

# Bedymo: a combined quasi-geostrophic and primitive equation model in sigma coordinates

Clemens Spensberger, Trond Thorsteinsson, and Thomas Spengler

Geophysical Institute and Bjerknes Centre for Climate Research, University of Bergen, Bergen, Norway

**Correspondence:** Clemens Spensberger (clemens.spensberger@uib.no)

**Abstract.** This paper introduces the idealised atmospheric circulation model Bedymo, which combines the quasi-geostrophic approximation and the hydrostatic primitive equations in one modelling framework. The model is designed such that the two systems of equations are solved as similarly as possible, such that differences can be unambiguously attributed to the different approximations, rather than the model formulation or the numerics. As a consequence, but in contrast to most other quasi-geostrophic models, Bedymo is using sigma-coordinates in the vertical. In addition to the atmospheric core, Bedymo also includes a slab ocean model and passive tracer module that will provide the basis for future idealised parametrisation of moisture and latent heat release. Further, Bedymo has a graphical user interface, making it particularly useful for teaching.

Bedymo is evaluated for three atmosphere-only test cases and one coupled test case including the slab ocean component. The atmosphere-only test cases comprise the growth of a cyclonic disturbance in a baroclinic environment and the excitation of Rossby waves by isolated orography, both in a mid-latitude channel, as well as the simulation of a mid-latitude storm track. The atmosphere-ocean coupled test case is based on an equatorial channel and evaluates the coupled response to an isolated equatorial temperature anomaly in the ocean mixed layer. For all test cases, results agree well with expectations from theory and results obtained with more complex models.

## 1 Introduction

Since the 1950ies, several studies introduced different quasi-geostrophic (QG; e.g. Charney and Phillips, 1953) and hydrostatic primitive-equation models (PE; e.g. Smagorinsky, 1958). Table 1 of Schär and Wernli (1993) lists a more recent selection of QG and PE models, and the development of idealised models is still ongoing (e.g. Hogg et al., 2003; Maze et al., 2006). Given this wealth of existing models, why should one develop another model? The main reason for developing the BERgen DYnamical MOdel (Bedymo) is to combine two approximations – quasi-geostrophy and the dry hydrostatic primitive equations – in one modelling framework. To our knowledge, there is no other model that combines several approximations in one numerical framework. Hence, Bedymo provides the only dynamical core that incorporates two levels in the Held (2005) hierarchy of models.

Typically, the approach to solve the underlying set of equations is different for each approximation. For example, QG models usually forecast the QG potential vorticity (QGPV) and diagnose the geostrophic wind and temperature field by inverting the QGPV (e.g. Charney and Phillips, 1953). In contrast, PE models often forecast vorticity, divergence and potential temperature

(e.g. Smagorinsky, 1958). As our main goal is to combine the different approximations in one model, we devise a common approach that allows to solve the respective set of equations as similarly as possible. In contrast to previous studies (e.g. Whitaker, 1993; Rotunno et al., 2000), we can then intercompare QG with PE without using different models.

Another reason for starting the model development from scratch was to make use of comparatively new features of Fortran 95 and 2003. These features aid the modularity and readability, and hence maintainability of the source code. In addition to the combined QG/PE atmospheric model, Bedyo also includes a slab ocean and atmospheric tracers as optional modules. Furthermore, the source code is organised in a way to make it easily accessible from Python. Besides allowing for flexible, yet easy-to-read runscripts, the Python bindings provide the basis for a graphical user interface (GUI) that allows to interactively run the model and watch the flow evolution “live” while the model is running. All these features make Bedyo an ideal tool not only for research, but also for education and student research projects.

## 2 The model

### 2.1 Atmospheric dynamics

Our joint approach to solve the equations for QG and for hydrostatic PE is based on the thermodynamic equation, because it features only small modifications between the different approximations. The only difference is the wind velocity components used in the advection (Tab. 1). In conjunction with a lower boundary condition provided by the forecasted surface pressure, the temperature distribution fully determines the atmospheric state in the QG system via hydrostatic and geostrophic balance. In PE, the horizontal wind velocity components evolve independently and hence must be forecasted as well.

In both systems, pressure and  $\sigma$  vertical velocity is required to integrate the thermodynamic equation forward in time. In QG, the pressure vertical velocity follows from an inversion of the omega-equation, which implicitly establishes the three-dimensional QG-balance, and  $\sigma$ -vertical velocity is derived therefrom. In PE, both vertical velocities are derived from the continuity equation, using the divergence of the forecasted horizontal flow and the local surface pressure tendency. In PE, the local surface pressure is given by the column-integrated mass flux divergence and thus also follows from continuity. In contrast, in QG the local surface pressure tendency is derived from the pressure vertical velocity at the lower surface, and thus by the lower boundary condition used for the  $\omega$ -inversion. This boundary condition is given by the vorticity equation evaluated at the lower surface such that in QG surface pressure evolves following QG vorticity dynamics.

In the following, we summarise the model equations for QG and PE. We use a  $\beta$ -plane approximation for the Coriolis parameter  $f = f_0 + \beta y$ . In order to derive a self-consistent QG system, we need to approximate the specific volumes by time-invariant and horizontally homogeneous background values  $\bar{\alpha} = \bar{\alpha}(\sigma)$ . This approximation is optional for PE, and we will introduce and evaluate both variants. All symbols used in the following equations are summarised in Tab. 2.

### 55 2.1.1 Full primitive equations

The PE equations, as used in Bedyano, are

$$\frac{du}{dt} - (f_0 + \beta y)v = -\frac{\partial \phi}{\partial x} - \alpha \sigma \frac{\partial p_s}{\partial x} - ru + D\nabla^2 u \quad (1)$$

$$\frac{dv}{dt} + (f_0 + \beta y)u = -\frac{\partial \phi}{\partial y} - \alpha \sigma \frac{\partial p_s}{\partial y} - rv + D\nabla^2 v \quad (2)$$

$$\alpha = \frac{RT}{\sigma p_s} \quad (3)$$

$$60 \quad \frac{\partial \phi}{\partial \sigma} = -\frac{RT}{\sigma} \quad (4)$$

$$\frac{dT}{dt} - \frac{\alpha}{c_p} \omega = \frac{J}{c_p} \quad (5)$$

$$\frac{1}{p_s} \frac{dp_s}{dt} + \nabla_\sigma \cdot \mathbf{v} + \frac{\partial \dot{\sigma}}{\partial \sigma} = 0 \quad (6)$$

In order to provide an energy sink for long and short waves, respectively, the momentum equations include scale-inselective linear Ekman friction and a scale-selective damping term.

65 In this system, we infer geopotential  $\phi$  by integrating the hydrostatic equation (4) upwards, starting from the time-invariant surface geopotential  $\phi_s$  which represents the model orography. The local surface pressure tendency results from continuity,

$$\frac{\partial p_s}{\partial t} = -\int_0^1 \nabla \cdot (\mathbf{v} p_s) d\sigma. \quad (7)$$

And, finally,

$$\dot{\sigma} = -\frac{\sigma}{p_s} \frac{\partial p_s}{\partial t} - \frac{1}{p_s} \int_0^\sigma \nabla \cdot (\mathbf{v} p_s) d\sigma, \text{ and} \quad (8)$$

$$70 \quad \omega = -\int_0^\sigma \nabla \cdot (\mathbf{v} p_s) d\sigma + \sigma \mathbf{v} \cdot \nabla p_s, \quad (9)$$

which closes the system of equations (1)-(6). All other parameters in the equations are either time-invariant fields, constants, or represent an external forcing.

### 2.1.2 Homogeneous density approximation

As a first step towards quasi-geostrophy, we first assume horizontally homogeneous density within the PE system. In mathe-  
 75 matical form, the approximation  $\alpha \approx \bar{\alpha}(\sigma)$  resembles the anelastic approximation in Cartesian  $z$ -coordinates. However, while the continuity equation for the anelastic approximation reduces to that for incompressible flow, the continuity equation in  $\sigma$ -coordinates is unchanged by this approximation. As a result of this difference, (barotropic) acoustic waves are still supported, while they are not with the anelastic approximation.

As a result of the homogeneous density approximation, the pressure gradient terms become linear, because  $\bar{\alpha}\sigma$  only varies  
 80 with height. In fact, using the ideal gas law  $\bar{\alpha}\sigma = \frac{R\bar{T}}{p_s}$ , the product  $\bar{\alpha}\sigma$  becomes constant with an isothermal background state.  
 Further, vertical temperature advection is approximated by advection of the homogeneous background state only,  $\dot{\sigma} \frac{\partial T}{\partial \sigma} \approx \dot{\sigma} \bar{\Gamma}$   
 with  $\bar{\Gamma} = \frac{\partial \bar{T}}{\partial \sigma}$ .

