal motion. SYI\_Sim2 and SYI\_Sim3 use turbulent diffusion at the interface between the ocean and the sea ice. The former uses a decreased half saturation constant for silicate uptake, just like SYI\_Sim1, whereas the latter uses the standard CICE value. The remaining SYI simulations (SYI\_Sim4 and 5) are like SYI\_Sim1 and 2, except for algalN that was set to zero. Simulations SYI\_Sim1 and SYI\_Sim2 were repeated but with different initial snow thickness of 30, 20 and 15 cm to further investigate the interplay between light and silicate limitation (see text). Modified parameter values from one simulation to the next are marked in bold, separately for RL and SYI simulations. Modified parameters are based on literature ranges [e.g. Brzezinski (1985) and Hegseth (1992), for ratio\_Si2N\_diatoms, Nelson and Treguer (1992), for K\_Sil diatoms], Urrego-Blanco et al. (2016), for R\_snw], or on previous model calibration work (Duarte et al., 2017). Parameters values were modified in the model input file ice\_in, except for algalN and  $\alpha_s$ , that are hard-coded.

Simulations	Modified parameters (bold types below indicate the parameter abbreviation used in Icepack)					
	Silica to nitrogen ratio in diatoms (ratio_Si2N_diatoms)	Half saturation constant for silicate uptake (K_Sil_diatoms, mM Si)	Ice algal concentration in the water (algalN, mM N)	Boolean to define the usage of either molecular (0) or turbulent diffusion (1) (Bottom_turb_mx)	Interface salt/nutrient turbulent exchange coefficient ( $\alpha_s$ )	Sigma coefficient for snow grain (R_snw)
RL_Sim1	1.0	2.2	11 $10^{-4}$	0	-	1.5

### 310 3. Results

311 The results of the simulations listed in Table 1 and presented below may be found in Duarte (2021d).

#### 312 3.1 Refrozen lead simulations

313 All simulations with turbulent diffusion (RL\_Sim2 – RL\_Sim5, Table 1), predict higher bottom chlorophyll *a* (*Chl a*)  
314 concentration than with the standard molecular diffusion formulation (RL\_Sim1) (Fig. 1a). Simulations RL\_Sim2 - 4 grossly  
315 overestimate observations. Simulation RL\_Sim3, using the lowest value for  $\alpha_s$ , is closer both to observations and to RL\_Sim1,  
316 as well as RL\_Sim5, with the latter having the same  $\alpha_s$  values of RL\_Sim4 but a half saturation constant for silicate limitation  
317 increased from its tuned value in Duarte et al. (2017) of 2.2  $\mu\text{M}$  to 5.0  $\mu\text{M}$  and algalN reduced (Table 1) to bring model results  
318 closer to observations. Patterns between simulations for the whole ice column and considering both standing stocks and net  
319 primary production, are similar to those observed for the bottom-ice (Fig. 1b). Algal biomass is concentrated at the bottom  
320 layers (Fig. 2). Concentrations in the layers located between the bottom and the top of the biogrid, defined by the vertical  
321 extent (brine height) of the brine network (green lines in the map plots) (Jeffery et al., 2011) are  $< 10 \text{ mg Chl } a \text{ m}^{-3}$ . Ice  
322 thickness, temperature and salinity profiles are extremely similar among these simulations (Figs. S1 and S2).

323 Results for the silicate and nitrogen limiting factors are based on brine concentrations. Limiting factors exhibiting lower values  
324 (more limitation) in RL simulations are silicate, followed by light (Figs. 3, S3 – S5). Limiting values for silicate range between  
325 zero (maximum limitation) and one (no limitation), with stronger limitation after May 13 in all simulations (Fig. 3). The most  
326 severe silicate limitation is for RL\_Sim1, where values drop to near zero around middle May. Despite the high average bottom  
327 *Chl a* concentration predicted in all simulations the bottom layer is where silicate limitation is less severe after May 13. This  
328 is more evident in simulations with turbulent bottom diffusion, where light limitation at the bottom-ice becomes more severe  
329 than silicate limitation around the end of May (Fig. S6).

330 Results obtained with RL\_Sim6-9, without algal exchanges between the ocean and the ice (see Table 1), show similar patterns  
331 of those observed with RL\_Sim1-5, respectively (Fig. 4 versus Fig. 2, Fig. S9 versus Fig. 3, Figs. S7 and S8 versus Figs. S1  
332 and S2, Figs. S10 – S12 versus Figs. S3 – S5).

