Abstract.

Nitrogen (N) plays a central role in marine biogeochemistry by limiting biological productivity in the surface ocean, influencing the cycles of other nutrients, carbon, and oxygen, and controlling oceanic emissions of nitrous oxide (N₂O) to the atmosphere. Multiple chemical forms of N are linked together in a dynamic N cycle that is especially active in oxygen minimum zones (OMZs), where high organic matter remineralization and low oxygen concentrations fuel aerobic and anaerobic N transformations. Biogeochemical models used to understand the oceanic N cycle and project its change often employ simple parameterizations of the network of N transformations and omit key intermediary tracers such as nitrite (NO₂⁻) and N₂O. Here we present a new model of the oceanic N cycle (**N**itrogen cycling in **O**xxygen **M**inimum **Z**ones, or NitrOMZ) that resolves N transformation occurring within OMZs, and their sensitivity to environmental drivers. The model is designed to be easily coupled to current ocean biogeochemical models by representing the major forms of N as prognostic tracers, and parameterizing their transformations as a function of seawater chemistry and organic matter remineralization, with minimal interference with other elemental cycles. We describe the model rationale, formulation, and numerical implementation in a one-dimensional representation of the water column that reproduces typical OMZ conditions. We further detail the optimization of uncertain model parameters against observations from the Eastern Tropical South Pacific OMZ, and evaluate the model ability to reproduce observed profiles of N tracers and transformation rates in this region. We conclude by describing the model sensitivity to parameter choices and environmental factors, and discussing the model suitability for ocean biogeochemical studies.

1 Introduction

Nitrogen (N) limits phytoplankton production over large swathes of the ocean (Moore et al., 2013). Most of the N in the ocean is present as dissolved dinitrogen gas (N_2); however, only fixed N, e.g., ammonium (NH_4^+) and nitrate (NO_3^-), can be readily
 20 utilized by planktonic microorganisms, with the exception of N-fixing diazotrophs (Capone et al., 2008). The inventory and chemical form of N in the ocean are controlled by an active nitrogen cycle, whereby different chemical forms of the element are utilized as substrates for growth by a variety of microorganisms, either to supply building blocks for organic molecules, or to fuel metabolism via redox reactions (Capone et al., 2008; Kuypers et al., 2018). As a result, the residence time of fixed N in
 25 the ocean is on the order of 3,000 years or less, about one order of magnitude shorter than for the macronutrient phosphorous (Gruber and Galloway, 2008; Wang et al., 2019).

Figure 1. Schematic of the main N cycle tracers and reactions represented by NitrOMZ. Tracers are shown in bold, ordered by the oxidation state of N, and consist of organic nitrogen (OrgN), ammonium (NH_4^+), nitrate (NO_3^-), nitrite (NO_2^-), nitrous oxide (N_2O), and dinitrogen (N_2). N transformation reactions are shown as arrows connecting reactants and products. Green arrows represent nutrient uptake and nitrogen fixation rates (not explicitly represented in the model, which focuses on subsurface reactions). The black arrow corresponds to (1, R_{rem}) release of NH_4^+ by organic matter remineralization (i.e., ammonification). Blue arrows denote aerobic transformations: (2a, $R_{ao}^{no_2}$) NH_4^+ oxidation to NO_2^- , (2b, R_{ao}^{no}) NH_4^+ oxidation to N_2O , and (3, R_{no}) NO_2^- oxidation to NO_3^- . Red arrows represent anaerobic processes: (4, R_{den1}) NO_3^- reduction to NO_2^- , (5, R_{den2}) NO_2^- reduction to N_2O , (6, R_{den3}) N_2O reduction to N_2 , and (7, R_{ax}) anaerobic NH_4^+ oxidation (anammox) with NO_2^- to N_2 .

The ocean's inventory of fixed N is dominated by NO_3^- , and the main N cycle reactions consist of uptake and assimilatory reduction of NO_3^- to NH_4^+ , and the oxidation of NH_4^+ back to NO_3^- following the decomposition of organic matter and nitrification (Fig. 1). Only when the concentration of dissolved oxygen (O_2) drops to suboxic or anoxic levels (typically below 5 mmol m^{-3} , additional metabolic pathways involving N become relevant, as observed in the ocean's oxygen minimum

30 zones (OMZs) and low- O_2 sediments (Lam and Kuypers, 2011). These reactions include the three main steps of heterotrophic denitrification, i.e., the oxidation of organic carbon (OrgC) with NO_3^- , nitrite (NO_2^-), and nitrous oxide (N_2O), and anammox, the chemolithotrophic oxidation of NH_4^+ with NO_2^- . Both denitrification and anammox lead to the production of N_2 , and thus remove fixed N from the ocean (Bianchi et al., 2012; DeVries et al., 2013, 2012). Ammonium oxidation is another source of N_2O — a powerful greenhouse gas and a leading agent of ozone destruction in the stratosphere. The number of N_2O molecules produced per NH_4^+ oxidized, i.e. the yield of this reaction, increases as O_2 declines (Goreau et al., 1980; Nevison et al., 2003). Because of denitrification and enhanced ammonium oxidation sources, OMZs are important sources of N_2O to the atmosphere (Naqvi et al., 2010; Yang et al., 2020), with the largest emissions observed right above shallow anoxic waters (Arévalo-Martínez et al., 2015).

The emerging picture for the ocean's N cycle is that of a web of inter-dependent transformations that is particularly active in OMZs, where overlapping aerobic and anaerobic reactions exchange nitrogen metabolites and substrates (Lam and Kuypers, 2011; Kuypers et al., 2018), ultimately controlling fixed nitrogen removal and N_2O production. While there is evidence that organic matter and O_2 regulate the rates and relative importance of N transformations (Babbin et al., 2014; Dalsgaard et al., 2014), our mechanistic understanding of these environmental controls against the backdrop of oceanic variability remains limited. Ocean biogeochemical models can shed light on the expression of the N cycle reactions in a dynamic environment. These models have included N as a macronutrient since the beginning, representing NO_3^- and NH_4^+ assimilation by phytoplankton and subsequent nitrification (Fasham et al., 1990; Sarmiento et al., 1993; Moore et al., 2004b). With the advent of more complex Earth System Models, biogeochemical representations have progressively expanded to include more detailed representations of the N cycle, including N fixation, denitrification and N_2O production (Aumont et al., 2015; Séférian et al., 2020; Stock et al., 2020; Long et al., 2021).

50 The ultimate goals of these models are multifold, and include improving predictability of oceanic N_2O emissions (Suntharalingam et al., 2012; Martinez-Rey et al., 2015; Battaglia, 2017; Buitenhuis et al., 2018; Ji et al., 2018); providing a more realistic representation of the redox state of seawater (Louca et al., 2016); or resolving aspects of microbial dynamics underlying the oceanic N cycle (Penn et al., 2016; Zakem et al., 2018; Penn et al., 2019).

The representation of N transformations in models often relies on crude assumptions that simplify the network of N reactions and their controls to simple empirical parameterizations. For example, models that include N_2O cycling often rely on parameterizations that link N_2O production to nitrification or aerobic respiration (Suntharalingam and Sarmiento, 2000; Nevison et al., 2003; Manizza et al., 2012; Jin and Gruber, 2003), overlooking N_2O surces and sinks by denitrification. These models also conflate anammox and denitrification into a single N_2 production term. Explicit cycling of NO_2^- under low O_2 , with the observed co-occurrence of NO_2^- production from NO_3^- dissimilatory reactions, reduction to N_2O and N_2 by denitrification and anammox, and reoxidation to NO_3^- are missing (Lam and Kuypers, 2011; Kalvelage et al., 2013; Babbin et al., 2014, 2015; Buchwald et al., 2015; Babbin et al., 2017).

