15 **Abstract**

16 Wildfire is an important ecosystem process, influencing land biogeophysical and
17 biogeochemical dynamics and atmospheric composition. Fire-driven loss of vegetation cover, for
18 example, directly modifies the surface energy budget as a consequence of changing albedo,
19 surface roughness, and partitioning of sensible and latent heat fluxes. Carbon dioxide and
20 methane emitted by fires contribute to a positive atmospheric forcing, whereas emissions of
21 carbonaceous aerosols may contribute to surface cooling. Process-based modeling of wildfires in
22 earth system land models is challenging due to limited understanding of human, climate, and
23 ecosystem controls on fire number, fire size, and burned area. Integration of mechanistic wildfire
24 models within Earth system models requires careful parameter calibration, which is
25 computationally expensive and subject to equifinality. To explore alternative approaches, we
26 present a deep neural network (DNN) scheme that surrogates the process-based wildfire model
27 with the Energy Exascale Earth System Model (E3SM) interface. The DNN wildfire model
28 accurately simulates observed burned area with over 90% higher accuracy with a large reduction
29 in parameterization time compared with the current process-based wildfire model. The surrogate
30 wildfire model successfully captured the observed monthly regional burned area during
31 validation period 2011 to 2015 (coefficient of determination, $R^2 = 0.93$). Since the DNN wildfire
32 model has the same input and output requirements as the E3SM process-based wildfire model,
33 our results demonstrate the applicability of machine learning for high accuracy and efficient
34 large-scale land model development and predictions.

35 1. Introduction

36 Wildfires burn ~500 million hectares of vegetated land surface each year, which
37 significantly modifies the physical properties and biogeochemical cycles of terrestrial
38 ecosystems [Andela *et al.*, 2017; Bond-Lamberty *et al.*, 2007; Pellegrini *et al.*, 2018; Randerson
39 *et al.*, 2006]. Living vegetation biomass, surface litter, and coarse woody debris are directly
40 combusted and removed by wildfire [Harden *et al.*, 2006; Walker *et al.*, 2019]. It has been
41 suggested that global forest would double if fire were eliminated [Bond *et al.*, 2005]. Fire has
42 multiple important consequences for the climate system, including directly releasing greenhouse
43 gases (*e.g.*, CO₂, CH₄) [Kasischke and Bruhwiler, 2002; Ross *et al.*, 2013] and aerosols [Jiang *et al.*, 2020];
44 changing land surface albedo and energy budgets [French *et al.*, 2016; Rother and De
45 Sales, 2020] and land-atmosphere exchanges of heat, mass, and momentum [Chambers and
46 Chapin, 2002]; limiting plant transpiration and regional water recycling [Brando *et al.*, 2020;
47 Holden *et al.*, 2018]; and reshaping forest composition [Mekonnen *et al.*, 2019]. In addition,
48 biomass burning emits a large amount of fine particulate matter that contributes to about 30% of
49 cloud condensation nuclei globally [Day, 2004]. Soil organic matter decomposition, nitrogen
50 mineralization, and the richness and diversity of soil fungal communities [Oliver *et al.*, 2015]
51 could also be influenced by wildfire through modifying litter substrate supply and degraded
52 enzymatic activities [Bowd *et al.*, 2019; Holden *et al.*, 2018; Pellegrini *et al.*, 2018; Pellegrini *et al.*, 2020].
53

54 Climate change and land use activities have jointly affected fire spatial distribution,
55 frequency, and intensity [Andela *et al.*, 2017; Kelley *et al.*, 2019; X Xu *et al.*, 2020] since the pre-
56 industrial era. For example, warmer and drier climate conditions enhance fuel aridity and favor
57 fire occurrence in forest ecosystems where fuels have built up over a period of decades and
58 centuries [Abatzoglou and Williams, 2016; Williams *et al.*, 2019]. Even if annual precipitation
59 does not decline, redistribution of precipitation towards wet season extreme rainfall events could
60 contribute to longer dry periods and thus more severe fire activity [X Xu *et al.*, 2020]. Human
61 activities often shape wildfire activity through regulating patterns of ignition and fire occurrence
62 (*e.g.*, powerline ignition) [Keeley and Syphard, 2018] and suppressing wildfire activity by means
63 of land fragmentation, fire management, and livestock grazing [Andela *et al.*, 2017]. In
64 California, fire density is highly associated with population density and the distance to the
65 wildland urban interface (WUI) [Syphard *et al.*, 2007]. At the global scale, along gradients of

66 increasing population density, fire frequency initially increases by up to 20% and then gradually
67 declines in more densely populated areas [Knorr et al., 2014].