333 Interface diffusivity (one of CICE diagnostic variables, corresponding to the diffusion coefficient between adjacent  
334 biogeochemical layers and between the bottom layers and the ocean) for simulations with turbulent exchanges ( $\alpha_{i,u} * H$ ) are up  
335 to two orders of magnitude higher at the bottom (diffusivity between the bottom layer and the ocean) than for the RL\_Sim1  
336 simulation with only molecular diffusion ( $D_m$ ) + the mixed length diffusion coefficient ( $D_{MLD}$ ) (refer 2.1 and Fig. 5).

367

### 368 3.2 Second year ice simulations

369 Simulations with turbulent diffusion (SYI\_Sim2 and 3), predict only slightly higher standing stocks and net primary production  
 370 than with the standard molecular diffusion formulation (SYI\_Sim1) (Fig. 6). The visual fit to the standing stock observations  
 371 is comparable between the various simulations. Changing the half saturation constant for silicate limitation from 2.2 to 4.0  $\mu\text{M}$   
 372 has no impact on model results. This is confirmed by analysing the evolution of *Chl a* concentration as a function of time and  
 373 depth in the ice (Fig. 7), with only minor differences being apparent towards the end of the simulation, when *Chl a* increases

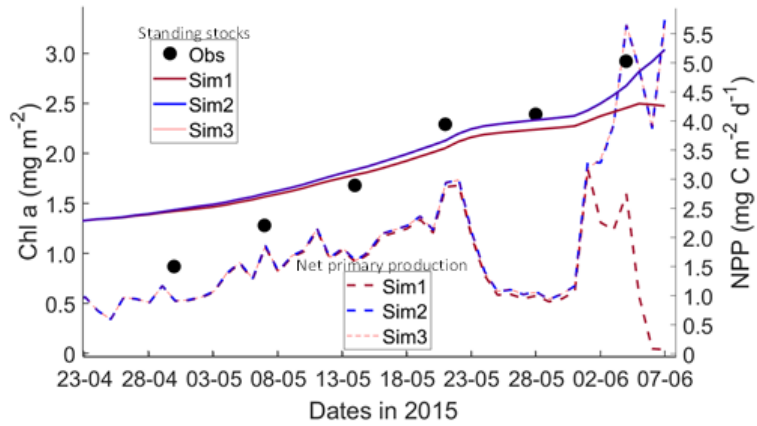

374 at the bottom layers in the simulations with turbulent diffusion (SYI\_Sim 2 and 3). Ice thickness, temperature and salinity  
375 profiles are extremely similar among these simulations (Fig. S13).

376 The dominant limiting factor in these simulations is light, followed by silicate (compare Fig. 8a, c and e with 8b, d and f and  
377 with Fig. S14). Light limitation is less severe after the onset of snow and ice melting at the beginning of June. Silicate limitation  
378 is very strong above the bottom ice. Nitrogen limitation is highest at a depth range between ~0.4 ~0.7 m below the ice top,  
379 with a large overlap with the depth range where a *Chl a* maximum is observed (Fig. 7). Maximal *Chl a* concentration predicted  
380 for the RL\_Sim1 and RL\_Sim5 simulations - those closer to observations - are two orders of magnitude higher than those  
381 predicted for SYI (Fig. 2a and e versus Fig. 7). However, standing stocks predicted for RL\_Sim1 and RL\_Sim5 simulations  
382 are smaller than for SYI simulations, as confirmed by the observations (Figs. 1b and 6). Opposite to what was described for  
383 the RL simulations, silicate limitation becomes more severe than light limitation at the bottom layer only in SYI\_Sim\_1, at the  
384 beginning of June, close to the end of the simulation (Fig. S15).

385 Results obtained without algal exchanges between the ocean and the ice (SYI\_Sim4 and 5, see Table 1), show the same patterns  
386 of those observed with SYI\_Sim1 and 2, respectively (Fig. 9 versus Fig. 7, Fig. S17 versus Fig. 8, Figs. S18 versus S14a - d  
387 and Figs. S16 versus S13a - d).

388 Interface diffusivity (one of CICE diagnostic variables, see above) for simulations with turbulent bottom exchanges are up to  
389 four orders of magnitude higher at the bottom ice than for simulations with only molecular diffusion (Fig. S19, showing a  
390 comparison between SYI\_Sim1 and SYI\_Sim2).