The goal of this paper is to present a new model of the oceanic N cycle designed to be incorporated in current ocean biogeochemical models, with a particular focus on processes occurring within OMZs. We refer to this model as NitrOMZ (Nitrogen cycling in Oxygen Minimum Zones). The model explicitly represents the major forms of N found in seawater as prognos-

65 tic tracers, and parameterizes the transformations that connect them as a function of seawater chemistry. This formulation is informed by recent observations that describe the response of N cycle reactions to environmental controls, in particular the availability of substrates and dissolved O₂. We detail the implementation of the model in an idealized one-dimensional (1D) representation of the water column that allows comparison to in situ observations, formal optimization, and studies of the model sensitivity to parameter choices and environmental conditions.

70 The rest of the paper is organized as follow: Sect. 2 discusses the rationale and formulation of the model; Sect. 3 the implementation of the model; Sect. 4 the model optimization against tracer and rate observations; Sect. 5 the performance of the model and its sensitivity to environmental parameters; and Sect. 6 discusses the implications and conclusions of the work.

2 Nitrogen cycle model formulation

2.1 Model Rationale

75 The NitrOMZ model is based on the current understanding of the N cycle in OMZs (Lam and Kuypers, 2011; Kuypers et al.,
2018) as mediated by 6 major species: N_2 , NO_3^- , NO_2^- , N_2O , NH_4^+ and organic nitrogen (OrgN) in either dissolved or
particulate form. For simplicity, we assume that OrgN is linked to OrgC by fixed stoichiometry (Anderson and Sarmiento,
1994). A schematic of the model's tracers and transformation is shown in Fig. 1. Our approach represents a natural progression
80 transformation reactions (Lam and Kuypers, 2011), rather than microbial ecology (Penn et al., 2016; Louca et al., 2016; Zakem
et al., 2018; Penn et al., 2019). That is, the model explicitly resolves N chemical tracers and their transformations, but not the
populations of microbes that are responsible for these reactions.

The underlying assumption is that the occurrence and rates of N transformations are controlled by, and can be predicted
from, the physical and chemical conditions of the oceanic environment. Implicitly, the model assumes that diverse populations
85 of microbes are always present in the water column, and that their activity (i.e., metabolic rate) is controlled by the abundance
of substrates, in analogy to chemical reactions, and dissolved O_2 , which inhibits anaerobic reactions (Kalvelage et al., 2011;
Babbin et al., 2014; Dalsgaard et al., 2014; Ji et al., 2018; Sun et al., 2021b). The focus on dissolved N forms and reaction rates
bypasses poorly-known aspects of microbial population dynamics, which are topics of ongoing research (Louca et al., 2016;
Zakem et al., 2018; Penn et al., 2019).

90 We assume that each reaction is implicitly mediated by specialized microorganism groups, each relying on a distinct
metabolism (Lam and Kuypers, 2011; Kuypers et al., 2018). Thus, the model represents a “modular” N cycle, with individual
reaction steps (i.e., individual redox reactions) represented separately, and connected by exchange of dissolved substrates (Graf
et al., 2014; Kuypers et al., 2018). This premise is grounded on observations of high specialization and streamlined genomes
for marine prokaryotes (Giovannoni et al., 2014), including microorganisms carrying genes for N-based metabolic reactions
95 (Ganesh et al., 2015; Kuypers et al., 2018).

These assumptions are sufficient to provide a broad representation of microbial N transformations and their environmental
expressions in the ocean, while limiting model complexity and the proliferation of poorly-constrained parameters. They are
also grounding steps towards models that explicitly represent microbial populations, their diversity and dynamics in OMZs
(Louca et al., 2016; Penn et al., 2016; Zakem et al., 2018; Penn et al., 2019).

100 2.2 Model tracers

The model focuses on microbial processes that take place below the euphotic zone, as driven by the flux of organic matter
produced near the surface and exported into the ocean interior by the biological pump (Boyd et al., 2019). We include het-
erotrophic and chemolithotrophic pathways that are commonly observed in the open ocean and require N species as substrates
(Kuypers et al., 2018) (Fig. 1). Additional pathways, for example involving sulfur or iron, could also be represented following
105 a similar approach.

Heterotrophic reactions resolved by the model (Fig. 1) consist of aerobic organic matter respiration (R_{rem} , pathway 1), which relies on O_2 as the oxidant, and the three main steps of denitrification: dissimilatory NO_3^- reduction to NO_2^- (R_{den1} , pathway 4), NO_2^- reduction to N_2O (R_{den2} , pathway 5), and N_2O reduction to N_2 (R_{den3} , pathway 6). Chemolithotrophic processes consist of aerobic oxidation of NH_4^+ to both NO_2^- (R_{ao}^{no2} , pathway 2a) and N_2O (R_{ao}^{n2o} , pathway 2b), aerobic
110 oxidation of NO_2^- to NO_3^- (R_{no} , pathway 3), and anammox, the anaerobic oxidation of NH_4^+ with NO_2^- to produce N_2 gas (R_{ax} , pathway 7). Reactions are parameterized as functions of substrates (i.e., model tracer concentrations) and environmental parameters such as dissolved O_2 and organic matter. Tracers are expressed as concentrations, with units of $mmol\ m^{-3}$.

We do not include an explicit representation of nitric oxide, NO , because of the poor understanding of its cycle in the marine environment (Ward and Zafiriou, 1988). NO is thought to be an obligate intermediate or a byproduct of N cycle reactions,
115 including nitrification and denitrification (Schreiber et al., 2012). However, it is a very reactive chemical with extremely low concentrations (on the order of $pmol\ m^{-3}$) and rapid turnover in seawater (Ward and Zafiriou, 1988). As a consequence, in situ NO observations are limited (Lutterbeck et al., 2018), and rate measurements targeting NO reactions are missing. Implicitly, we assume that NO cycles so rapidly that accumulation and transport by the oceanic circulation are negligible, and that its dynamics can be folded into the cycle of other N tracers.

120 2.3 Model equations

Heterotrophic reactions (i.e., organic matter remineralization) are parameterized as a function of the respective oxidants and organic matter concentration, and expressed in carbon units per unit volume and time. Heterotrophic reaction rates are assumed to be first order in the concentration of organic matter, and limited by the oxidant following a Michaelis-Menten formulation (Johnson and Goody, 2011). Anaerobic reactions are inhibited by the presence of O_2 , based on an exponential limitation term
125 (Dalsgaard et al., 2014). The resulting equation for a general heterotrophic reaction is:

$$R_H = k_H \cdot \frac{[X]}{[X] + K_H^X} \cdot e^{-\frac{O_2}{K_H^{O_2}}} \cdot POC \quad (1)$$

Here, H indicates the heterotrophic process considered (e.g., dissimilatory reduction of NO_3^- to NO_2^-), R_H the heterotrophic reaction rate ($mmol\ C\ m^{-3}\ s^{-1}$); k_H the specific reaction rate (s^{-1}); $[X]$ the concentration of the oxidant (i.e., O_2 , NO_3^- , NO_2^- or N_2O); K_H^X the half saturation constant for oxidant uptake ($mmol\ m^{-3}$); $K_H^{O_2}$ the scale for inhibition of the reaction by O_2
130 ($mmol\ m^{-3}$); and POC the concentration of particulate organic matter in units of $mmol\ C\ m^{-3}$. No O_2 inhibition is applied to aerobic respiration (i.e., $K_H^{O_2}$ can be thought of as arbitrarily large).