68 Although global wildfire burned area has declined over the recent two decades [Andela et
69 al., 2017], many vulnerable ecosystems and geographic regions have experienced significant
70 increases in wildfire activity [Abatzoglou and Williams, 2016; Walker et al., 2019] resulting in
71 large losses of natural resources and economic assets [Papakosta et al., 2017; Stephenson et al.,
72 2013]. Over western U.S. forests, wildfire has dramatically increased, costing billions of dollars
73 each year and gaining wide public attention. This regional wildfire increase is mainly driven by
74 concurrent increases of spring temperature and declining snowpack [Westerling et al., 2006],
75 mid-summer increases in vapor pressure deficit [Williams et al., 2019], and increases in drought
76 stress during fall [Goss et al., 2020]. The enhancement of wet and dry oscillations favors initial
77 vegetation growth and subsequent wildfire activity [Heyerdahl et al., 2002; Saha et al., 2019].

78 Wildfire models have played an important role in many aspects of wildfire research,
79 including monitoring fire spread [Finney, 1998; Radke et al., 2019], analyzing controllers of
80 wildfire short-term and long-term variability [Kelley et al., 2019], predicting severity of the
81 upcoming fire seasons [Preisler and Westerling, 2007] and climate-scale fire variability
82 [Girardin and Mudelsee, 2008; Yue et al., 2013], and understanding the complex climate-
83 wildfire-ecosystem feedbacks [Clark et al., 2004; Mekonnen et al., 2019; Zou et al., 2020]. Two
84 types of wildfire models are widely used: process-based models and data-driven statistical
85 models [Hantson et al., 2016]. Process-based wildfire models consider detail processes related to
86 natural fire ignition [Prentice and Mackerras, 1977], anthropogenic ignition [Venevsky et al.,
87 2002], fire spread and duration [Thonicke et al., 2010], fire suppression [Lenihan and Bachelet,
88 2015], and fire mass and heat fluxes [F Li et al., 2012]. Process-based wildfire models have been
89 widely used in dynamic vegetation models and coupled earth system models (ESMs) with
90 various complexities of parameterization [Fang Li et al., 2019; Rabin et al., 2017]. As more and
91 more detailed fire processes are considered and parameterized, structural and parametric
92 uncertainties may increase due to incomplete representation of individual processes and
93 imperfect mathematical formulation [Riley and Thompson, 2017]. Historically, data-driven
94 models were often used for fire behavior modeling and aim to track the ignition, spread,
95 duration, and extinction of individual fires [Finney, 1998; Radke et al., 2019] at fine spatial and
96 temporal scales. This group of models are more relevant to operational fire research. While

97 process-based wildfire models in the context of global vegetation models or earth system land
98 models focuses on the gridcell aggregated fire burned area dynamics that are more relevant to
99 researches on large scale patterns and climate scale predictions [Fang Li et al., 2019; Rabin et
100 al., 2017]. This study particularly focuses on the second category of wildfire models.

101 Although explicit processes are simulated, the accuracy of process-based wildfire models
102 are highly dependent on parameterization, which is computationally expensive [Teckentrup et
103 al., 2018; L Xu et al., 2021; Zhu and Zhuang, 2014]. Data-driven models, however, directly link
104 the driving variables (e.g., climate factors) to the fire activity using simple statistical models or
105 more sophisticated machine learning techniques, ignoring the explicit processes and feedbacks
106 associated with wildfire [Ganapathi Subramanian and Crowley, 2018; Radke et al., 2019; Tonini
107 et al., 2020]. Through training and validation, statistical representations of wildfire dynamics are
108 learned by models using principles from machine learning. Data-driven wildfire models are
109 diverse in terms of driving variables and model structure. For example, many current machine
110 learning wildfire models rely on remote oceanic dynamics (e.g., sea surface temperature
111 variability) and atmospheric teleconnections to simulate land surface fire activities [Chen et al.,
112 2020; Chen et al., 2011; Yu et al., 2020]. Another group of data-driven wildfire models draws
113 more heavily upon regional climate, plant functional type, and human infrastructure driver
114 variables [Coffield et al., 2019; Sayad et al., 2019].

115 In this study, we develop a machine learning wildfire model using the process
116 representation of wildfire in the Energy Exascale Earth System Model (E3SM) land model
117 (ELMv1) [Zhu et al., 2019], five observationally inferred burned area products [Andela et al.,
118 2019; Giglio et al., 2018; Lizundia-Loiola et al., 2020; Lizundia-Loiola et al., 2018; Van Der
119 Werf et al., 2017], and a deep neural network approach [Goodfellow et al., 2016]. We
120 implemented a deep learning model that can better capture the complex and non-linear
121 interactions between controlling factors and wildfire activity. The objectives of this study are to
122 surrogate the wildfire parameterization in ELMv1 with the deep neural network and improve the
123 model simulated wildfire burned area across various fire regions [Giglio et al., 2013].