In summary, the resulting momentum and thermodynamic equations are

$$\frac{du}{dt} - (f_0 + \beta y)v = -\frac{\partial \phi}{\partial x} - \bar{\alpha}\sigma \frac{\partial p_s}{\partial x} - ru + D\nabla^2 u, \quad (10)$$

$$85 \quad \frac{dv}{dt} + (f_0 + \beta y)u = -\frac{\partial \phi}{\partial y} - \bar{\alpha}\sigma \frac{\partial p_s}{\partial y} - rv + D\nabla^2 v, \quad (11)$$

$$\frac{d_h T}{dt} + \bar{\Gamma} \dot{\sigma} - \frac{\bar{\alpha}}{c_p} \omega = \frac{J}{c_p}. \quad (12)$$

Continuity (eq. 6), hydrostasy (eq. 4) and eqs. (7)-(9) that determine the surface pressure tendency and the vertical velocities  
 all remain unchanged.

### 2.1.3 Quasi-geostrophy

90 In QG, the geostrophic wind follows from the geostrophic streamfunction  $\psi_g$ ,

$$\mathbf{v}_g = -\mathbf{k} \times \nabla \psi_g, \quad (13)$$

which is in turn defined by

$$f_0 \psi_g = \phi + \bar{\alpha}\sigma p_s. \quad (14)$$

The prognostic equations are

$$95 \quad \frac{d_g T}{dt} + \bar{\Gamma} \dot{\sigma} - \frac{\bar{\alpha}}{c_p} \omega = \frac{J}{c_p} \text{ and} \quad (15)$$

$$\frac{d_g p_s}{dt} = \frac{\partial p_s}{\partial t} + \mathbf{v}_{gs} \cdot \nabla p_s = \omega_s, \quad (16)$$

in which the surface pressure tendency equation (16) is evaluated at the lower surface ( $\sigma = 1$ ), indicated by the subscripts  $s$ .

The remaining unknown variables at this point are the vertical wind  $\dot{\sigma}$  and the pressure vertical velocity  $\omega$ . Starting from the  
 following form of continuity

$$100 \quad \nabla_\sigma \cdot \mathbf{v}_a + \frac{1}{p_0} \frac{\partial \omega}{\partial \sigma} = 0, \quad (17)$$

the pressure vertical velocity can be derived from the  $\omega$ -equation

$$\bar{s} \nabla_\sigma^2 \omega + \frac{f_0^2}{p_0} \frac{\partial^2 \omega}{\partial \sigma^2} = 2 \nabla_\sigma \cdot (Q_1, Q_2) + \beta f_0 \frac{\partial v_g}{\partial \sigma} + f_0 \frac{\partial r \zeta_g}{\partial \sigma} - f_0 \frac{\partial D \nabla^2 \zeta_g}{\partial \sigma} - \frac{\kappa}{\sigma} \nabla^2 J, \quad (18)$$

in which  $Q_1$  and  $Q_2$  represent the two components of the Hoskins et al. (1978) Q-vector

$$Q_1 = +f_0 \frac{\partial \mathbf{v}_g}{\partial x} \cdot \nabla_\sigma \frac{\partial \psi_g}{\partial \sigma}, \quad (19)$$

$$105 \quad Q_2 = -f_0 \frac{\partial \mathbf{v}_g}{\partial y} \cdot \nabla_\sigma \frac{\partial \psi_g}{\partial \sigma}. \quad (20)$$

Further,  $\bar{s} = \bar{s}(\sigma)$  is a horizontally homogeneous stability parameter

$$\bar{s} = -\frac{\bar{\alpha} c_v}{\sigma c_p} - \frac{\partial \bar{\alpha}}{\partial \sigma}. \quad (21)$$

In order to solve the elliptic  $\omega$ -equation (18), we require a condition for  $\omega$  at the lower surface. We obtain  $\omega_s$  from the vorticity tendency equation evaluated at the lower surface. The resulting condition is

$$110 \quad \bar{\alpha}_s \nabla^2 \omega_s - \frac{f_0^2}{p_0} \frac{\partial \omega}{\partial \sigma} \Big|_s = -\mathbf{v}_{gs} \cdot \nabla (\nabla^2 \phi_s) - \beta f_0 v_{gs} - f_0 r_s \zeta_{gs} + f_0 D_s \nabla^2 \zeta_{gs}, \quad (22)$$

in which the subscript  $s$  again indicates variables that are evaluated at the surface. Finally, after using  $\omega_s$  to obtain  $\omega$  for the entire model domain, we derive  $\dot{\sigma}$  from

$$\dot{\sigma} = \frac{1}{p_0} (\omega - \sigma \omega_s - \sigma (\mathbf{v}_g - \mathbf{v}_{gs}) \cdot \nabla p_s), \quad (23)$$

which closes the system of equations.

115 QG potential vorticity  $q$  is not used anywhere in the model. Nevertheless, for reference,  $q$  takes the form

$$q = \nabla_\sigma^2 \psi_g + \beta y + \frac{f_0^2}{p_0} \frac{\partial}{\partial \sigma} \left[ \frac{1}{\bar{s}} \frac{\partial \psi_g}{\partial \sigma} \right] \quad (24)$$

in this QG system.

## 2.2 Ocean dynamics

In addition to the atmospheric component, BedyMo also includes a slab ocean. The slab ocean is intended to represent an  
 120 oceanic mixed layer that interacts with the atmosphere on time scales on which the internal ocean dynamics can be neglected. Nevertheless, as the oceanic heat transport might play a role even at these time scales, we provide several options to provide oceanic flow and heat transport.

The only prognostic variable in the slab ocean model is the mixed layer temperature  $T^o$ ,

$$\frac{\partial T^o}{\partial t} = -\frac{F_{sh}}{\rho^o c_p^o H} - OHT - \alpha (T^o - T_e^o). \quad (25)$$

125 It can change due to sensible heat exchange  $F_{sh}$  between the ocean and the atmosphere and oceanic heat transport  $OHT$ . In addition, the model includes a relaxation term towards a prescribed climatological temperature  $T_e^o$ , which may be used to crudely represent the neglected oceanic circulation (see Tab. 2 for other symbols).

The heat exchange is parameterised with a bulk flux formulation,

$$F_{sh} = \rho_s^a c_p^a C_{sh} |\mathbf{v}_s^a| (T_s^a - T^o). \quad (26)$$

130 Here and in the following, atmospheric variables are denoted by a superscript  $a$ , and the index  $s$  denotes values at the interface between the atmosphere and ocean. Details on how these surface variables are defined are given in section 2.4.

The options for parametrising the oceanic heat transports are

$$OHT = \begin{cases} 0 & \text{for a 0.5-layer model,} \\ \mathbf{v}^o \cdot \nabla_h T^o & \text{for a 1-layer model, and} \\ \nabla \cdot (\mathbf{u}^o T^o) & \text{for a 1.25-layer model.} \end{cases} \quad (27)$$

The first option represents a motionless ocean, while the other two options differ in the way divergence in the flow field is treated, with  $\mathbf{u}^o$  denoting the 3D-flow field and  $\mathbf{v}^o$  the horizontal part of the flow. Whereas divergence does not influence the mixed layer temperature in the 1-layer model, the 1.25-layer model assumes a compensating vertical flow (positive upwards)

$$w^o = \nabla_h \cdot \mathbf{v}^o$$

that transports water from a lower layer of temperature  $T_2^o$  into the mixed layer,

$$\nabla \cdot (\mathbf{u}^o T^o) = \nabla_h \cdot (\mathbf{v}^o T^o) - \begin{cases} w^o T^o & \text{if downwelling, } w^o < 0, \\ w^o T_2^o & \text{if upwelling, } w^o \geq 0. \end{cases}$$

The temperature  $T_2^o$  might vary spatially, but is kept constant over time. By not letting  $T_2^o$  vary with time, we implicitly assume the deeper layer to be motionless and to have infinite heat capacity.

Formally, both the 1-layer model and the 1.25-layer model for the  $OHT$  do not conserve energy, because the average mixed layer temperature can change without temperature relaxation or heat exchange with the atmosphere. Upwelling in the 1.25-layer model lets the average mixed layer temperature approach the deep layer temperature, without the latter changing due to the downwelling required by continuity. The 1.25-layer model reduces to the 1.0-layer model if  $T_2^o = T^o$ , such that the average mixed layer temperature will over time approach the local mixed layer temperature in locations of divergent flow.