Chemolithotrophic reactions are proportional to the respective substrates. A maximum reaction rate is modulated by the concentration of oxidants and reductants, following Michaelis-Menten dynamics. For anaerobic reactions (here, anammox), an O_2 -dependent inhibition term limits the reactions when O_2 is present. The resulting equation for a general chemolithotrophic
135 reaction is:

$$R_A = k_A \cdot \frac{[X]}{[X] + K_A^X} \cdot \frac{[Y]}{[Y] + K_A^Y} \cdot e^{-\frac{O_2}{K_A^{O_2}}} \quad (2)$$

Here, A indicates the chemolithotropic process considered (e.g. anammox), R_A the reaction rate ($\text{mmol N m}^{-3} \text{ s}^{-1}$); k_A the maximum reaction rate when the process is not limited ($\text{mmol N m}^{-3} \text{ s}^{-1}$); $[X]$ and $[Y]$ the concentrations of the oxidant and reductant respectively (e.g., NO_2^- and NH_4^+ for anammox); K_A^X and K_A^Y the half saturation constants for oxidant and reductant uptake respectively (mmol m^{-3}); and $K_A^{\text{O}_2}$ the scale for inhibition of the reaction by O_2 (mmol m^{-3}). For aerobic reactions, $K_A^{\text{O}_2}$ is set to infinite, removing O_2 inhibition.

Equations for each of the heterotrophic and chemolithotropic reactions are presented in Appendix A1 and A2, respectively; parameter names, units, and suggested values from the literature are presented in Table 1.

2.4 Model assumptions and parameterizations

In the model, we assume that heterotrophic reactions proceed at a rate proportional to the concentration of organic matter, thus all organic matter can be utilized by microorganisms without saturation at high concentrations. Because of the low abundance of organic matter in seawater, and extensive colonization of particles by heterotrophic bacteria, this is a reasonable first order assumption. However, see Nguyen et al. (2022) for a discussion of microbial-particle interactions in ocean biogeochemical models, and more complex aspect of their dynamics. For simplicity, we represent organic carbon by a single component. This assumption is easily relaxed to include multiple carbon species, for example separate particulate or dissolved forms.

We do not explicitly model conversion of dissolved CO_2 to organic matter by chemolithotrophy, because of the small rates compared to the remineralization of organic matter in the upper ocean. This assumption can also be relaxed in future implementations of the model, allowing a more complete integration between chemolithotrophy and the carbon cycle.

The use of an exponential inhibition term for anaerobic reactions by O_2 is based on the observation that they are limited at O_2 concentrations of few mmol m^{-3} or smaller (Dalsgaard et al., 2014; Babbín et al., 2015). However, coexistence of anaerobic and aerobic reactions at O_2 concentrations of 10–20 mmol m^{-3} or higher is also observed (Kalvelage et al., 2011), perhaps related to the presence of redox microenvironments within organic particles (Bianchi et al., 2018; Smriga et al., 2021), which are not explicitly considered here. The exponential inhibition formulation has the advantage of being controlled by a single parameter, allows anaerobic reactions at finite O_2 concentrations, and approximates empirical rates from incubation experiments reasonably well (Dalsgaard et al., 2014).

Parameter values for maximum reaction rates, half saturation constants, and O_2 inhibition terms (Eq. (1) and (2)), are informed by analysis of previous work, and further optimized against in situ observations of tracers and rates (Sect. 4). Table 1 presents a list of the model parameters and measured values based on a review of the literature. Note that these studies are based on shipboard and laboratory incubations that differ in the setup, conditions, and microbial populations tested. Despite these caveats, experimental results provide valuable starting points to further constrain parameter values in the model.

Table 1. Summary of the main NitrOMZ parameters, with typical values from the literature.

Parameter	Description	Units	Value(s)	Source(s)
k_{rem}	Maximum aerobic remineralization rate	d^{-1}	0.08	Babbin et al. (2015)
k_{ao}	Maximum NH_4^+ oxidation rate	$\mu mol N m^{-3} d^{-1}$	45.56 ± 4.8 37.10 ± 1.2 20 - 100	Bristow et al. (2016) Peng et al. (2016) Ward (2008)

3 Model implementation

3.1 One-dimensional model setup

We implement the model for a 1D water column that includes physical transport by vertical advection and turbulent diffusion (Wyrtki, 1962), and, if required, parameterized lateral transport by horizontal currents and eddies (Gnanadesikan et al., 2013; 170 Bettencourt et al., 2015). The model is configured to represent the typical weak upwelling conditions that characterize open-ocean oxygen minimum zones, following previous work (Babbin et al., 2015).

In the 1D framework, the conservation equation for the concentration $[C]$ of a generic dissolved tracer can be written as:

$$\frac{\partial[C]}{\partial t} = -\frac{\partial(w_u \cdot [C])}{\partial z} + \frac{\partial}{\partial z} K_v \frac{\partial[C]}{\partial z} + \sum_{i=1}^{N_H} (r_{C,H}^i \cdot R_H^i) + \sum_{i=1}^{N_A} (r_{C,A}^i \cdot R_A^i) + LT \quad (3)$$

Here, w_u is the vertical upwelling velocity (m s^{-1}) and K_v is the vertical turbulent diffusion coefficient ($\text{m}^2 \text{s}^{-1}$), both 175 of which can be a function of depth. The first and second summation are respectively over the N_H heterotrophic and N_A chemolithotrophic processes that involve the tracer (Eq. (1) and (2)), with $r_{C,H}^i$ and $r_{C,A}^i$ the corresponding stoichiometric ratios. LT represents any parameterized lateral transport process. The explicit equations for each of the model tracers are detailed in Appendix A5.

The lateral transport terms LT can be included to parameterize horizontal circulation by advection and diffusion in the 1D 180 framework. Typically, these terms are simplified by a linear restoring to far-field tracer concentration profiles (Babbin et al., 2015), $[C]^{far}$, with a relaxation timescale τ_C (s):

$$LT = -\frac{1}{\tau_C} \cdot ([C] - [C]^{far}) \quad (4)$$

For typical open ocean conditions, τ_C can be estimated as the minimum of an advective timescale $\frac{L}{U}$ and a diffusive timescale, $\frac{L^2}{K_H}$, where L , U , K_H are respectively the horizontal spatial scale, the horizontal velocity scale, and the horizontal eddy 185 diffusion. Assuming L on the order of 1000 km, U on the order of 0.01 m s^{-1} , and K_H on the order of $1000 \text{ m}^2 \text{ s}^{-1}$ results in a timescale $\tau_C = 10^8 \text{ s}$, i.e., on the order of 3 years.

3.2 Organic matter remineralization

In the 1D model implementation, we represent organic matter (OrgC and OrgN) as a single particulate organic carbon (POC) class that sinks through the water column. We assume that this sinking is rapid compared to advection and diffusion, leading 190 to a steady-state distribution of POC that is only controlled by sinking and remineralization (Kriest and Oschlies, 2008). Since remineralization rates are proportional to the concentration of organic matter, the resulting steady-state 1D equation for POC is:

$$\frac{\partial(w_s \cdot \text{POC})}{\partial z} = -\sum_{i=1}^{N_H} R_H^i = \sum_{i=1}^{N_H} (k_H^{eff,i}) \cdot \text{POC} \quad (5)$$

Here, w_s is the depth-dependent sinking speed of POC in the water column, and $k_H^{eff,i}$ (s^{-1}) are the effective rate constants for each heterotrophic process, i.e., the maximum rate constants multiplied by the respective substrate limitation and O_2 inhibition terms (Eq. (1)).