391 SYI\_Sim1 and 2 were repeated with varying snow thickness (Table 1 and Figs. 10 and 11). In the former simulation (Fig. 10a),  
392 as snow height decreases, there is a reduction in light limitation and a sharp increase in silicate limitation, overtaking light  
393 limitation (values becoming lower) as early as mid-May. In the latter simulation (Fig. 10b), light limitation prevails irrespective  
394 of snow height, except in the case of the lower snow height of 15 cm where silicate becomes more limiting towards the end of  
395 the simulation. With the decrease in snow height, there is an increase in *Chl a* concentration in all simulations. Highest values  
396 for SYI\_Sim2 are ~one order of magnitude larger than those for SYI\_Sim1. Moreover, the decrease in snow heights is followed  
397 by an earlier and more intense bottom ice algal bloom.

 426 upper regions of the graphs, above the green line with zero values, are above the CICE biogrid and have no brine network. The  
 427 magenta line represents sea level, and the cyan line represents the top of the snow layer. Refer to Table 1 for a description of model  
 428 simulations.

429 **4. Discussion**

430 The results obtained in this study support the initial hypothesis, showing that considering the role of velocity shear on turbulent  
 431 nutrient exchanges between the ocean and the sea ice, formulated in a way consistent with heat exchanges, leads to a reduction  
 432 in nutrient limitation that supports a significant increase in ice algal net primary production and *Chl a* biomass accumulation  
 433 in the bottom ice layers, when production is nutrient limited. Therefore, our results are in line with empirical evidence provided  
 434 by Cota et al. (1987) and Dalman et al. (2019) but, to the best of our knowledge, experimental evidence from properly designed  
 435 experiments is still lacking to test our hypothesis. Moreover, our results do not imply necessarily that experiments carried out

436 with other sea-ice models would render the same trends. The implementation of turbulent mixing considerably relieved silicate  
437 limitation in the RL simulations, leading to an increase in NPP, in the duration of the algal growth period, in bottom *Chl a*  
438 concentration and in-ice light absorption, increasing light limitation due to shelf-shading [in the CICE model, optical ice  
439 properties are influenced by ice algal concentrations (Jeffery et al., 2016)].

440 In the N-ICE2015 biogeochemical dataset (Assmy et al., 2016), the median of dissolved inorganic nitrogen to silicate ratios in  
441 all surface and subsurface water masses, is above 1.7 (unpublished data), which is the upper limit for the nitrogen to silicate  
442 ratio for polar diatoms (e.g. Takeda, 1998; Krause et al. 2018). Therefore, it can be expected that, in the region covered by the  
443 N-ICE2015 expedition, silicate is more limiting than nitrogen for the production yields of the pennate diatoms characteristic  
444 of the bottom-ice communities [the dominant algal functional group in bottom ice, e.g. Leu et al. (2015), van Leeuwe et al.  
445 (2019)]. Elsewhere in the Arctic the opposite may be true, considering nitrate and silicate concentrations presented in Leu et  
446 al. (2015) and the number of process studies documenting such limitation [e.g., Campbell et al. (2016)]. However, the  
447 conclusions taken here about the effects of turbulent mixing are independent of the limiting nutrient.

448 Implementing turbulent diffusion between the ice and the ocean has obvious implications for model tuning. Our results for the  
449 RL show that with this formulation it was necessary to increase the half saturation constant for silicate uptake and to reduce  
450 the ocean concentration of algal nitrogen (algalN), reducing the colonization of bottom ice by ice algae, to obtain *Chl a* values  
451 comparable to those observed (RL\_Sim5). Therefore, whereas Duarte et al. (2017) had to reduce silicate limitation to improve  
452 the fit between modelled and observational data, the opposite approach was required when using turbulent diffusion in line  
453 with results reported in Lim et al. (2019) for Antarctic sea ice diatoms. This is an example of how one can get good model  
454 results by the wrong reasons with difficult to predict consequences on model forecasts under various scenarios.

455 In the SYI case, only a minor increase in bottom *Chl a* concentration was observed towards the end of simulations SYI\_Sim\_2  
456 and SYI\_Sim\_3, when light limitation due to the thick snow cover was relieved by snow melt. Silicate limitation was not as  
457 severe as in SYI\_Sim\_1, due to greater bottom exchanges in the former simulations. The importance of snow cover in  
458 controlling ice algal phenology has been stressed before [e.g., Campbell et al. (2015), Leu et al. (2015)].