The total transporting flow  $\mathbf{v}^o = \mathbf{v}_e + \mathbf{v}_p$  is a combination of a user-prescribed flow pattern  $\mathbf{v}_p$  and the wind-driven Ekman-flow  $\mathbf{v}_e$ . Our formulation of  $\mathbf{v}_e$  also includes a small parameter  $\epsilon$  in addition to the standard Ekman flow,

$$\mathbf{v}_e = \frac{\rho_s^a C_D |\mathbf{v}_s^a|}{\rho^o H (\epsilon^2 + f^2)} (\epsilon \mathbf{v}_s^a - f \mathbf{k} \times \mathbf{v}_s^a), \quad (28)$$

which controls the magnitude of the non-rotating flow excited by wind stresses. This addition results in finite Ekman velocities at the equator. Codron (2012) refers to  $\epsilon$  as the inverse damping timescale of oceanic currents.

## 2.3 Numerics

### 2.3.1 Coordinate system and discretisation

Bedymo uses Cartesian coordinates in the horizontal and a terrain-following pressure coordinate  $\sigma$  in the vertical, which is defined by

$$\sigma = \frac{p}{p_s}. \quad (29)$$

Variations in surface pressure thus affect the coordinate system throughout the atmospheric column up to the model top at  $p = 0$ .

160 In both the horizontal and the vertical directions, the velocity components are staggered with respect to the main grid points, following the C-grid setup of Arakawa and Lamb (1977). Temperature, geopotential, specific volume, and surface pressure are all defined on the unstaggered grid.

165 Bedyimo uses the 3<sup>rd</sup>-order Runge-Kutta time integration scheme in conjunction with a 3<sup>rd</sup>-order upwind-biased interpolation of the advected quantities to determine the advective fluxes at the staggered locations of the wind speed components, following the derivations of Smolarkiewicz (1982) and Tremback et al. (1987). Only for the first grid point inside a lateral wall, a 1<sup>st</sup>-order upwind-biased interpolation is used, and analogously for vertical advection in the uppermost and lowermost layer of the model domain. The remainder of the model is discretised using 2<sup>nd</sup>-order centred differences and interpolations.

### 2.3.2 Elliptical solver

170 In QG-mode, an elliptic equation has to be solved to determine the vertical velocity. Through extensive testing, we found the Full Multigrid Method (e.g. Saad, 2003) in conjunction with the Bi-Conjugate gradient Stabilised (BiCGstab) Method of van der Vorst (1992) to be the most effective and stable configuration for Bedyimo. We use BiCGstab both to solve the elliptic equation on the coarsest grid and to iteratively refine the solution on finer grids.

### 2.4 Boundary conditions

175 The boundaries of the model domain are located at staggered grid points. At the model top,  $p = 0$  and also both vertical velocities vanish,  $\dot{\sigma} = 0$  and  $\omega = 0$ . At the surface,  $\dot{\sigma} = 0$ , but  $\omega_s \neq 0$  as surface pressure can change both locally and in a Lagrangian reference frame. In QG,  $\omega_s$  is determined through a condition derived from the surface vorticity tendency (eq. 22); in PE, it is derived from continuity (eq. 9).

There are two available options for boundary conditions along the lateral boundaries. The first option represents periodic boundaries in the respective direction, and the second option features an impermeable free-slip “wall” with zero boundary-normal fluxes.

## 180 3 Evaluation

We subject Bedyimo to several test cases to evaluate the performance of the model. We chose different test cases to isolate pertinent aspects of the atmospheric and coupled dynamics. Furthermore, we chose test cases that have been studied comprehensively, such that the expected results are well established. The first three test cases focus on important aspects of the mid-latitude atmospheric dynamics in isolation. In a fourth test case, we evaluate the PE model in conjunction with the slab 185 ocean by simulating the coupled response to a temperature anomaly in the ocean mixed layer located at the equator.

### 3.1 Atmospheric test cases

The first atmosphere-only test case evaluates the representation of baroclinic cyclogenesis in a mid-latitude channel on the  $f$  and  $\beta$ -plane, as well as the sensitivity of the baroclinic development to the magnitude of the initial baroclinicity. Second, we extend the baroclinic channel setup by including temperature relaxation and friction and evaluate the long-term zonal-mean  
190 statistics of the storm track simulated by BedyMo. Finally, test case three evaluates the development towards the stationary barotropic Rossby wave response to isolated orography.

#### 3.1.1 Baroclinic cyclogenesis on an $f$ and $\beta$ -plane

The baroclinic channel for the cyclogenesis test case is 16000km long and periodic in the zonal direction. In the meridional direction it is 10000km wide and bounded by impermeable walls. We initialise a baroclinic zone with a temperature contrast  
195 of in total about 32K distributed over about 3000km. Temperature stratification is determined by  $\bar{\Gamma} = 0.8\bar{\Gamma}_d$ , with  $\bar{\Gamma}_d$  the dry adiabatic lapse rate in sigma-coordinates. This corresponds approximately to an overall Brunt Vaisala frequency  $N^2 = 1.2 \cdot 10^{-4} \text{ s}^{-2}$ . The baroclinic zone is meridionally centred in the channel. There is no initial surface pressure gradient and thus no initial surface winds. With Coriolis parameters corresponding to a latitude of 50°N, the baroclinic zone is initially balanced by a jet of maximum intensity of about  $50 \text{ m s}^{-1}$  in the uppermost layer ( $\sigma = 1/6$ ).

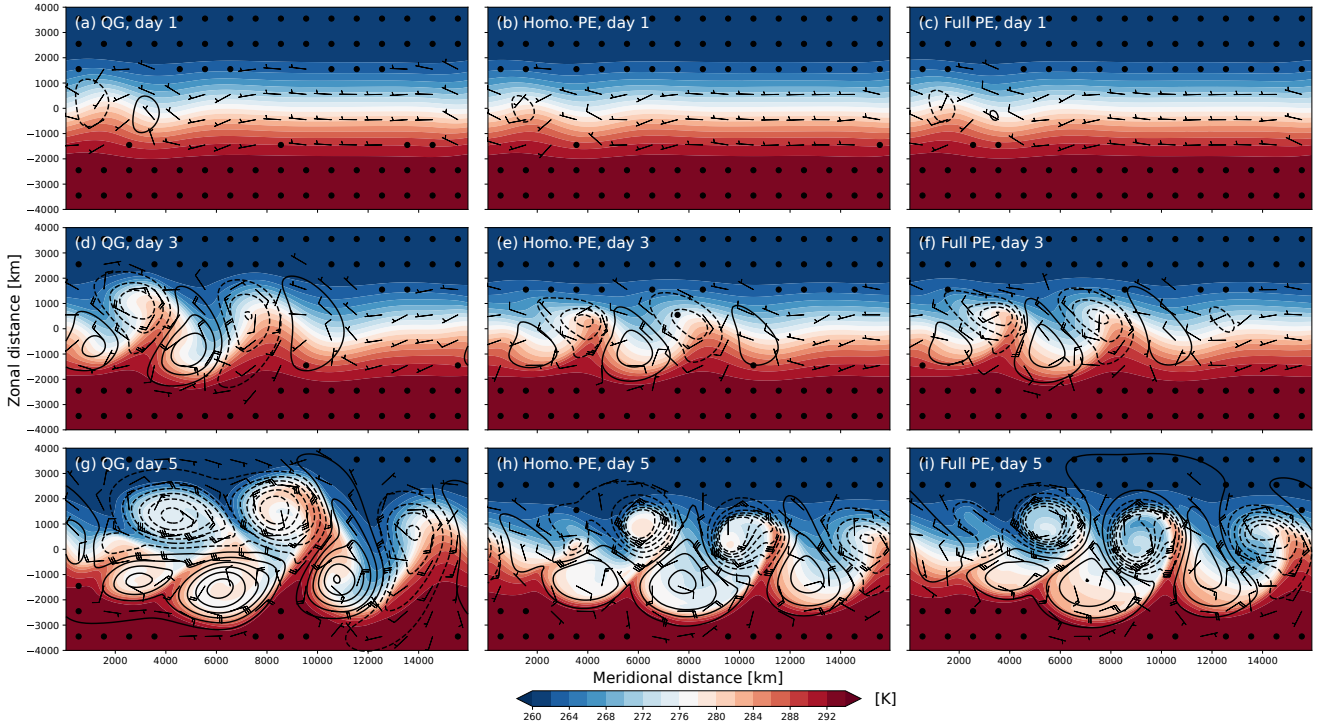

200 To localise the baroclinic development, we perturb this initial state by a warm anomaly of 2 K located at the center of the baroclinic zone. The temperature perturbation is invariant with height and has a zonal and meridional extent corresponding to the width of the baroclinic zone (approx. 3000 km). The perturbation is initially balanced by a perturbation thermal wind.