124

125 **2. Methodology**

126 **2.1 ELMv1 wildfire model**

127 The process-based wildfire model in ELMv1 originates from the Community Land
128 Model (CLM4.5) [*F Li et al.*, 2012]; we take this wildfire model as the baseline (hereafter refer
129 to as BASE-Fire) without modification on process representation. BASE-Fire combines
130 information regarding ignition, fuel conditions, surface climate, and anthropogenic suppression
131 to simulate total burned area based on the fire counts and spread area of each fire (Figure 1). The
132 fire count in BASE-Fire is modeled as the sum of anthropogenic ignition and natural ignition,
133 where the latter is proportional to lightning density [*Prentice and Mackerras*, 1977] and the
134 former is determined by population density [*Venevsky et al.*, 2002]. Human activity may also
135 intentionally suppress wildfire occurrence if the fire is detected at early stage. For example,
136 developed regions with high population density and gross domestic product are less likely to use
137 fire to remove surface biomass. On the other hand, developed regions more likely suppress fire
138 given more effective fire management policy and suppression capability. Fire count is also
139 affected by surface fuel availability (aboveground biomass) and fuel combustibility (relative
140 humidity, topsoil temperature and moisture). The fire spread area in BASE-Fire is modeled as an
141 elliptical shaped region controlled by wind speed and fuel wetness [*Rothermel*, 1972] (using
142 topsoil (0 – 15 cm) moisture as a proxy). The fire duration is set to be one day based on a study
143 that reported years 2001-2004 mean global fire persistence [*Giglio et al.*, 2006a]. BASE-Fire
144 also does not explicitly consider roads, rivers, and firefighting activity [*Arora and Boer*, 2005].
145

146

147 **Figure 1.** Schematic representation of the ELMv1 process-based BASE-Fire model and the
 148 components to be surrogated with the Deep Neural Network (DNN) model (dark grey).

149

150 2.2 Deep neural network wildfire surrogate model

151 We developed the new fire model in two steps: (1) surrogating BASE-Fire with a deep
 152 neural network (DNN) approach and (2) improving that surrogate model using five
 153 observationally inferred burned area products (Table S1). First, we surrogated BASE-Fire with a
 154 DNN approach (hereafter refer to as DNN-Fire) that uses the same input and output variables as
 155 BASE-Fire but treats the explicit intermediate processes (*e.g.*, ignition, fire spread) as latent
 156 variables coded by hidden layers in the DNN (Figure 1). DNN-Fire was developed with five
 157 hidden layers and five neurons in each layer for burned area simulation. The DNN approach uses
 158 a fully-connected feedforward neural network [*Schmidhuber, 2015*] that comprises input, hidden,
 159 and output layers:

$$h_1 = f_1(W_1 I + b_1) \quad (1)$$

$$h_2 = f_2(W_2 h_1 + b_2) \quad (2)$$

$$h_3 = f_3(W_3h_2 + b_3) \quad (3)$$

$$h_4 = f_4(W_4h_3 + b_4) \quad (4)$$

$$h_5 = f_5(W_5h_4 + b_5) \quad (5)$$

$$O = f_6(W_6h_5 + b_6) \quad (6)$$

160 where I denotes the input layer (*e.g.*, climate factors) with 11 neurons, each corresponding to an
 161 input variable listed in Table 1. h_1 , h_2 , h_3 , h_4 , and h_5 are five hidden vectors that are calculated
 162 with two steps. First is a linear combination of previous layers' input vector (h) and the trainable
 163 weight parameter matrix [W_1 , W_2 , W_3 , W_4 , W_5 , W_6], considering biases b_1 , b_2 , b_3 , b_4 , b_5 , and b_6 .
 164 Then, nonlinear activation functions f_1 , f_2 , f_3 , f_4 , f_5 , and f_6 . are applied to the output from the
 165 previous step. In this study we used *softplus* as the activation function [Zheng *et al.*, 2015] that is
 166 a non-linear transformation of input signals. O denotes the output layer that summarize the latent
 167 variables from the last hidden layer (h_5) and calculate burned area.