459 Duarte et al. (2017) used the delta-Eddington parameter, corresponding to the standard deviation of the snow grain size  
460 ( $R_{\text{snow}}$ ) (Urrego-Blanco et al., 2016), to tune model predicted shortwave radiation at the ice bottom. However, there was  
461 still a positive shortwave model bias in June. Therefore, our conclusion about the main limiting role of light in SYI is  
462 conservative. Moreover, in part of SYI cores sampled during the N-ICE2015 expedition, in the period covered by our  
463 simulations, with an unusually high snow thickness (~40 cm), there was no *Chl a* bottom maximum (Duarte et al., 2017; Olsen  
464 et al., 2017).

465 The dominant role of light limitation in SYI was confirmed in the simulations with reduced snow thickness and alleviated light  
466 limitation, with a bottom-ice algal *Chl a* maximum emerging earlier at snow thickness  $\leq 20$  cm. The reduction of snow  
467 thickness had a much larger effect in increasing *Chl a* concentration at the bottom layer when turbulent mixing was used, due  
468 to lower silicate limitation. Reducing snow thickness led to a relatively early shift from light to silicate limitation when we  
469 used molecular and mixed length diffusion, whereas this shift occurred only at the very end of the simulated period when we

470 used turbulent diffusion at the ice-ocean interface, driven by velocity shear, instead of molecular diffusion. The effects of  
471 different types of diffusion, upon reduction of the snow cover and the possible development of a bottom ice algal bloom, are  
472 critical aspects when simulating ice algal phenology and attempting to quantify the contribution of sea ice algae to Arctic  
473 primary production.

474 Simulated shear-driven turbulent diffusivities are up to four orders of magnitude higher than molecular + mixed length  
475 diffusivities at the bottom ice and the results presented herein emphasize their potential role in sea ice biogeochemistry. The  
476 number and intensity of Arctic winter storms has increased over the 1979–2016 period (Rinke et al., 2017; Graham et al.,  
477 2017) and the effect of more frequent and more intensive winter storms in the Atlantic Sector of the Arctic Ocean is a thinner,  
478 weaker, and younger snow-laden ice pack (Graham et al., 2019). Storms that occur late in the winter season, after a deep  
479 snowpack has accumulated, have the potential to promote ice growth by dynamically opening leads where new ice growth can  
480 take place. The young ice of the refrozen leads does not have time to accumulate a deep snow layer until the melting season,  
481 which could lead to light limitation of algal growth. All things considered, it can be expected that ongoing trends in the Arctic  
482 will lead to a release from light limitation in increasingly larger areas of the ice pack in late winter, which will lead to more  
483 likely nutrient limitation earlier in spring (e.g. Lannuzel et al. 2020). These effects will be further amplified under thinning of  
484 the snowpack as observed in western Arctic, and in the Beaufort and Chukchi seas, over the last decades (Webster et al., 2014).  
485 Therefore, properly parameterizing nutrient exchanges between the ice and the ocean in sea-ice biogeochemical models is of  
486 utmost importance to avoid overestimating nutrient limitation and thus underestimating sea ice algal primary production.

487 In existing sea-ice models there are “natural” differences between the way budgets for non-conservative tracers such as  
488 nutrients are closed compared to those of heat and salt, which are related to the biogeochemical sinks and sources (e.g., equation  
489 18 in Vancoppenolle et al., 2010), but also some “inconsistencies”, related with the way their transfers between the ocean and  
490 the ice are computed. Interestingly, some models (e.g., Jin et al., 2006, 2008 and Hunke et al., 2016) apply the diffusion  
491 equation to calculate exchanges across the bottom ice not only to dissolved tracers, but also to algal cells. This is to guarantee  
492 a mechanism of ice colonization by microalgae. However, the usage of the same coefficient for dissolved and particulate  
493 components creates significant uncertainty.

494 Molecular diffusion is a slow process compared with turbulent exchanges. This justifies the usage of diffusion coefficients  
495 which are much higher than molecular diffusivity, as in Jin et al. (2006), using a value of  $1.0 \cdot 10^5 \text{ m}^2 \text{ s}^{-1}$ , four orders of  
496 magnitude higher than the value indicated in Mann and Lazier (2005) –  $1.5 \cdot 10^9 \text{ m}^2 \text{ s}^{-1}$  – or the parameterization of molecular  
497 diffusivity as a function of friction velocity as in Mortenson et al. (2017). The approach proposed herein, formulating botto-  
498 m-ice nutrient exchanges in a way that is consistent with heat exchanges, provides a physically sound, consistent, and easy to  
499 implement alternative.