In our control setup, we use the  $\beta$ -plane approximation, as it is this setup we will later extend to multi-decadal storm track simulations. We will compare this control setup to simulations on an  $f$ -plane and to simulations in which we vary the initial  
205 baroclinicity to yield a balanced initial jet of either about  $30 \text{ m s}^{-1}$  or  $70 \text{ m s}^{-1}$ , respectively.

The baroclinic development for the control setup and the three model variants is summarised in Figure 1. For the first three days, the evolution in the three model variants is quite similar (Fig. 1a-f), and only at day 5 structural differences become apparent between QG and the two PE variants (Fig. 1g-i). In QG, cyclones are considerably larger in scale than in the PE variants and largely symmetric in size and structure compared to the anticyclones. In contrast, PE cyclones are smaller, more  
210 circular, and surrounded by steeper pressure gradients than PE anticyclones. Further, only PE produces qualitatively realistic fronts with near-discontinuities in the temperature field. This is expected from theory, as Hoskins (1975) showed that advection by ageostrophic winds must be taken into account in order to realistically capture the evolution of fronts.

Comparing the two PE variants, only minor differences occur up to day 5 (Fig. 1h-i). The two most apparent differences are a slightly slower cyclone intensification with homogeneous density PE, and, potentially related, changes in the temperature  
215 structure. In the homogeneous density PE, cyclone cores are comparatively warmer, and anticyclones comparatively cooler than their counterparts in full PE. Given that the only differences between the two PE variants is linearised vertical advection and a linearised pressure gradient force, it seems implausible that these differences in temperature originate from the linearised

**Figure 1.** Baroclinic development in a three-layer channel model on an  $\beta$ -plane for (a,d,g) QG and (b,e,h) homogeneous density PE, and (c,f,i) full PE. From top to bottom, the rows show the development after (a-c) 1 days, (d-f) 3 days, and (g-i) 5 days lead time, respectively. The shading shows temperature in Kelvin and barbs the winds in  $\text{m s}^{-1}$ , both representing the lowest of the three layers at  $\sigma = 5/6$ . The contours show surface pressure with a contour interval of 10 hPa centred on 1000 hPa, which contours below 1000 hPa dashed. Note that the not the entire model domain is shown in the  $y$ -direction.

vertical advection. Warmer cyclones and colder anticyclones yield an overall somewhat reduced baroclinicity in homogeneous density PE compared to full PE, which is consistent with the slightly slower intensification in homogeneous density PE.

220 Considering the growth rate of the eddy kinetic energy, both variants of PE develop somewhat slower and later than QG (Fig. 2), with maximum growth rates of 17.7 hours (QG), 19.0 hours (full PE), and 21.1 hours (homo. PE). For our channel setup, the Rossby deformation radius is approximately 930 km (e.g. Vallis, 2006), which implies a most unstable wave length of about 3600 km, and a maximum Eady growth rate of

$$\sigma_E = 0.31 \frac{u_{max}}{L_d} \approx 1.66 \cdot 10^{-5} \text{ s}^{-1},$$

225 for the control jet intensity of  $50 \text{ m s}^{-1}$ . This corresponds to an e-folding time scale of  $\tau_E = 16.7$  hours, which fits quite well, in particular with the QG variant.

Further, the simulated evolution generally follows the expectations from theory for varying magnitudes of the baroclinicity. For a stronger jet of  $70 \text{ m s}^{-1}$ , the Eady growth time scale reduces to 11.9 hours. This fits almost perfectly to the simulated

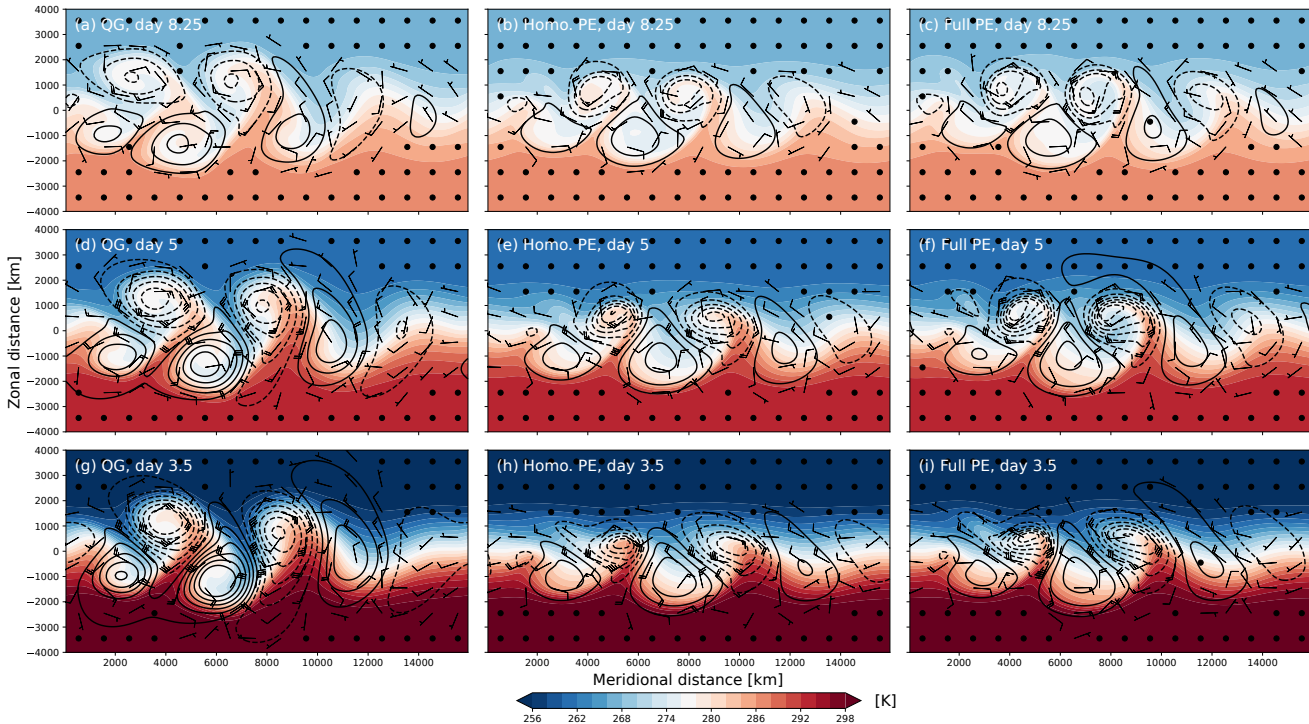

**Figure 2.** Growth rate of eddy kinetic energy averaged over 24-hour periods, for (grey-black) the default baroclinicity maximum winds of  $50\text{ m s}^{-1}$ , (blue) strong baroclinicity with maximum winds of  $70\text{ m s}^{-1}$ , and (orange) weak baroclinicity with maximum winds of  $30\text{ m s}^{-1}$ . The opacity shows the different model variants with opaque, slightly transparent, and more transparent denoting QG, Full PE, and Homo. PE, respectively.

maximum intensification with a time scale of 11.7 hours in the QG variant (darkest blue line in Fig. 2). The two PE variants  
230 are again somewhat slower and later in their development (lighter blue lines in Fig. 2). For the weaker jet of  $30\text{ m s}^{-1}$ , the  
correspondence between theory and simulation is less tight, with an Eady growth time scale of 27.8 hours and a QG maximum  
intensification with a time scale of 35.6 hours. This might, at least partly, be due to the beta-effect and downstream development  
playing a comparatively larger role with weaker baroclinicity. But this cannot be the full explanation, because for full PE the  
reduction in the peak growth rate (about 44%) is only slightly larger than the reduction in baroclinicity (40%).

235 Despite these differences in growth rate, structurally the evolution remains very consistent across the three tested magnitudes  
of the baroclinicity (Fig. 3). Considering lead times normalised by the different jet intensities, the wave structures are nearly  
identical within each model variant (columns in Fig. 3), showing that downstream propagation of wave energy scales largely  
linearly with the jet intensity despite the considerable amplitude of the waves.