Considering the flux of sinking POC, Φ_{POC} ($mmol\ C\ m^{-2}\ s^{-1}$):

$$\Phi_{POC} = w_s \cdot POC, \quad (6)$$

Equation 5 can be written as:

$$\frac{\partial \Phi_{POC}}{\partial z} = - \sum_{i=1}^{N_H} R_H^i = - \sum_{i=1}^{N_H} \left(k_H^{eff,i} \right) \cdot POC, \quad (7)$$

or, equivalently,

$$\frac{\partial \Phi_{POC}}{\partial z} = - \frac{\sum_{i=1}^{N_H} \left(k_H^{eff,i} \right)}{w_s} \cdot \Phi_{POC} \quad (8)$$

Equation 7 can be recast to relate the concentration of POC in the water column to the remineralization of the POC flux with depth:

$$POC = - \frac{1}{\sum_{i=1}^{N_H} \left(k_H^{eff,i} \right)} \cdot \frac{\partial \Phi_{POC}}{\partial z} \quad (9)$$

The advantage of Equation 9 is that it allows to diagnose sinking POC concentrations when the POC flux and remineralization rate constants are known. In the 1D implementation of the model, we parameterize the POC flux following a typical depth-dependent power-law function, or Martin curve (Martin et al., 1987; Berelson, 2001; Primeau, 2006):

$$\Phi_{POC} = \Phi_{POC}(z_0) \cdot \left(\frac{z}{z_0} \right)^{-b}, \quad (10)$$

where z_0 is the upper boundary of the model, and b the power-law or Martin coefficient. A plot of the model POC is shown in Fig. C1. Another advantage of this formulation is that it allows coupling NitrOMZ to more complex parameterizations for the remineralization of organic matter in ocean biogeochemical models, some of which rely on explicit representation of sinking organic particles, and some of which only represent sinking organic particle fluxes in the water column (Moore et al., 2004a; Dunne et al., 2010; Aumont et al., 2015; Stock et al., 2020; Long et al., 2021). Because NitrOMZ's equation can be cast as a function of prescribed vertical organic matter flux or remineralization profiles, the model can be coupled to existing biogeochemical models with minimal interference with their formulation of organic matter cycles.

3.3 Numerical implementation of the 1D model

For the purpose of testing and illustration, we implement NitrOMZ in a 1D representation of the water column, following previous work (Babbin et al., 2015). Model tracers are discretized on a 1D vertical grid, with equal spacing $\Delta z = 10\ m$, where z is depth. Boundary conditions are set at the top (z_0) and bottom grid (z_{bot}) cells, as Dirichlet (or fixed concentration) boundary

conditions, with values taken from observations. The conservation equation for each tracer (following Eq. (3), see Sect. A5 for full equations) is then solved using a forward in time, centered in space numerical scheme, with a constant vertical grid spacing, and the option for a variable or constant timestep. In the baseline simulations (Fig. 2), we adopt a timestep of 5 days for the initial 650 year spinup, and decrease it to 3 hours for the final two years of the simulation (years 698 and 699) to increase
225 accuracy.

The model is forced at the uppermost boundary by a flux of sinking POC, $\Phi_{\text{POC}}(z_0) = w_s(z_0) \cdot \text{POC}(z_0)$, where $\text{POC}(z_0)$ provides the boundary condition for POC. The flux Φ_{POC} remineralizes in the water column based on a Martin curve profile (Eq. (10)). At each depth, the steady-state conservation equation for POC (Eq. (8)) is solved with a forward-in-space method, using a depth-dependent sinking speed w_s chosen to produce, together with the maximum aerobic remineralization rate constant, k_{rem} , a POC flux profile matching a Martin curve with exponent b appropriate for the oxygenated ocean (Primeau, 2006; Weber and Bianchi, 2020). To this end, the sinking speed is calculated at each depth as:

$$w_s = \frac{k_{rem} \cdot z}{b} \quad (11)$$

The concentration of POC in the water column is then diagnosed using Equation 9, and used to calculate the heterotrophic remineralization rates R_H in Equation 1 (see Sect. A1).

235 Under constant forcings and boundary conditions, the model tracers evolve towards steady-state ($\frac{\partial[C]}{\partial t} \approx 0$, Fig. 2) with a timescale τ_{SS} that can be estimated from the advection velocity w_u , the turbulent vertical diffusion K_v , and the vertical scale H , as the minimum between $\frac{H}{w_u}$ and $\frac{H^2}{K_v}$. For w_u on the order of 10 m y^{-1} , K_v on the order of $10^{-5} \text{ m}^2 \text{ s}^{-1}$, and a vertical scale of 1000 m, the timescale to approach steady-state is $\tau_{SS} = 3 \cdot 10^{10} \text{ s}$, or about 100 years.

Fig. 2 shows an example of model spinup to steady state in NitrOMZ, with parameters taken from an optimal solution
240 discussed in Sect. 5.2, and uniform initial tracer concentrations in the water column. At the start of the simulation, high water column O_2 leads the aerobic remineralization (R_{rem}) to dominate total POC consumption. As the simulation proceeds, an O_2 minimum develops in subsurface waters, reaching suboxic ($< 10 \text{ mmol O}_2$) concentrations around year 100. NO_3^- reduction rates (R_{den1}) are relieved of O_2 inhibition and begin to take up a larger fraction of total POC remineralization, as revealed by the depletion of N^* , signaling NO_3^- consumption in the water column. Reduction of NO_3^- also leads to a subsurface peak in
245 NO_2^- within the O_2 -minimum (Fig. 2). With newly available NO_2^- substrate and low O_2 conditions, NO_2^- reduction (R_{den2}) begins, resulting first in a subsurface spike in N_2O . With further decrease in O_2 concentrations, N_2O is reduced to N_2 , leading to a layer of low N_2O concentrations within the OMZ that persists to the end of the simulation. Anammox (R_{ax}) is similarly relieved of O_2 inhibition as the O_2 -minimum is established, reaching maximum values near the upper oxycline, reflecting relatively high supply of both NO_2^- and NH_4^+ .

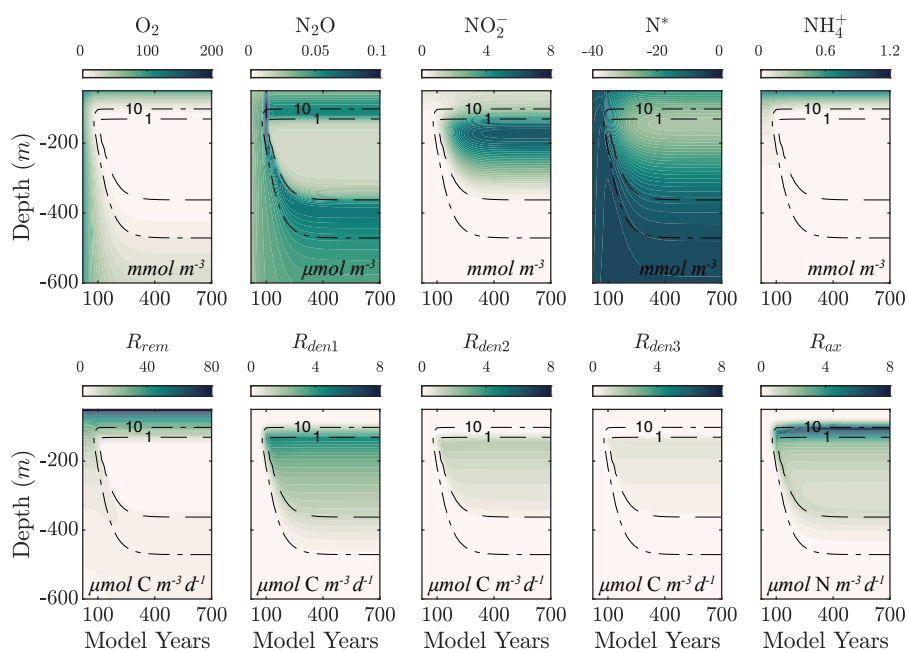

Figure 2. Example of spinup of the model. (top) Temporal evolution of O_2 , N_2O , NO_2^- , N^* , and NH_4^+ from initial ETSP boundary conditions at year 0 to the final model solution at year 700 using the selected parameter set (Opt_{sel}) discussed in Sect. 5.2. Dashed black curves highlight the 1 and 10 $mmol\ m^{-3}$ contours. (bottom) Same as (top), but for the heterotrophic rates of aerobic respiration (R_{rem}), NO_3^- reduction (R_{den1}), NO_2^- reduction (R_{den2}), and N_2O reduction (R_{den3}). The chemolithotrophic anammox rate (R_{ax}) is also shown in the far right panel.