168 **Table 1.** Input and output variables of ELMv1 BASE-Fire and surrogate DNN-Fire models

Variable category	Variable name	Data source and reference
<i>Input variables</i>		
Fuel conditions	Tree coverage	LUH2 [Hurtt <i>et al.</i> , 2020]
	Fuel load	ELMv1 total biomass [Zhu and Riley, 2015; Zhu <i>et al.</i> , 2019]
	Fuel wetness	ELMv1 topsoil moisture [Zhu and Riley, 2015; Zhu <i>et al.</i> , 2019]
	Fuel temperature	ELMv1 topsoil temperature [Zhu and Riley, 2015; Zhu <i>et al.</i> , 2019]
Climate factors	Precipitation	GSWP3 [Dirmeyer <i>et al.</i> , 2006]
	Near surface temperature	GSWP3 [Dirmeyer <i>et al.</i> , 2006]
	Wind speed	GSWP3 [Dirmeyer <i>et al.</i> , 2006]
	Relative humidity	GSWP3 [Dirmeyer <i>et al.</i> , 2006]
Ignition	Population density	[Dobson <i>et al.</i> , 2000]
	Lightning frequency	NASA-LIS/OTD [Cecil <i>et al.</i> , 2014]
Anthropogenic suppression	GDP	[van Vuuren <i>et al.</i> , 2007]
	Population density	[Dobson <i>et al.</i> , 2000]

<i>output variable</i>	
Burned area	ELMv1 percentage burned area [Zhu and Riley, 2015; Zhu et al., 2019]

169

170 Second, we improved the surrogate DNN-Fire by fine-tuning the weight parameters using
 171 observations (hereafter refer to DNN-Fire-OBS). Between 2001 and 2010, we initialized
 172 DNN-Fire-OBS’s weight parameters (W_1 , W_2 , W_3 , W_4 , W_5 , and W_6) using results from DNN-Fire,
 173 replaced the BASE-Fire burned area by the ensemble mean of five observationally inferred
 174 burned area products including GFEDv4s [Van Der Werf et al., 2017], Fire_CCI51 [Lizundia-
 175 Loiola et al., 2020], Fire_CCILT11 [Lizundia-Loiola et al., 2018], MODIS MCD64 [Giglio et
 176 al., 2018], and Fire_Atlas [Andela et al., 2019] (Table S1), and adjusted weight parameters until
 177 the model best reproduced the observed burned area. This two-step approach will also allow
 178 rapid parameterization of the Fire model as new fire data and baseline fire model results become
 179 available. DNN-Fire-OBS can be more easily generalized since BASE-Fire provides explicit
 180 physical guidance and a larger-than-observation input and output feature space for development
 181 of the machine learning fire model. One limitation is the large discrepancy among five burned
 182 area products. Tuning DNN-Fire towards the ensemble mean of the five products will potentially
 183 compromise the data difference, however, future work is needed to improve the burned area data
 184 quality and consistency.

185 **2.3 Model setup and simulation protocol**

186 We ran ELMv1 with BASE-Fire at 1.9° by 2.5° spatial resolution [Zhu et al., 2020; Zhu
 187 et al., 2016] to generate training and testing datasets for the DNN wildfire model. BASE-Fire
 188 was first spun up for 600 years with accelerated soil decomposition followed by 200 years
 189 regular spinup with regular soil decomposition [Koven et al., 2013]. The spinup simulations were
 190 forced with constant atmospheric CO₂ concentration (285 ppmv) and 1901-1920 repeated
 191 climate forcing from GSWP3 (Global Soil Wetness Project) [Dirmeyer et al., 2006]. The purpose
 192 of the spinup was to initialize ecosystem carbon pools and stabilize plant and soil carbon and
 193 water fluxes. Restarting from the “spunup” conditions, a transient simulation was then conducted
 194 from 1901 to 2015 with GSWP3 transient climate forcing, atmospheric CO₂ concentrations, and
 195 nitrogen and phosphorus deposition [Lamarque et al., 2005; Mahowald et al., 2008]. Wildfire
 196 associated variables were selected for output with a monthly temporal resolution (Table 1).