The evolution of the cyclone is qualitatively similar on the  $f$  and  $\beta$ -plane for all three model variants (compare Figs. 1 & A1).  
240 In particular the differences in the size and shape of cyclones and anticyclones translate from the  $\beta$  to the  $f$ -plane. However,  
at day 5 it becomes apparent that meridional movement is much less constrained on the  $f$ -plane compared to the  $\beta$ -plane. The  
meridional scale of the synoptic systems is markedly larger, and soon after day 5 the large cold sectors in the zonal center of  
the domain start to interact with the southern boundary of the domain.

Overall, the structure and sensitivities of the simulated cyclone development is very much in line previous simulations  
245 of idealised cyclones with more complex models (e.g., Schemm et al., 2013, Terpstra and Spengler, 2015, and the cyclones  
in the colder environments of Tierney et al., 2018). This consistency is not surprising given the much earlier results of for

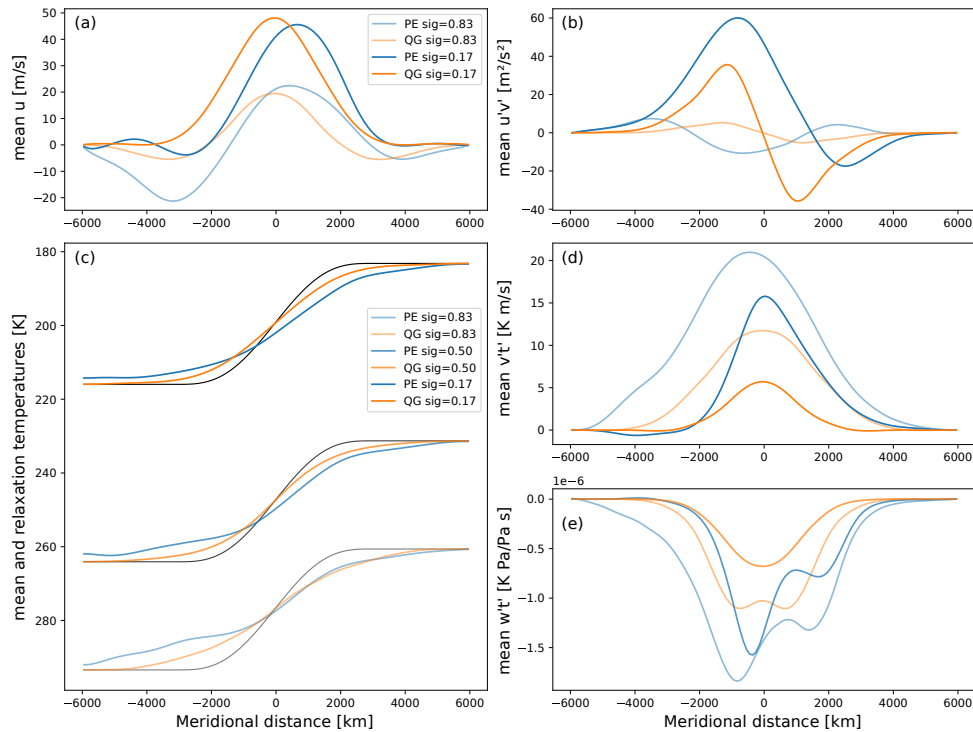

**Figure 3.** Sensitivity of the downstream development in a three-layer channel model on an  $\beta$ -plane for (a,d,g) QG and (b,e,h) homogeneous density PE, and (c,f,i) full PE. From top to bottom, the rows show the development after (a-c) 8.25 days, (d-f) 5 days, and (g-i) 3.5 days lead time, respectively. The presented lead times are scaled linearly with the initialised jet speed. Barbs and contours as in Fig. 1, and panels (d-f) identical to panels (g-i) of Fig. 1 except for the temperature scale.

example Simmons and Hoskins (1978), which used a model similar in complexity to Bedymo to study cyclogenesis. But the consistency remains worth noting, because these more recent studies typically employ a factor of 5-10 higher resolution in both the horizontal and vertical and use a full suite of physics parametrisations.

### 250 3.1.2 Mid-latitude storm track

The control setup for the baroclinic instability test case also serves as the basis for long-term simulations to evaluate the representation of a mid-latitude storm track in Bedymo. In order to achieve a statistically stationary storm track, we follow Held and Suarez (1994) and add simple parametrisations for three physical processes to the model setup. First, we enable a temperature relaxation towards the initial state with a time scale of  $10^6$  s  $\approx$  11.6 days throughout the model domain to represent  
 255 all process that replenish baroclinicity in real storm tracks. Second, we enable linear Ekman friction in the lowest model layer with  $r = 10^6$  s. Finally, we enable bi-harmonic diffusion that damps  $2\Delta x$ -waves with a time scale of  $10^5$  s  $\approx$  28 hours. This time scale increases quadratically with increasing wave length and thus predominantly affects the shortest waves. The storm

**Figure 4.** Statistical equilibrium state of the QG and full PE storm tracks, respectively. Color and opacity of the lines are consistent throughout the panels, with blue lines representing full PE, and orange lines QG, respectively. Transparency indicates the vertical level with the most opaque lines representing the uppermost of the three layers.

track simulations cover a time period of 32 years of 360 days each, of which the first two years are discarded as spin-up. After 1-1.5 years there is no discernible trend anymore in the distribution of sea-level pressure in any of the simulations, which we take as an indication that a statistical equilibrium has been reached.

Because of the absence of any zonal asymmetries, the resulting storm track is zonally symmetric. Figure 4 thus presents the zonal and time average state for the last 30 years of the simulations. In addition to the average temperature and zonal winds, we also show the eddy momentum and heat fluxes, in which the temperature and wind perturbations (indicated by primes) are taken to be the deviations from the zonal-and-time average. These fluxes are interesting, because, for example  $\frac{\partial}{\partial y} \overline{u'v'} < 0$  indicates a convergence of eddy momentum fluxes in the time mean, and analogously for  $\frac{\partial}{\partial y} \overline{v'T'} < 0$  and  $\frac{\partial}{\partial \sigma} \overline{\sigma'T'} < 0$  that indicate a convergence of heat in the meridional and vertical, respectively. To keep the line plots legible, we restrict our presentation and discussion to QG and full PE.

In QG, the resulting storm track is symmetric and centred on the imposed baroclinic zone. In the angular momentum budget, weak surface easterlies on either side of the baroclinic zone balance the near-surface westerlies under the jet (Fig. 4a). Maximum zonal winds in the uppermost level are just below  $50 \text{ m s}^{-1}$ , which would be the wind speed required to thermally balance the initial and relaxation temperature gradient in the absence of near-surface winds. Consistent with the mean zonal

winds, the mean convergence of momentum is symmetric around the imposed baroclinic zone with maximum momentum convergence at the jet core which is also strongest at the jet level (Fig. 4b). In contrast, heat transports are strongest in the lowest level (Fig. 4d,e), consistent with the largest deviation of mean temperature from the relaxation state (Fig. 4c). The described QG storm track is qualitatively similar to the storm tracks produced by other models (e.g., Held and Suarez, 1994; Vallis et al., 2004; Frierson et al., 2006; Voigt and Shaw, 2016) and the ones seen in reality (e.g., Figs. 7.7 and 11.8 of Peixoto and Oort, 1992).

In contrast to QG, the simulated PE storm track is not symmetric around the imposed baroclinic zone. The core of the jet is shifted poleward at all levels, and near-surface easterlies mainly occur on the equatorward side of the imposed baroclinic zone. This asymmetry is likely related to the asymmetry between cyclones and anticyclones observed in the cyclogenesis test case (Fig. 1). As discussed there, the strongest gradients in both sea-level pressure and temperature occur around cyclones, and thus on average somewhat poleward of the imposed baroclinic zone (Fig. 1). It thus seems plausible that the time mean reflects this asymmetry. If this interpretation is correct, the asymmetric storm track would thus be another consequence of taking into account advection by the ageostrophic winds (cf., Hoskins, 1975; Wolf and Wirth, 2015).

The storm tracks observed on Earth display a similar meridional asymmetry with regards to the surface winds. Near-surface easterlies are much more pronounced in the subtropics, on the equatorward side of the baroclinic zone, compared to the polar regions. Despite the similarity, the mechanisms leading to these easterlies might nevertheless be different. For real storm tracks, both the Hadley circulation and the spherical geometry of the Earth certainly introduce meridional asymmetries that cannot be captured in a Cartesian mid-latitude channel. In fact, some setups of the spherical 1-layer QG model of Vallis et al. (2004) yield meridional asymmetries similar to the one seen here for PE.