250 4 Model optimization strategy

The model contains 23 major parameters that control the N cycle, some of which are relatively well constrained by observations whereas others are poorly known and can plausibly span a broad range of values (Table 1). In the model, these parameters approximate complex or poorly known aspects of microbial physiology, metabolism and ecology, and thus are intrinsically uncertain. In order to select a set of parameters that produces a realistic representation of the N cycle in OMZ, we adopt
255 a “metaheuristic” approach based on application of an optimization algorithm, following an established strategy in ocean biogeochemistry (Schartau and Oschlies, 2003; Ward et al., 2010; Kriest et al., 2017).

To conduct this optimization, we compile available tracer and biogeochemical rate observations for the Eastern Tropical South Pacific (ETSP) OMZ from a July 2013 cruise aboard the R/V Nathaniel B. Palmer, for which abundant trace and rate measurements are available (Fig. 5) (Ji et al., 2015b; Peng et al., 2016; Babbín et al., 2017, 2020), as well as from other
260 cruises in the region (Kalvelage et al., 2013). The observations are then used to define a cost function based on normalized squared deviations between model profiles and observations. The cost function is minimized by applying a Covariance Matrix Adaptation Evolutionary Strategy algorithm (CMA-ES, discussed in Section 4.1), which finds a local optimal solution in the model’s multi-dimensional parameter landscape.

The optimization is characterized by large dimensionality, strong non-linearity, a significant computational cost (requiring
265 several 10,000s model runs to converge), and inherent flexibility in the formulation of the cost function (Schartau and Oschlies, 2003; Kriest et al., 2017). Thus, instead of seeking a single global optimal solution, we generate an ensemble of optimal solutions that provide equally acceptable representations of OMZ processes based on the cost function. To this end, we apply the optimization multiple times, varying the formulation of the cost function slightly, and assigning a random error to the observations for each optimization. As a result, we produce a set of equally plausible optimal solutions that we further evaluate
270 to select a final parameter set based on additional comparisons with observations, which we use for further analysis.

4.1 Optimization algorithm

The CMA-ES is a stochastic, population-based algorithm that seeks to minimize an objective cost function (Hansen et al., 2009). The CMA-ES falls within the broader class of evolutionary optimization algorithms, where search for an optimal solution proceeds by an iterative improvement of a population of parameters, with each iteration including a stochastic “evo-
275 lutionary” element, in loose analogy with biological processes of mutation, recombination and selection (illustrated in Fig. 3). In contrast with typical evolutionary computation algorithms such as Genetic Algorithms, in the CMA-ES the mutation and recombination operations are substituted by sampling from a multivariate normal distribution in which parameters (the covariance matrix) are deterministically updated based on previous iteration steps (Hansen, 2006).

The CMA-ES has been shown to be more efficient (i.e., requiring fewer objective function evaluations), accurate (i.e., able
280 to approximate the global optimum), and robust (i.e., not overly sensitive to the initial choice of parameters), compared to other optimization algorithms, when applied to multi-dimensional, non-linear optimization problems (Hansen et al., 2009; Hansen, 2016). These properties make it suitable for optimization of ocean biogeochemical models (Kriest et al., 2017). A detailed

description of the algorithm procedure can be found in Hansen (2016); an overview of the main steps of the algorithm, and its application to ocean biogeochemistry are presented in Krist et al. (2017).

Figure 3. Flowchart of the CMA-ES optimization algorithm used to constrain uncertain model parameters.

285 4.2 Optimization implementation

As an illustration of NitrOMZ, we perform a series of optimizations against ETSP OMZ observations. For this configuration, we set a constant upwelling velocity but impose a variable vertical diffusion (K_v) profile, with lower diffusion in upper stratified layers, and a transition to higher diffusion in deeper layers (Fischer et al., 2013) (Fig. C1, left panel). Since this simulation targets the core of the OMZ, we turn off far-field tracer restoring. This simplifies analysis of model balances between transport and reaction rates, while resulting in realistic tracer distributions. Top and bottom boundary conditions are listed in Table B3 and are extracted from observations.

As a first step, we select parameters that control aerobic remineralization processes (R_{rem}) and lead to a realistic vertical O_2 profile relative to ETSP observations, including the vertical position and thickness of anoxic waters ($O_2 < 5 \text{ mmol m}^{-3}$) (Fig. 5). These consist of the vertical diffusion (K_v) and upwelling (w_{up}) magnitude, the Martin curve coefficient (b), and the upper ocean POC flux (Φ_{poc}^{top}), based on values consistent with observations (Table B2 and Fig. C1). For simplicity, we also set the maximum aerobic remineralization rate (k_{rem}) and the NH_4^+ and NO_2^- half saturation constants for NH_4^+ and NO_2^- oxidation ($K_{ao}^{nh_4}$ and $K_{no_2}^{no_2}$, respectively) to reported values in the literature (see Table 1). We then employ the CMA-ES algorithm in NitrOMZ to optimize the remaining 20 parameters that control heterotrophic and chemolithotrophic reactions in Fig. 1, using the range of parameter values listed in Table B1.

To optimized more uncertain parameters that control the anaerobic N cycle, we then conduct 4 sets of optimizations, with cost functions devised to match desired characteristics of tracer and rate profiles in the ETSP OMZ. Briefly, the cost function is calculated as the mean square of the difference between observations and model output profiles for a series of variables that include tracers and N transformation rates (listed in Table B2). Before each optimization, a random error of 20% is assigned to each observation to increase the variability of observational constraints and improve the robustness of the optimization ensemble by preventing it to always converge in the neighborhood of a specific local minimum controlled by non-relevant features of the observations. Three additional constraints are imposed to improve the fit to observations for N cycle processes occurring within the core of the OMZ. First, different weights are assigned to each tracer, giving higher weight to N_2O and

NO₂, which are central to the anaerobic N cycle. Because of possible influence from horizontal advection in observations, discrepancies exist between modelled and observed NO₃⁻ and PO₄³⁻. To compensate for this, we also assign lower weights to
310 NO₃⁻ and PO₄³⁻, and higher weight to N*. Second, a depth-dependent weighting scheme is included to emphasize the match to observations in the OMZ interior. This vertical weight is shaped as a Gaussian curve centered at the core of the observed OMZ, so that values within the core of the OMZ are weighted up to twice as much as values outside the OMZ. Finally, N cycle transformation rates are shifted vertically to match their depth relative to the oxycline (here defined as O₂=1 mmol m⁻³) in
315 only difference between the 4 sets of optimization are the relative weights assigned to each tracer, listed in Table B2. In total, we obtain 382 optimized parameter sets for further analysis.

5 Results and sensitivity

5.1 Optimization results

The distributions of the parameter values from the 382 sets of optimizations (see Sect. 4.2 and Table B4) are shown in Fig. C2. Rather than converging always to the same set of parameters, the optimization shows some variability for specific parameters. This reflects the stochastic nature of the CMA-ES algorithm, the inclusion of random variations in the observations, and the highly non-linear nature of the optimization problem, which may allow for non-unique optimal solutions. Optimized maximum rates (such as k_{ao} , k_{no} , k_{den1} , and k_{den3}) and exponential O_2 inhibition parameters for step-wise denitrification (K_{den2}^{o2} and K_{den3}^{o2}) reveal more variability than half-saturation concentration coefficients (K terms), which often settle to the minimum or maximum allowed value (Table B1).