197 BASE-Fire output from years 1981 to 2010 were used to train, test, and fine-tune
 198 DNN-Fire. We developed 14 region-specific models, corresponding to 14 widely used GFED
 199 regions. For each region, all land gridcells (comprising no fire history, infrequent fire, and
 200 repeated fire) were concatenated into one data matrix (where rows consist of the number of
 201 samples and columns of the number of variables). 80% of the data matrix was randomly sampled
 202 for the training dataset and the remaining 20% of the data were reserved for testing. Furthermore,
 203 the random sampling was stratified in order to reduce the risk of sampling, e.g., adjacent high
 204 fire grid cells. All grid cells were first divided into three “strata”: low burn (0-33% percentile),
 205 median burn (33%-66% percentile), and high burn (67-100% percentile) grid cells based on the
 206 magnitude of the burn. The stratified random sample assured the sampled grid cells for training
 207 and testing had the same ratios of low/medium/high burn, thus eliminating the sampling bias
 208 from spatial autocorrelation [Wang *et al.*, 2012]. In addition to random sampling, we also
 209 investigated the impacts of data choice on the model performance, by sampling the testing
 210 datasets within specific years (*e.g.*, 2001-2002, 2003-2004, 2005-2006, 2007-2008, 2009-2010)
 211 and used the rest of the years for training. We found neglected differences among the models
 212 (Figure S1) indicating the choice of training/testing data years were not impactful. Therefore, we
 213 will discuss the results with stratified random sampling approach as the major results throughout
 214 the paper.

215 All training and testing datasets were normalized to the range [0, 1] with the following
 216 scaler:

$$X = \frac{X - X_{min}}{X_{max} - X_{min}} \quad (7)$$

217 where X is the variable vector of interest and X_{min} and X_{max} are minimum and maximum values of
 218 X , respectively. During the training stage, we randomly initialized the weighting parameters (Eq.
 219 1-6) and optimized them using the Adaptive Moment Estimation method [Kingma and Ba,
 220 2014], which is a variant of the gradient descent optimization method but considers adaptive
 221 learning rate and momentum-like exponentially decaying gradients. The parameter optimization
 222 aimed to minimize a mean squared error cost function:

$$J = \frac{1}{n} \sum_{i=1}^n (y_i^{DNN} - y_i^{BASE})^2 \quad (8)$$

223 where y_i^{DNN} and y_i^{BASE} are DNN-Fire and BASE-Fire generated burned area, respectively. i
 224 represents different gridcell. Cost function J summarizes the overall magnitude of the error

225 between the surrogate DNN-Fire and BASE-Fire. We then evaluated model performance using
 226 metrics of mean absolute error (Eqn. 9), Pearson correlation (Eqn. 10), and coefficient of
 227 determination (Eqn. 11).

$$228 \quad MAE = \frac{1}{n} \sum_{i=1}^n |y_i^{DNN} - y_i^{BASE}| \quad (9)$$

$$229 \quad p = \frac{covariance(y^{DNN}, y^{BASE})}{\sqrt{variance(y^{DNN})variance(y^{BASE})}} \quad (10)$$

$$230 \quad R^2 = 1 - \frac{\sum_{i=1}^n (y_i^{DNN} - y_i^{BASE})^2}{\sum_{i=1}^n (y_i^{BASE} - y_{mean}^{BASE})^2} \quad (11)$$

231

232 **3. Results and discussion**

233 **3.1 Evaluation of wildfire surrogate model**

234 BASE-Fire performed reasonably well for total global burned area (508 ± 53 Mha yr⁻¹
 235 (million hector per year) between years 2001 and 2010 compared with the observational long-
 236 term average of 424~484 Mha yr⁻¹; Figure 2, Table S1). BASE-Fire also captured the global
 237 declining trend of wildfire burned area over this time period, attributed to a decrease in tropical
 238 fires [Andela *et al.*, 2017]. At the regional scale, however, BASE-Fire underestimated tropical
 239 (S23.5° - N23.5°) burned area and overestimated temperate (N23.5° - N67.5°) and boreal (N67.5°
 240 above) burned area (Figure 2). Large spatial heterogeneity existed for BASE-Fire regional bias.
 241 For example, over tropical GFED regions, BASE-Fire overestimated wildfire burned area over
 242 Southern Hemisphere South America (SHSA), but underestimated wildfire burned area over both
 243 Southern and Northern Hemisphere Africa regions (SHAF and NHAF), despite an overall
 244 underestimation over the tropical region (Figure 3). In contrast, consistent overestimation
 245 occurred over all temperate GFED regions. For example, wildfire burned was overestimated by
 246 about a factor of 16 (~1 versus 16 Mha yr⁻¹) over the Europe GFED region (EURO) (Figure 3).
 247 Although there is room to improve BASE-Fire performance, the parameterization would involve
 248 large ensemble simulations and computational resources. Instead, we first used BASE-Fire
 249 generated data as training and testing datasets to parameterize DNN-Fire, then we fine-tuned the
 250 DNN-Fire model against observed burned area.