In addition to the asymmetries, the PE storm track features larger heat and momentum fluxes at all levels compared to QG. Nevertheless, the meridional profiles of these fluxes are generally consistent across QG and PE at all levels. The only exception is near-surface eddy momentum transport, but here amplitudes are quite small both in QG and PE. Consistent with the more vigorous heat transport in PE, the average temperature deviations from the relaxation state are larger in PE than in QG. On the equatorward side of the mean jet, weak but noticeable temperature deviations extend all the way to the southern boundary. Interactions with the boundary do however not affect the PE storm track, as the meridional profiles of all parameters remain nearly unchanged in a simulation with a meridionally wider channel.

Finally, the simulated storm track remains largely consistent across a range of temperature relaxation time scales (Fig. 5). In addition to the default relaxation with a time scale of 11.6 days, we conducted simulations with full PE using time scales of 3.47 and 34.7 days, respectively. These simulations are called “weak” and “strong” in Fig. 5, respectively. Within this range of parameters, stronger relaxation yields a more vigorous storm track with more intense heat and momentum transports as well as stronger jets (Fig. 5).

### 3.1.3 Rossby waves excited by orography

The third and final mid-latitude test case evaluates the developing stationary wave response to isolated orography. Orographically forced stationary waves are one of the main ingredients determining the zonal asymmetries in the Northern Hemisphere

**Figure 5.** Sensitivity of the full PE storm track to the strength of temperature relaxation. The panels (a-c) here correspond to panels (a), (b) and (d) in Fig. 4, with the control simulation here being identical to the PE simulation there. Line color and opacity is consistent across panels.

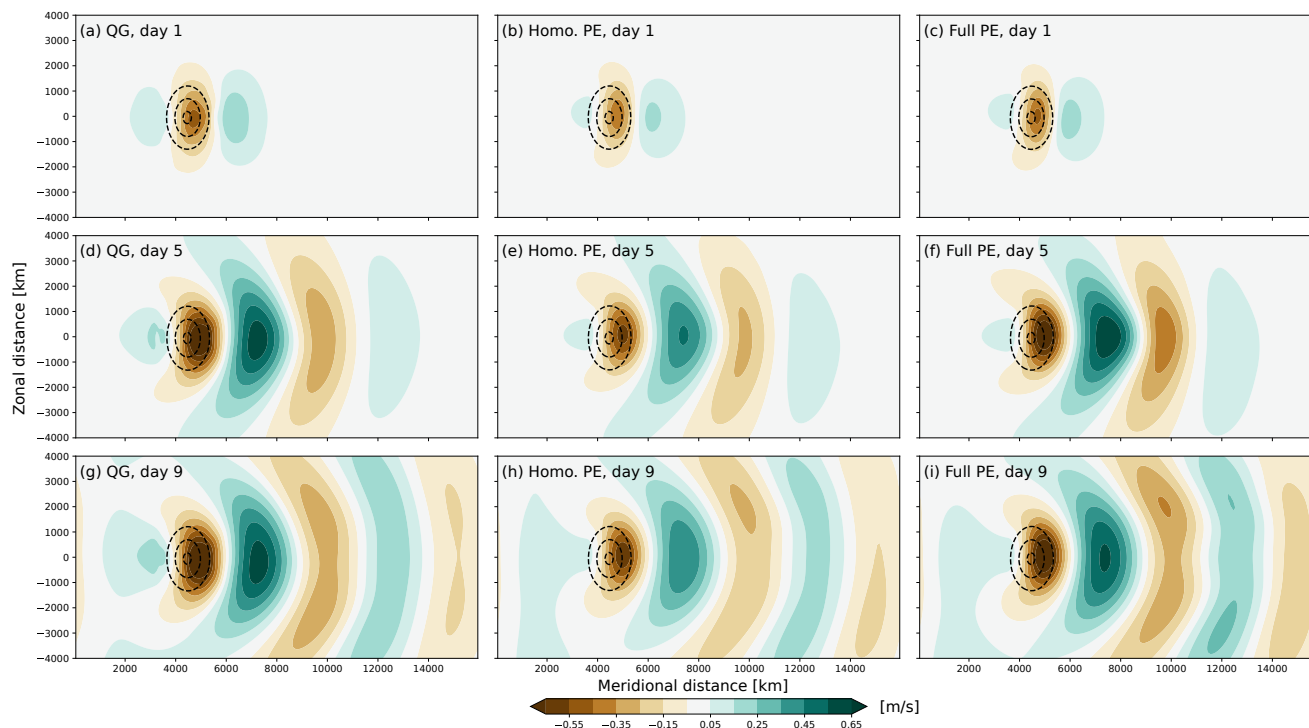

storm tracks (Held et al., 2002). The test case considered here uses the same mid-latitude channel used in the previous test cases, but the model is initialised by homogeneous zonal winds of  $10\text{ m s}^{-1}$  which are balanced by a surface pressure gradient. The setup is barotropic, and temperatures thus set to be dynamically inactive by replacing  $T$  by  $\bar{T}$  in hydrostasy (4). Orography is introduced as an isolated Gaussian mountain, meridionally centred in the domain, with a meridional scale of 1500 km, a zonal scale of 500 km, and a height of 1000 m.

Figure 6 shows the developing Rossby wave train excited by the mountain for the three model variants. As expected from theory, the QG response is meridionally symmetric. In contrast, the two variants of the PE again show slight meridional asymmetries. But overall the response is very consistent in both shape and amplitude across the three model variants. Further, the response fits qualitatively well to the response expected from linear wave theory (Hoskins and Karoly, 1981; Held et al., 2002).

### 3.2 Coupled tests

In addition to the mid-latitude test case, we subject Bedymo to a test case centred on tropical air-sea interaction. The model domain remains a zonally periodic channel with a meridional width of 10000 km. Zonally, the channel is extended to cover the actual circumference of the Earth of 40000 km and the Coriolis parameter is adapted to represent an equatorial  $\beta$ -plane. As the model domain contains the equator, we use only the two PE variants of Bedymo for this test case.

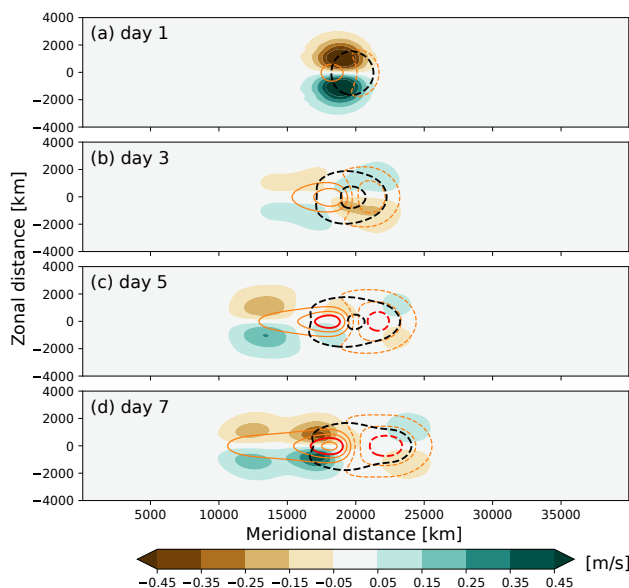

Initial surface air temperatures and sea-surface temperatures (SSTs) are homogeneous 288 K except for a +5 K SST anomaly with a radius of 1500 km centred on the equator. Below this warm mixed layer is a 15 K colder deeper ocean layer without heat anomaly. In case of the 1.25-layer ocean model, this cold deep water can be upwelled to affect the ocean mixed layer temperature and thus the SST. The atmosphere is initialised with homogeneous and barotropic easterlies with a wind speed of  $10\text{ m s}^{-1}$  that is balanced as far as possible and necessary by a meridional surface pressure gradient. Temperature stratification in the atmosphere is as in the cyclogenesis test case, corresponding approximately to  $N^2 = 1.2 \cdot 10^{-4}\text{ s}^{-2}$ . Neither ocean nor atmospheric temperatures are relaxed.

**Figure 6.** Developing stationary Rossby wave response to orographic forcing on a  $\beta$ -plane for (a,d,g) QG and (b,e,h) homogeneous density PE, and (c,f,i) full PE. From top to bottom, the rows show the development after (a-c) 1 days, (d-f) 5 days, and (g-i) 9 days lead time, respectively. The shading shows the (barotropic) meridional wind in  $\text{m s}^{-1}$ . The contours show surface pressure anomaly with respect to the balanced initial conditions with a contour interval of 4 hPa, showing only the surface pressure anomaly associated with the orography. Note that not the entire model domain is shown in the  $y$ -direction.