Pairwise correlations in Fig. 4 reveal several parameters pairs which exhibit strong relationships, reflecting the fact that, in a significantly non-linear optimization, similar results can be obtained by trade-offs between different parameters and processes. Notably, the exponential O_2 inhibition constants for NO_2^- and N_2O reduction (K_{den2}^{o2} and K_{den3}^{o2} , respectively) are strongly correlated with each other ($R = 0.73$) and with other parameters controlling the denitrification steps. These include positive correlations with the maximum rate parameters for NO_3^- and NO_2^- reduction (k_{den1} and k_{den2} , respectively) and negative correlations with the half-saturation constants for NO_2^- and N_2O reduction (K_{den2}^{no2} and K_{den3}^{n2o} , respectively). These correlations suggests tight couplings between modelled denitrification steps, wherein high/low maximum denitrification rates can be compensated by lower/higher half-saturation coefficients, respectively.

Figure 4. Pairwise correlations between model parameters for model solutions optimized for the ETSP OMZ. See Table B1 for a list and a description of the model parameters. Correlation is shown as the Pearson correlation coefficient, with dots representing p -values < 0.01 .

335 Considering the overall variability in the optimal parameter sets, N-cycle tracers show similar profiles across all optimal solutions (Fig. 5, top panels). When compared to observations, the majority of parameter sets are able to skillfully model (1) the vertical distribution of O_2 , including the anoxic layer between roughly 100 to 400 m, (2) the subsurface maximum in NO_2^- , (3) the rapid attenuation of NH_4^+ with depth, and (4) the subsurface minimum in N^* .

N cycle transformation rates also show similar consistency in their vertical profiles, albeit with more notable discrepancies with observations, possibly reflecting the higher variability and more complex and indirect nature of these measurements. In general, rates of NO_2^- production from NH_4^+ oxidation (R_{ao}^{no}) are $\mathcal{O}(100)$ times larger than N_2O production ($R_{ao}^{n_2o}$) and, along with NO_2^- oxidation rates (R_{no}), attenuate rapidly with depth, consistent with observations (Ji et al., 2015a, 2018; Santoro et al., 2021). The step-wise denitrification rates (R_{den1} , R_{den2} , and R_{den3}) show remarkably similar vertical profiles, with higher NO_3^- reduction rates (R_{den1}) and nearly identical magnitudes between R_{den2} and R_{den3} . Anammox (R_{ax}) shows a similar profile as denitrification, albeit with enhanced local maxima near the upper and lower oxycline depths surrounding the OMZ core, consistent with observations (Kalvelage et al., 2013).

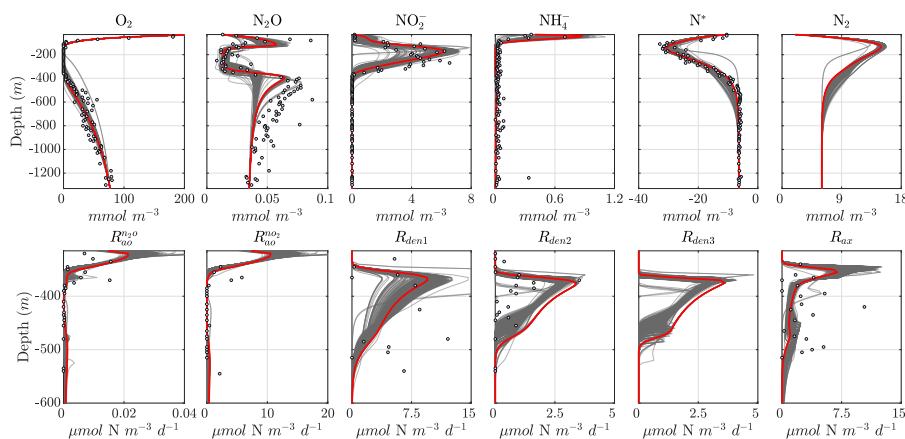

Figure 5. Results from the optimized ensemble of model solutions. (top) Tracer (O_2 , N_2O , NO_2^- , NH_4^+ , N^* , and N_2) profiles from all 382 optimized ETSP parameter sets. The bold red curves show the selected parameter set (Opt_{sel}) discussed in Sect. 5.2. Observations used to define the optimization cost function are shown as circles in each panel. (bottom) Same as in (top), but for reaction rate profiles of N_2O and NO_2^- production from NH_4^+ oxidation ($R_{ao}^{n_2o}$ and R_{ao}^{no} , respectively), NO_3^- NO_2^- , and N_2O reduction (R_{den1} , R_{den2} , and R_{den3} , respectively) and anammox (R_{ax}).

Several robust features emerge from the optimized parameter solutions, suggesting underlying mechanisms that need to be captured for a faithful representation of the OMZ N cycle. In particular, the differences in the exponential O_2 inhibition parameters for denitrification, shown in Fig. 6 (left panel), reveal the existence of progressively lower O_2 tolerance for step-wise denitrification ($K_{den3}^{o2} < K_{den2}^{o2} < K_{den1}^{o2}$) from all optimized parameter sets. As a result, denitrification can stop at either N_2O or NO_2^- as O_2 increases above anoxic levels, leading to “incomplete” denitrification (Babbin et al., 2015).

350 Within the anoxic core of the OMZ (~ 100 to 350 m depth), O_2 is low enough in all optimizations to allow each of the steps to proceed unimpeded (Fig. 5). The large differences between NO_3^- and NO_2^- reduction ($R_{den1} - R_{den2}$, middle panel of

Fig. 6) allows accumulation of a characteristic subsurface peak in NO_2^- near the OMZ core. Conversely, N_2O produced via NO_2^- reduction (R_{den2}) is quickly consumed via N_2O reduction (R_{den3}) leading to a pronounced N_2O deficit near the OMZ core. The progressive O_2 inhibition of the three steps of denitrification results in a decoupling between these reactions that is particularly evident in the oxycline layers above and below the OMZ, where N_2O accumulation dominates as N_2O reduction (i.e., consumption) is more strongly inhibited by O_2 than NO_2^- reduction (i.e., N_2O production, right panel of Fig. 6). Thus, the O_2 range defined by $K_{den2}^{o_2}$ and $K_{den3}^{o_2}$ can be thought of as a N_2O -production “window” that allows net N_2O accumulation in the water column (Babbin et al., 2015).

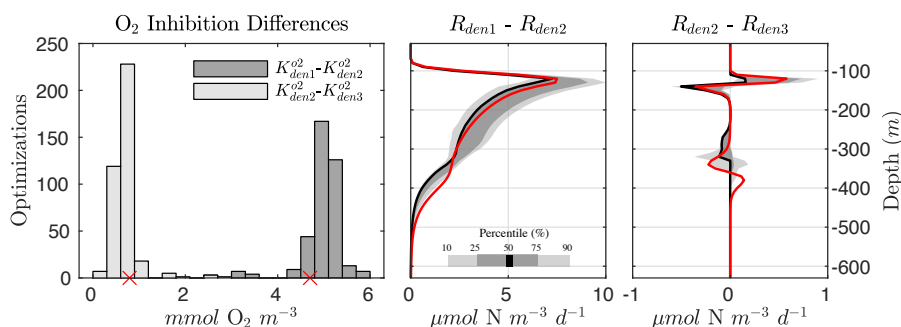

Figure 6. Progressive O_2 inhibition of denitrification steps. (left) Histogram showing the distribution for all optimized solutions of the difference in the O_2 inhibition constant for NO_3^- and NO_2^- reduction ($K_{den1}^{o_2}$ and $K_{den2}^{o_2}$, in dark gray), and NO_2^- and N_2O reduction ($K_{den2}^{o_2}$ and $K_{den3}^{o_2}$, in light gray). The small red markers denote the values from Opt_{sel} . (middle) Rate differences between NO_3^- and NO_2^- reduction (R_{den1} and R_{den2}). Shading represents the 10/90 and 25/75 percentile at each vertical level from the 382 analyzed parameter sets. The bold red curves denote Opt_{sel} results. (right) Same as (middle), but for the difference in NO_2^- and N_2O reduction rates (R_{den2} and R_{den3}).