251
 252 **Figure 2.** ELMv1 process-based model (BASE-Fire) simulated and five observationally inferred
 253 burned area products (Table S1) at (a) global scale; (b) Tropical (S23.5° -N23.5°); (c) Temperate
 254 (N23.5° - N 67.5°); and (d) Boreal (north of N 67.5°) regions.
 255

256
 257 **Figure 3.** A comparison of wildfire burned area between estimates from the ELMv1 process-
 258 based model (BASE-Fire), Deep Neural Network wildfire model (DNN-Fire), Deep Neural
 259 Network wildfire model fine-tuned with observed burned area (DNN-Fire-OBS), and
 260 observations over 14 GFED fire regions.
 261

262 Next we parameterized and compared DNN-Fire with BASE-Fire outputs. Using BASE-
 263 Fire generated $1.9^\circ \times 2.5^\circ$ resolution datasets of surface fuel conditions (fuel load (vegetation
 264 biomass), fuel temperature (topsoil temperature), and fuel wetness (topsoil moisture)) with
 265 gridded climate forcing (GSWP3) [Dirmeyer *et al.*, 2006], land use (LUH2 dataset) [Hurtt *et al.*,
 266 2020], and social economic [Dobson *et al.*, 2000; van Vuuren *et al.*, 2007] factors, DNN-Fire
 267 captured the spatial pattern of BASE-fire predicted wildfire activity (Figure 4, Figure S2).
 268 Across all GFED regions, mean absolute error of DNN-Fire was 4.4 Mha yr^{-1} (<1% of total burn
 269 area), with median and maximum errors of 1.8 and 13.0 Mha yr^{-1} , respectively (Figure 3).
 270 Equatorial Asia (EQAS), Northern Hemisphere South America (NHSA), Central America
 271 (CEAS), and Europe (EURO) regions had the lowest DNN-Fire errors (< 1.0 Mha yr^{-1}), while
 272 Southern Hemisphere Africa (SHAF), and Boreal Asia (BOAS) had the largest errors (10-13
 273 Mha yr^{-1}). Overall, the correlation coefficient between BASE-Fire and DNN-Fire simulated
 274 burned area was 0.91 (p value < 0.01) and the coefficient of determination (R^2) was 0.79. Across
 275 seasons, DNN-Fire also reasonably captured the BASE-Fire peak fire months (June to October),
 276 which were dominated by Southern Hemisphere Africa and Southern Hemisphere South
 277 America (Figure 5).

278 By surrogating BASE-Fire, DNN-Fire is expected to have similar biases and
 279 uncertainties. The deficiency of BASE-Fire model will propagate to DNN-Fire. In our future
 280 work we will overcome such limitation by training multiple DNN-Fire models with ensemble
 281 simulations of BASE-Fire models that differ in critical parameters and vary in model structures.
 282

283

284 **Figure 4.** The performance of the Deep Neural Network wildfire model (DNN-Fire), compared
285 with the original ELMv1 process-based wildfire model (BASE-Fire) over 14 GFED regions
286 between years 2001 and 2010.

287

288 **3.2 Calibrating the wildfire surrogate model using observations**

289 Although the global pattern was reasonably captured, BASE-Fire had relatively large
290 biases in several GFED regions, as discussed above. Since DNN-Fire was trained and validated
291 only with BASE-Fire generated inputs (*e.g.*, fuel conditions) and outputs (burned area), we
292 expect that, at best, DNN-Fire would have comparable biases as BASE-Fire. Starting from
293 DNN-Fire, we further calibrated the model weighting parameters to create DNN-Fire-OBS and
294 validated DNN-Fire-OBS performance using observed burned area from five existing burned
295 area products (Table S1) between years 2001 and 2010. The calibration time cost several minutes
296 with Intel Xeon Phi Processor 7250 processor.

297 Dramatic improvements were found in most of the 14 regions simulated by DNN-Fire-
298 OBS (Figure 3). Overall, DNN-Fire-OBS simulated global long-term average burned area was
299 458 Mha yr⁻¹ (compared with observational average 467 Mha yr⁻¹). Averaged across 14 regions,
300 73% reduction of mean absolute error was achieved by DNN-Fire-OBS, compared with the
301 BASE-Fire model. Pearson correlation coefficient between the DNN-Fire-OBS simulated and
302 observational burned area was 0.98 (*p* value < 0.001) with an *R*² of 0.97. Bias reduction was
303 disproportionally distributed across the GFED regions (Figure 3). For example, severely burned
304 regions, including Southern and Northern Hemisphere Africa (SHAF and NHAF) and Southern
305 Hemisphere South America (SHSA) greatly benefited from the tuning and their regional biases
306 were reduced by 88, 65, and 51 Mha yr⁻¹ (or 88%, 89%, 98% reduction), respectively. Although
307 Temperate Northern America (TENA) and Europe (EURO) wildfire burned area is relatively
308 small (1-3 Mha yr⁻¹), the impacts of wildfire activity were significant due to their high population
309 densities. DNN-Fire tended to overestimate the burned area in TENA and EURO by 47 and 13
310 Mha yr⁻¹, while DNN-Fire-OBS significantly reduced biases in both regions to less than 0.3 Mha
311 yr⁻¹ (a 97-98%% reduction).