The initial transient atmospheric response to the surface heating is shown in Figure 7. As the ocean heat transport only has a minor influence within the initial seven days shown in Figure 7, and as homogeneous density PE and full PE yield very similar results (cf. Figs. 7 & A2), we here focus on the combination of full PE with the 0.5-layer ocean which ignores ocean heat transport (eq. 27).

The initial atmospheric response to equatorial surface heating is consistent with the stationary Matsuno-Gill response derived in Matsuno (1966) and Gill (1980). The solution consists of a pair of cyclonic vortices, symmetric on either side of the equator, on the western side of the heating. These vortices represent the Rossby wave-component of the response as derived in Matsuno (1966). These Rossby waves are accompanied by a (baroclinic) Kelvin wave propagating eastwards along the equator Gill (1980). When comparing our transient solution to those in Gill (1980), it is important to remember that Gill (1980) includes a large amount of damping in order to arrive at a stationary solution. We only apply weak scale-selective damping as described in the storm track test case, and the excited Rossby and Kelvin waves can thus propagate away from the wave source.

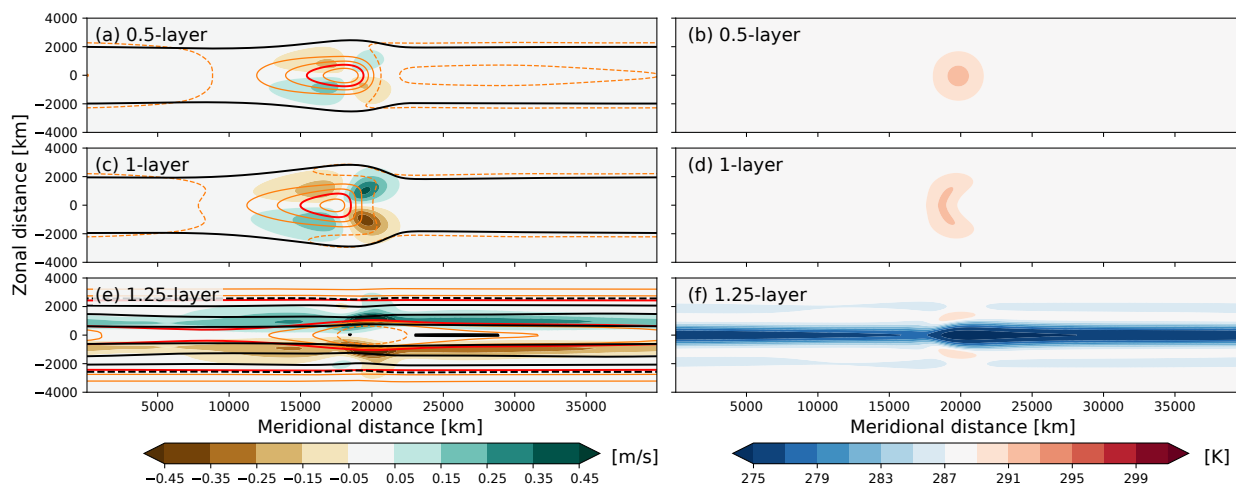

**Figure 7.** Developing wave response in response to an equatorial SST anomaly on a  $\beta$ -plane for full PE. From top to bottom, the rows show the development after (a) 1 day, (b) 3 days, (c) 5 days, and (d) 7 days lead time, respectively. The panel setup is as in Fig. 6, but showing wind in the lowest of three levels ( $\sigma = 5/6$ ) and with the contour interval for the surface pressure anomaly decreased to 1 hPa. The additional orange-red contours show zonal wind anomalies relative to the initialisation with a contour interval of  $1 \text{ m s}^{-1}$  centered around zero and the  $\pm 2.5 \text{ m s}^{-1}$ -contour highlighted.

After 60 days lead time, the atmosphere achieved a near-equilibrium, which is only slowly evolving in tandem with the  
340 evolving ocean. At this time, the coupled solution depends strongly on the chosen parametrisation for the ocean heat transport (Fig. 8). We here again focus the discussion on the simulations using full PE, as the homogeneous density PE solutions are very consistent (cf. Figs. 8 & A3).

With the 0.5-layer ocean, the shape of the initial SST anomaly is entirely intact after 60 days (Fig. 8b), because the ocean  
itself does not internally redistribute heat. Nevertheless, the ocean mixed layer lost about a quarter of its initial heat anomaly to  
345 the atmosphere and the SST anomaly decreased by about 1.2 K. The atmospheric response is much weaker in amplitude than the initial shock-like response to the heating (cf. Figs. 7 & 8a), but it is now following the stationary solution in Gill (1980) more closely, as the transient response has largely dissipated due to numerical and parameterised diffusion.

With the 1.0-layer ocean, direct wind-induced currents and associated ocean heat transports considerably deformed the SST  
anomaly over 60 days (Fig. 8d). With this parametrisation of the ocean-heat transport, diverging currents do not change the  
350 mixed-layer temperature. Atmospheric easterlies induce divergent ocean currents along the equator, thereby increasing the area covered by the warm anomaly without decreasing its amplitude. Overall this leads to a slightly larger ocean heat content with the 1.0-layer compared to the 0.5-layer ocean (compare Fig. 8d and Fig. 8b). Consistent with the slightly larger ocean heat

**Figure 8.** Near-stationary wave response to a coupled equatorial SST anomaly on a  $\beta$ -plane for full PE after 60 days of lead time. From top to bottom, the rows show the development of (a) the 0.5-layer model, (b) the 1-layer model, and (c) the 1.25-layer model, respectively. The panel setup for the left column is as in Fig. 7, but to accommodate the much larger sea-level pressure anomalies in (e), black contours are shown at  $-1.5\text{hPa}$  through  $1.5\text{hPa}$  in steps of  $1\text{hPa}$  as well as at  $5$  and  $10\text{hPa}$ , and zonal wind contours are omitted beyond  $2.5\text{m s}^{-1}$ . The maximum zonal wind anomaly on either side of the equator is about  $7\text{m s}^{-1}$ . The right column shows ocean mixed-layer temperatures in Kelvin.

anomaly, the atmospheric response in the 1.0-layer ocean setup is slightly larger in amplitude than for the 0.5-layer ocean (Fig. 8a, c).

355 Finally, with the 1.25-layer ocean, divergent currents along the equator lead to the upwelling of considerably colder water, leading to large negative SST anomalies along the equator (Fig. 8f). This upwelling is larger in amplitude than the initially positive SST anomaly, which thus largely disappeared after 60 days. In fact, the coldest SSTs appear just eastward of the location of the initial SST anomaly, because the initial response intensified the surface winds in this region. With the warm anomaly largely disappeared, both the SST anomaly field and the atmospheric response is to a first approximation zonally symmetric (Fig. 8e, f). The colder SSTs lead to a marked increase in surface pressure over the equator and a zonally-average meridional flow component away from the equator on either side.

360 In summary, BedyMo successfully captures both the transient (cf., Matsuno, 1966) and (near-)stationary response (cf., Gill, 1980) to equatorial heating. Beyond these theoretical expectations, the comparison of the different parametrisations of the ocean heat transport demonstrates that both ocean-internal dynamics and air-sea exchange have a profound influence on the coupled solution on time scales longer than a week or so. A caveat with this conclusion is that BedyMo so far cannot represent dynamical balances in the ocean, and thus cannot represent the ocean gyre circulations in the mid-latitudes.

#### 4 Conclusions

We introduced a joint approach to consistently solve the quasi-geostrophic (QG) and two variants of the primitive equations (PE). In all systems, we forecast temperature and surface pressure. In PE, the horizontal wind velocity components also need  
370 to be forecasted, whereas all other variables follow diagnostically in QG.

We implemented this approach in the BERgen DYnamic MOdel (Bedymo) and demonstrated the feasibility of the approach as well as the performance of Bedymo on the basis of four test cases. These cases are (a) the baroclinic development of a cyclonic disturbance, (b) the representation of mid-latitude storm tracks, (c) the excitation of Rossby waves by isolated orography, and (d) the coupled response of the PE models with a slab ocean to an equatorial temperature anomaly in the ocean mixed layer. In  
375 all cases, the model results agree well with either an analytical solution for the corresponding linearised problem or conceptual models.