The vertical profile of the step-wise denitrification rates (R_{den1} , R_{den2} , and R_{den3}) shows remarkable agreement across solutions, with only a small subset of parameter sets that behave as outliers (Fig. 5). As a consequence, the fraction of POC remineralized by each heterotrophic reaction remains consistent across optimizations (Fig. 7, top panels). Near the base of the euphotic zone, around 30 m depth, aerobic remineralization (R_{rem}) far exceeds denitrification, reflecting O_2 inhibition of the latter. However, as O_2 decreases to suboxic levels around 100 m depth, NO_3^- reduction becomes the dominant remineralization pathway (up to 60% of total remineralization). As O_2 drops further within the OMZ core (~100 to 350 m depth), NO_2^- and N_2O reduction rapidly take up the remaining fraction (~25% and 15%, respectively), albeit with more variability than near the euphotic zone. Below the OMZ, as the water column reverts to oxic conditions, aerobic remineralization dominates, and by 500 m depth, all solutions show essentially no denitrification.

The processes responsible for fixed nitrogen loss (anammox, NO_2^- reduction, and N_2O production from NH_4^+ oxidation) are also consistent across optimizations (Fig. 7, bottom panels). Within oxygenated waters, N_2O production from NH_4^+ oxidation ($R_{ao}^{n_2o}$) is by far the dominant fixed N loss term. Anammox (R_{ax}) becomes the dominant term within the upper and lower oxycline, consistent with observations (Babbin et al., 2020). In the anoxic OMZ core, NO_2^- reduction contributes up to 60%,

with anammox making up the remainder 40% (Fig. 5). This is somewhat higher than expected from purely stoichiometric constraints (Koeve and Kähler, 2010; Bianchi et al., 2014), likely reflecting vertical transport of NO_2^- and NH_4^+ , co-occurrence of aerobic and anaerobic processes, and the higher O_2 threshold for anammox inhibition in oxygenated waters.

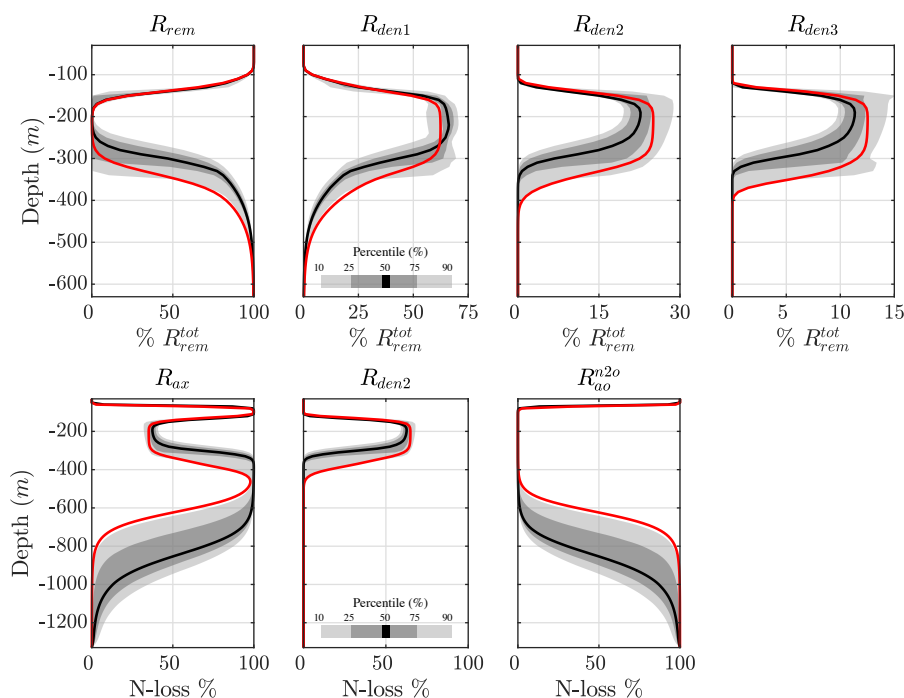

Figure 7. Contribution of different reactions to organic matter remineralization and fixed N loss. (top) Fraction of total POC remineralized by each heterotrophic rate (R_{rem} , R_{den1} , R_{den2} , and R_{den3}). Shading represents the 10/90 and 25/75 percentile at each vertical level from the 382 analyzed parameter sets. The bold red curves denote the selected parameter set (Opt_{sel}) discussed in Sect. 5.2. (bottom) Same as (top), but for the fraction of total fixed nitrogen loss (via production of N_2 and N_2O) from anammox (R_{ax}), NO_2^- reduction (R_{den2}), and N_2O production from NH_4^+ oxidation (R_{ao}^{n2o}).

5.2 Selected solution for the Eastern Tropical South Pacific

Among tracers, N_2O profiles show significant variability between optimizations, with only a subset able to reproduce the observed magnitude of the secondary N_2O peak at the lower oxycline (roughly 500 m depth, see Fig. 5). Additionally, while most optimizations are able to reproduce the OMZ peak in NO_2^- , significant variability in its magnitude exists. Given the central roles of N_2O and NO_2^- in both nitrification and denitrification pathways (Fig. 1), and the importance of oceanic N_2O emissions to the atmosphere, we assign high priority to optimizations that reproduce realistic features in the distribution of these tracers, in particular a higher magnitude for the secondary N_2O maximum. To this end, we select a parameter set (hereafter

Opt_{sel}) which results in N₂O and NO₂⁻ profiles closer to observations (bold red curves in Fig. 5, with parameter values reported in Table B1). We use this Opt_{sel} parameter set for further analysis of the model sensitivity.

385 Compared to the other parameter sets, Opt_{sel} is characterized by weaker maximum NH₄⁺ and NO₂⁻ oxidation rates (k_{ao} and k_{no} , respectively) and lower half saturation constants for reductant uptake ($K_{ao}^{nh_4}$ and $K_{no}^{no_2}$, respectively) (Fig. C2). In surface oxygenated waters, this results in relatively higher NH₄⁺ and NO₂⁻ (Fig. 5). In contrast, maximum denitrification rates (k_{den1} , k_{den2} , and k_{den3}) are close to the median values from all optimizations. Rates of NO₂⁻ and N₂O reduction (R_{den2} and R_{den3} , respectively) are generally larger than other solutions, in particular near the lower oxycline (Fig. 5). This
390 increases POC consumption within this depth range via denitrification compared to other solutions (Fig. 7). As a consequence, the residual between the NO₃⁻ and NO₂⁻ reduction ($R_{den1} - R_{den2}$, see Fig. 6) leads to higher NO₂⁻ accumulation at these depths, providing the necessary NO₂⁻ substrate to fuel either NO₂⁻ reduction (i.e. N₂O production) or anammox. Since the parameterization scheme in Opt_{sel} also results in reduced NO₂⁻ oxidation (R_{no}) and anammox (R_{ax}) rates (see Fig. 5), likely because of higher half saturation constants for substrate uptake ($K_{ax}^{nh_4}$ and $K_{ax}^{no_2}$), more NO₂⁻ is available for reduction by
395 denitrification, leading to a surplus in production (R_{den2}) relative to consumption (R_{den3}), and high concentrations of N₂O at the lower oxycline.