312 BASE-Fire tended to overestimate inter-annual variability (IAV) and had opposite burned
313 area anomalies between years 2001 and 2005. DNN-Fire dampened BASE-Fire's IAV, but had
314 systematic overestimation of burned area. DNN-Fire-OBS agreed well with the observed IAV

315 between years 2001 and 2010 (Figure 5a). The seasonal cycle was also improved in DNN-Fire-
 316 OBS in terms of reducing BASE-Fire's overestimation of burned area during peak fire seasons
 317 (Figure 5b, Figure S3), although we note that DNN-Fire-OBS is biased high during low fire
 318 seasons (March and April).
 319

320
 321 **Figure 5.** Inter-annual variation of burned area from years 2001 to 2010 (a) and the averaged
 322 seasonal cycle (b) of burned area estimated by the ELMv1 process-based wildfire model (BASE-
 323 Fire), Deep Neural Network wildfire model (DNN-Fire), Deep Neural Network wildfire model
 324 fine-tuned with observations (DNN-Fire-OBS), and observations.
 325

326 3.3 Prognostic simulation and limitations

327 We next evaluated the DNN-Fire-OBS model against observations for the period 2011 to
 328 2015, using data which were not used to train and validate the model. Overall, DNN-Fire-OBS
 329 simulated 469-514 Mha yr⁻¹ global burned area, compared with observations 349-509 Mha yr⁻¹.
 330 Note that the large observational ranges were mainly due to the differences among the five
 331 burned area products rather than the inter-annual variability (Figure 6). Regionally, DNN-Fire-
 332 OBS overestimated NHAF, SHAF and SHSA annual burned area by 8, 6, 2 Mha yr⁻¹,
 333 respectively (Figure 6) compared with the observational mean. Averaged latitudinal distribution
 334 of simulated burned area during this period showed that global wildfire activity peaked around
 335 S10°- S15° and N5°-N10°, together accounting for burning 12-16% of the land surface (Figure
 336 7). These two peaks were dominated by large burned area over Southern (SHAF) and Northern
 337 Hemisphere Africa (NHAF) fire regions. Compared with observations, DNN-Fire-OBS
 338 simulated reasonable burned area latitudinal distributions (Figure 7). We also compared the nine

339 FireMIP models [Rabin *et al.*, 2017; Teckentrup *et al.*, 2018] and found diverse latitudinal
 340 distribution of burned area. The across model differences were much larger than the inter-annual
 341 variation simulated by each individual model, which indicated large model structural
 342 uncertainties. Validation was also conducted for the historical period 1981-2000, when most of
 343 the satellite based burned area data were not available. Compared with charcoal index inferred
 344 burned area during 1981-2000 (Figure S4), DNN-Fire-OBS model reasonably captured the
 345 declining of burned area from $\sim 530 \text{ Mha yr}^{-1}$ to 490 Mha yr^{-1} . In summary, DNN-Fire-OBS
 346 simulation is reasonably accurate and: (1) improved the simulated wildfire spatial and temporal
 347 distributions in ELMv1; (2) enabled effective and efficient parameterization of fires at regional
 348 scale.
 349

350
 351 **Figure 6.** Prognostic simulation of annual wildfire burned area with the Deep Neural Network
 352 wildfire model fine-tuned with observations (DNN-Fire-OBS) compared with five burned area
 353 products (Table S1) over 2011-2015 for 14 GFED regions.
 354

355
 356 **Figure 7.** Prognostic simulation of wildfire burned area (2011-2015) with the Deep Neural
 357 Network wildfire model fine-tuned with observations (DNN-Fire-OBS) compared with
 358 observations and nine FireMIP models outputs.