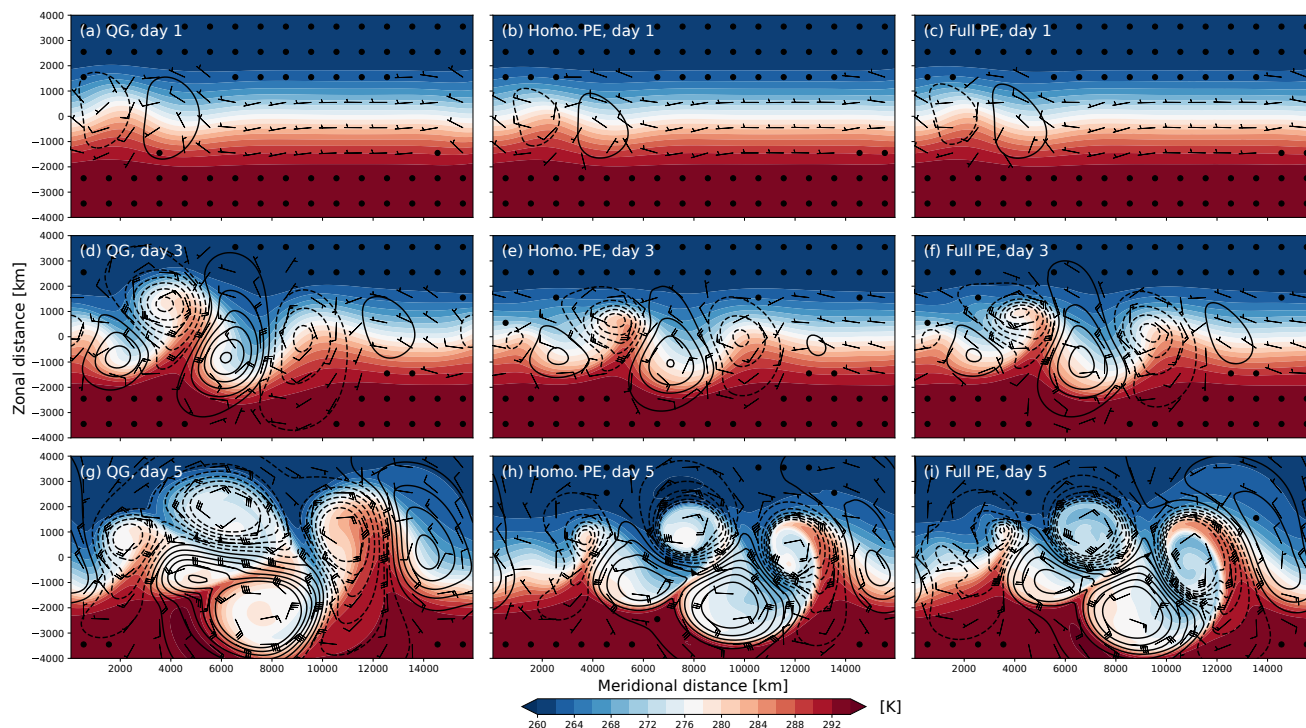

By successfully combining QG and PE into one consistent model, Bedymo considerably simplifies the comparison of the dynamical differences between QG and PE, because it eliminates all error sources associated with comparing two different models. The ability to simply switch between the approximations is especially valuable in cases where the formal validity of  
380 QG becomes questionable. One such example is the treatment of orography, because the assumptions underlying QG formally require orographic slopes to be negligibly small.

*Code availability.* The exact version of the model used to produce the results used in this paper is archived on Zenodo (Spensberger and Thorsteinsson, 2021), as are input data and scripts to run the model and produce the plots for all the simulations presented in this paper (Spensberger, 2021).

385 *Author contributions.* CS designed the model and prepared the manuscript, both with considerable support by TS. CS implemented the model infrastructure and atmospheric component from scratch and prepared the Figures. TT designed, implemented, and documented the slab-ocean component.

*Competing interests.* We declare no competing interests.

390 *Acknowledgements.* During the course of the model development, the authors have benefited strongly from discussions with a number of people. In particular we want to thank Thomas Toniazzo for in-depth mathematical and conceptual discussions on an earlier version of the model. Further, we thank Joe LaCasce, Alistair Adcroft, Michael Reeder, Robert Hallberg, Steve Garner, and Isaac Held for interesting and instructive discussion on even earlier versions of the model and QG dynamics in general. Trond Thorsteinsson was in parts supported through internal funding from the Centre for Climate Dynamics (SKD) at the Bjerknes Centre, University of Bergen.

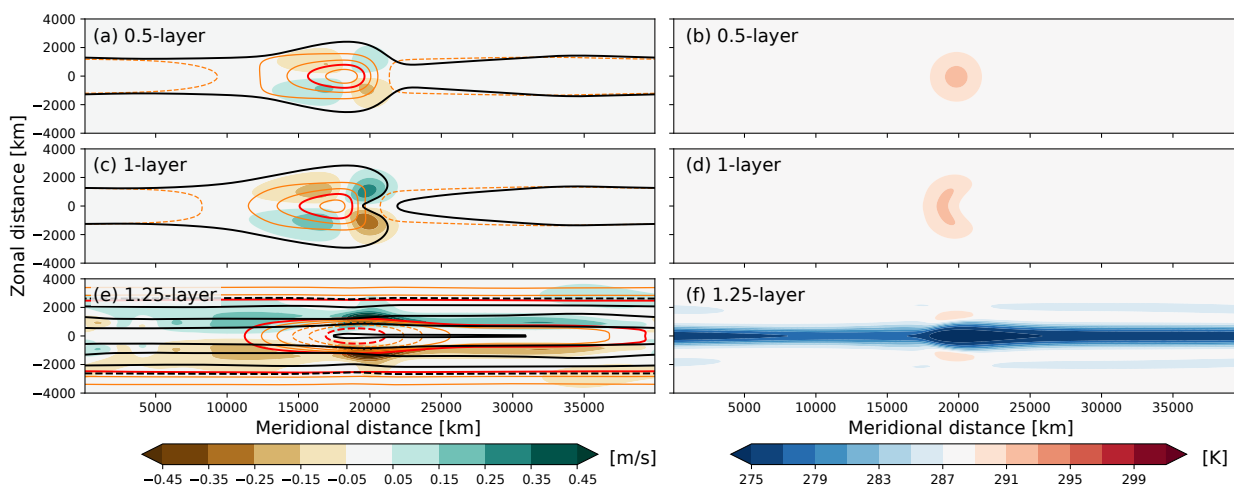

**Figure A1.** As Figure 1, but for simulations in on an  $f$ -plane instead of a  $\beta$ -plane.

Table 2: List of symbols. Where ambiguous, superscripts *a* or *o* denote atmospheric or oceanic variables, respectively.

Symbol	Explanation
$x, y$	Horizontal Cartesian coordinates.
$\sigma$	Vertical coordinate defined by $\sigma = \frac{p}{p_s}$ .
$p_s$	Surface pressure.
$u, v$	Horizontal atmospheric or oceanic flow velocity components.
$u_g, v_g$	Geostrophic flow velocity components.
$\omega, \dot{\sigma}$	Pressure and $\sigma$ vertical velocity, respectively.
$u_e, v_e$	Ekman flow velocity in the ocean.
$u_p, v_p$	Prescribed flow velocity in the ocean.
$\mathbf{u}$	Three-dimensional atmospheric or oceanic flow velocity vector.
$\mathbf{v}$	Horizontal atmospheric or oceanic flow velocity vector.
$f$	Spatially variable Coriolis parameter
$f_0, \beta$	Spatially constant Coriolis and $\beta = \frac{\partial f}{\partial y}$ parameters.
$\bar{s}$	Stability parameter defined in eq. (21).
$\alpha, \bar{\alpha}$	Specific volume, with $\bar{\alpha} = \bar{\alpha}(\sigma)$ as with the homo. dens. approximation.
$\bar{T}, \bar{\Gamma}$	Background state temperature profile and stratification.
$\phi$	Hydrostatic geopotential.
$\psi_g$	Geostrophic stream function defined by eq. (14).
$r$	Linear (Ekman) friction coefficient.
$D$	Scale-selective damping coefficient.
$R$	Ideal gas constant for air.
$c_p, c_v$	Isobaric and isochoric specific heat capacity for air.
$\phi_s$	Constant surface geopotential, representing orography.
$J$	Specific diabatic heating rate, unit $\text{J kg}^{-1} \text{s}^{-1}$ .

---

Symbol	Explanation
$Q_1, Q_2$	Components of the Hoskins et al. (1978) $Q$ -vector.
$H$	Depth of the slab ocean mixed layer.
$F_{sh}$	Sensible heat transport between the atmosphere and ocean.
$\epsilon$	Small non-rotating flow coefficient for wind-driven flow in the ocean.
$C_{sh}, C_D$	Exchange coefficients for sensible heat and momentum fluxes.