500 Calculating diffusion fluxes across the molecular sublayer may be challenging, since it is necessary to estimate the boundary  
501 concentrations of this layer, which is only a few tenths of millimetre thick (e.g. Lavoie et al., 2005). This implies resolving  
502 with a great detail the ocean surface layer (sensu MacPhee, 2008), which is not practical with standalone sea ice models but  
503 doable with coupled ocean-sea ice models. Moreover, one needs to know whether exchanges of heat, salt and nutrients are

Formatted: Superscript

Formatted: Superscript

504 dominated by molecular exchange or by turbulent exchange. This may be challenging on its own since it depends not only on  
505 knowing friction velocities but also on knowing the roughness of the bottom ice (e.g. Olsen et al.2019). Ideally, when using  
506 coupled ocean-sea ice models, and assuming it is practical to estimate the type of dominant exchanges, one may use either the  
507 approach described by Lavoie et al. (2005) or the approach described herein based on McPhee (2008) and grounded on  
508 experimental work. Whatever the case, it seems rather likely that we still lack the measurements to properly evaluate these  
509 various approaches and find an optimal solution. The way forward implies the availability of eddy covariance data for 3D  
510 current velocity, temperature, salinity and ideally, a limiting nutrient, collected at the sea ice-ocean interface over periods of  
511 sea ice growth and melting. Such data should be accompanied by vertical profiles for the same tracers, at high resolution,  
512 across the surface and the mixing layers (*sensu* McPhee, 2008) and by sea ice bottom samples. Such experiments may be  
513 carried out in the sea and in sea ice laboratories under controlled conditions, and they will help to evaluate the results presented  
514 herein and improving the parameterizations used in models for the sea ice-ocean interface. Another layer of complexity are  
515 the effects of sea ice ridges and keels on the turbulent exchange coefficients (Tsamados et al., 2014). According to these  
516 authors such effects are important for regional sea ice modelling, which reinforces the need of experimental studies of the type  
517 mentioned above.  
518

## 519 **5. Conclusions**

520 Considering the role of velocity shear on turbulent nutrient exchanges at the interface between the ocean and the ice in a sea-  
521 ice biogeochemical sub-model, leads to a reduction in nutrient limitation and a significant increase in ice algal net primary  
522 production and *Chl a* biomass accumulation in the bottom-ice layers, when production is nutrient limited. The results presented  
523 herein emphasize the potential role of bottom-ice nutrient exchange processes, irrespective of brine dynamics and other  
524 physical-chemical processes, in delivering nutrients to bottom-ice algal communities, and thus the importance of properly  
525 including them in sea-ice models. The relevance of this becomes even more apparent considering ongoing changes in the  
526 Arctic icescape, with a predictable decrease in light limitation as ice becomes thinner and more fractured, with an expected  
527 reduction in snow cover.

### 528 **Code availability**

529 The software code used in this study may be found at:

530 <https://doi.org/10.5281/zenodo.4675097>

and ~~<https://doi.org/10.5281/zenodo.4675021>~~

531 <https://doi.org/10.5281/zenodo.5795034>

532 This code is in a fork derived from the CICE Consortium repository (<https://github.com/CICE-Consortium>).

533 The Consortium’s codes are open-source with a standard 3-clause BSD license and are is under the following Copyright  
534 license, available at (<https://cice-consortium-cice.readthedocs.io/en/master/intro/copyright.html>)

535

#### 536 **Data availability**

537 Model forcing function files may be found at: <https://doi.org/10.5281/zenodo.4672176>

538 Results from model simulations described above, in the form of CICE daily netCDF history files iceh.\* may be found at:  
539 <http://doi.org/10.5281/zenodo.4672210>

540 There is one directory for each simulation, and it includes besides the historical files the input file (ice\_in) with the simulation  
541 parameters.

542

#### 543 **Authors contribution**

544 Pedro Duarte made the software changes, designed the experiments, performed the simulations and prepared the manuscript  
545 with contributions from all co-authors.

546 Philipp Assmy contributed to the writing of the manuscript.

547 Karley Campbell contributed to the writing of the manuscript.

548 Arild Sundfjord contributed to the writing of the manuscript and to funding acquisition.

549

#### 550 **Competing interests**

551 The authors declare that they have no conflict of interest.

#### 552 **Acknowledgements**