359
 360 This study focuses on design, development, and parameterization of the DNN fire model
 361 within the E3SM model interface. In this way the DNN model can be readily coupled in the
 362 future and iteratively simulate climate, ecosystem fuel conditions, and fire dynamics. Although
 363 no feedbacks exist between biomass/tree cover and burned area were allowed under current
 364 offline mode, this study is an important step towards fully coupling E3SM and the DNN-Fire
 365 models in the future. We acknowledge several challenges and limitations in our modeling
 366 framework. First, the DNN model uncertainty was subject to the accuracy of climate forcings as
 367 well as other physical driving variables simulated by the physical wildfire model (ELMv1). For
 368 example, in this work ELM simulation of soil temperature, soil moisture, fuel load and so on is
 369 subject to the uncertainty of GSWP3 forcings. Furthermore, those simulated variables served as
 370 inputs for the DNN model and would result in burned area prediction uncertainty. It was
 371 challenging to eliminate the forcing uncertainties in this work, but we could at least evaluate the
 372 magnitude of these uncertainties. We ran the DNN-Fire-OBS model with alternative forcings of
 373 CRU-JRA, NCEP-DOE2, and CDAS soil moisture from 2001 to 2010 and compared the results
 374 with DNN-Fire-OBS driven by default inputs (Figure S5). The results showed relatively larger
 375 uncertainties from climate forcing than that from soil moisture forcing particularly over the

376 major fire regions (e.g., SHSA, SHAF, and NHAF). For fuel load, although no transient dataset
377 of global living biomass existed yet, we directly compared the ELM model simulated biomass
378 with the global estimate (GEOCARBON ~ 455 Pg C). We found that the modeled present-day
379 biomass continuously increased from 425 to 470 Pg C and compared reasonably well with the
380 global benchmark (Figure S6). Future work will focus on evaluating the uncertainties from dead
381 fuel load and fuel temperature variables.

382 Second, the original ELMv1 wildfire model has a unified mathematical representation of
383 how fuel, climate, and social-economic conditions control wildfire burned area [*F Li et al.*,
384 2012]. However, training one single DNN wildfire model across the globe will produce a model
385 dominated by gridcells that have high burned area (e.g., Africa). The performance of the trained
386 DNN model, therefore, will likely have larger biases over the low fire gridcells although the
387 globally aggregated burned area could be reasonable. We partly overcame this challenge by
388 applying the widely used 14 GFED fire regions that assume unique and relatively uniform
389 dynamics over each region [*Giglio et al.*, 2006b], and employed stratified random sampling
390 method for training and testing datasets. Although the regionally specific wildfire model
391 introduces additional complexity, it better represents distinct characteristics of wildfire activity
392 over different climate regimes and biomes [*Zhu and Zhuang*, 2013; *Zou et al.*, 2019] and allows
393 for future analyses of how the relevant controllers vary across the globe.

394 Thirdly, the cost function and the training of DNN model relied on the normality
395 assumption of burned area data. Therefore, the DNN model error might be dominated by highly
396 burned gridcells. A potential solution is to use *log* transformation on non-normal data or the
397 resultant cost function [*Kelley et al.*, 2021]. Finally, our GFED region-based parameterization
398 strategy relied on the combination of climate and biome types, while an alternative
399 parameterization strategy for DNN-Fire model could be based on plant functional type
400 distributions. Based on our analysis, the PFT-based DNN-Fire model had similar performance
401 compared with the GFED-based model (Figure S7, S8). Since the GFED regions were defined by
402 present-day climate and fire regimes, our GFED-based models may not fully capture the changes
403 of future fire dynamics due to longer-time scale climate and fire regimes changes.

404

405 **4. Conclusions**

406 In this study, we first surrogated the baseline ELMv1 wildfire model with a Deep Neural
407 Network (DNN) approach (Pearson correlation coefficient = 0.91 (p value < 0.01), $R^2 = 0.79$).
408 The development was based on inputs and outputs from the baseline ELMv1 wildfire simulation,
409 which is process-based and reasonably simulates global burned area, although regional biases
410 existed. We then calibrated the neural network weights using the years 2001-2010
411 observationally inferred burned area. The final calibrated DNN wildfire model (DNN-Fire-OBS)
412 was shown to be more accurate over the 14 GFED regions. For example, reductions in absolute
413 error over Africa, South America, and Europe were by ~90%. More importantly, the DNN-Fire-
414 OBS model parameters could be calibrated within minutes, compared with traditional ELMv1
415 parameterization ensemble simulations that consume a large amount of computational time. The
416 improved DNN-Fire-OBS model also accurately prognosed global and regional burned area in
417 the five-year period following the training period from 2011 to 2015 (modeled 469-514 Mha yr⁻¹).
418 We conclude that the improved surrogate wildfire model (DNN-Fire-OBS) developed in this
419 study can serve as an effective alternative to the process-based fire model currently used in
420 ELMv1. More broadly, we conclude that machine learning techniques can facilitate earth system
421 model development, parameterization, and uncertainty reduction with high efficiency and
422 accuracy.