5.3 Sensitivities to model parameters

As shown in Sect. 5.1 and Fig. 4, strong correlations exist between parameter pairs in the optimization ensemble. Since Opt_{sel} demonstrates good comparisons with ETSP tracer and rate observations, we perform a series of sensitivity tests around parameters (P) most responsible for controlling specific features (F) of the tracer distributions. These include surface concentrations
400 of NH₄⁺ and NO₂⁻, the peak NO₂⁻ concentration in the OMZ, the N₂O concentrations at the primary and secondary N₂O maxima, and the minimum in the OMZ NO₃⁻ deficit (i.e., N^{*}). Additionally, we evaluate which parameters govern total N loss, including the fractional contribution of anammox, the partitioning of POC consumption via NO₃⁻, NO₂⁻, and N₂O reduction, and total N₂O production and air-sea flux (here, approximated by the vertical transport at the upper model boundary). To this
405 end, we calculated the sensitivity coefficient (ϕ_{ij}) for each P and F pairing by evaluating the impact of varying each Opt_{sel} P value by $\pm 5\%$ of its range in Table B1, and recording the resulting relative change in the F :

$$\phi_{ij} = \frac{P_i}{F_j} \cdot \frac{\partial F_j}{\partial P_i} \quad (12)$$

The results demonstrate high sensitivity to changes in the maximum rates for all reactions (Fig. 8). Specifically, higher maximum rates correlate negatively with the concentrations of their substrates, and positively with the concentrations of their
410 products. For example, increasing k_{den1} results in an increase in OMZ NO₂⁻, and a decrease in OMZ N^{*}. Similarly, increasing k_{den2} decreases OMZ NO₂⁻ and increases N₂O concentrations in the upper and lower oxycline, and its flux to the atmosphere. These impacts are further modulated by the half saturation and O₂ inhibition constants.

Fig. 9 and 10 further summarize the sensitivities to the maximum denitrification rates and their inhibition by O₂, detailing the resulting changes to N₂O, NO₂⁻, and N^{*} profiles. As expected, changes in maximum rates affect reaction substrates
415 and products in opposite ways. For example, a positive perturbation of k_{den2} increases N₂O (and N^{*}), and decreases NO₂⁻

Figure 8. Sensitivity coefficient ($\phi_{ij} = \frac{P_i}{F_j} \cdot \frac{\partial F_j}{\partial P_i}$) for Opt_{sel} parameters (P_i) and features (F_j) of the model solution. Here, each parameter is varied by $\pm 5\%$ of their respective CMA-ES allowed ranges in Table B1 to evaluate the relative impact to each feature of the model solution.

nearly everywhere. However, these sensitivities have also specific depth-dependent signatures. While changes in NO_2^- are more pronounced within the OMZ core, in particular the upper section, changes in N_2O are stronger at the upper and lower oxyclines, i.e., within the N_2O production window defined by $K_{den2}^{O_2}$ and $K_{den3}^{O_2}$ (see Sect. 5.1).

Fig. 8 and 10 highlight significant sensitivities to the O_2 inhibition constants, which control O_2 -dependent modulation of the maximum reaction rates. These effects are particularly evident at the boundaries of the OMZ. For example, an increase in $K_{den2}^{O_2}$ allows for more NO_2^- reduction at higher O_2 , leading to a slight depletion in OMZ NO_2^- and, as a consequence, an increase to suboxic N_2O concentrations (Fig. 10, middle panels). In a similar manner, an increase in $K_{den3}^{O_2}$ leads to more N_2O reduction, reducing the magnitude of both the primary and secondary N_2O peaks, while leaving other OMZ tracers (NO_2^- , N^*) relatively unaffected.

5.4 Sensitivities to environmental variables

The main features of the OMZ simulated by the model are strongly dependent on environmental parameters such as upwelling and mixing, organic matter fluxes, and the model boundary conditions. While each of these parameters control OMZ tracer profiles and N cycle reactions in complex ways, the main responses can be ascribed to changes in the position, thickness, and strength of the anoxic OMZ layer. Perturbations that replenish O_2 above the thresholds for anoxic processes have thus cascading impacts on anaerobic N cycle intermediates such as NO_2^- and N_2O , and on the fixed N removal and NO_3^- deficit.

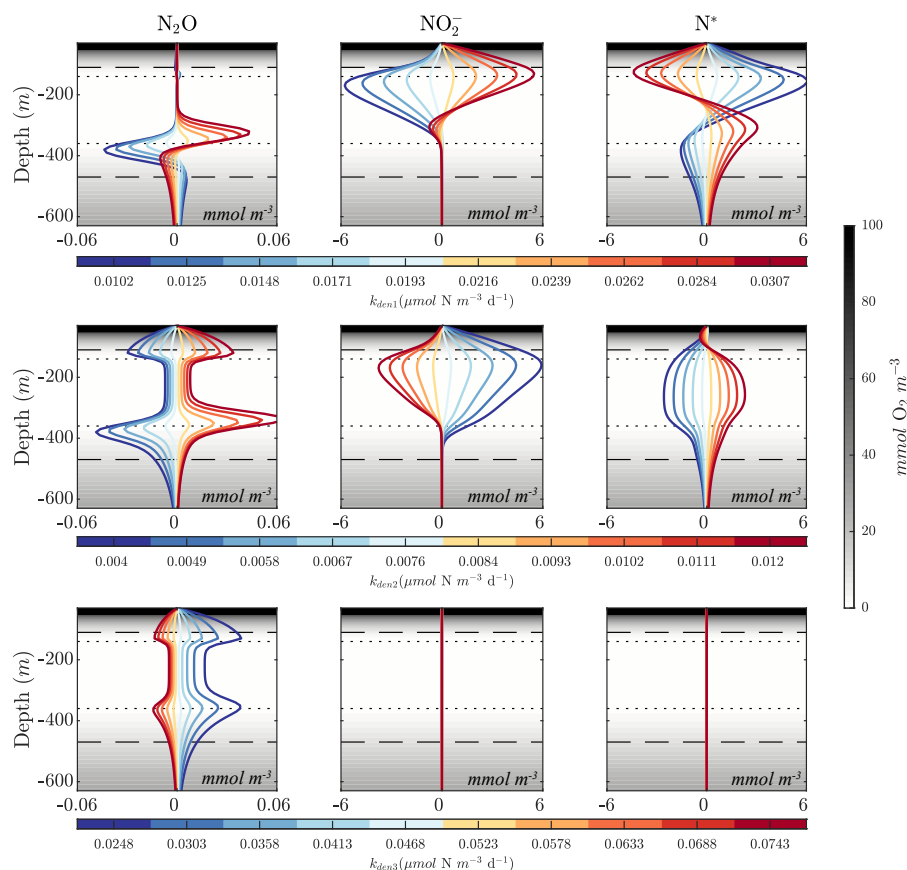

Figure 9. Model sensitivity to parameter values. Panels show changes to N_2O , NO_2^- , and N^* for the Opt_{sel} parameter set after varying the maximum NO_3^- , NO_2^- , and N_2O reduction rate parameters (k_{den1} , k_{den2} , and k_{den3} by $\pm 5\%$ of their Opt_{sel} value B1. Background gray shadings show O_2 concentrations, with horizontal lines highlighting $\text{O}_2=1 \text{ mmol m}^{-3}$ (dotted lines) and $\text{O}_2=10 \text{ mmol m}^{-3}$ (dashed lines)

Fig. 11 shows the sensitivity of the optimal solution Opt_{sel} to the magnitudes of vertical upwelling (w_{up}) and turbulent diffusion (K_v). Increasing w_{up} results in higher O_2 supply from below the OMZ, leading to increasing O_2 concentrations, and an upward shift and thinning of the anoxic layers. At high upwelling, the anoxic layer is effectively wiped out and is replaced by a suboxic layer. Similar results are obtained with higher K_v values, with an increase of diffusive O_2 supply from both above and below the OMZ, resulting in a progressive shrinking of the anoxic layer. As the anoxic layer vanishes, anaerobic processes cease, drastically reducing the concentration of NO_2^- and the N deficit in the OMZ core. Notably, as the OMZ reaches the brink of anoxia, i.e., as the minimum O_2 concentration falls within the N_2O production window, the upper and lower N_2O maxima merge into a single N_2O spike with particularly high N_2O concentrations, reflecting the largest imbalance between production and consumption. Opposite changes are observed for a reduction in both w_{up} and K_v , which result in an expansion of the OMZ layer, increased NO_3^- , NO_2^- , and N_2O reduction, a larger OMZ NO_2^- peak, and a broader separation of the upper and lower N_2O maxima.

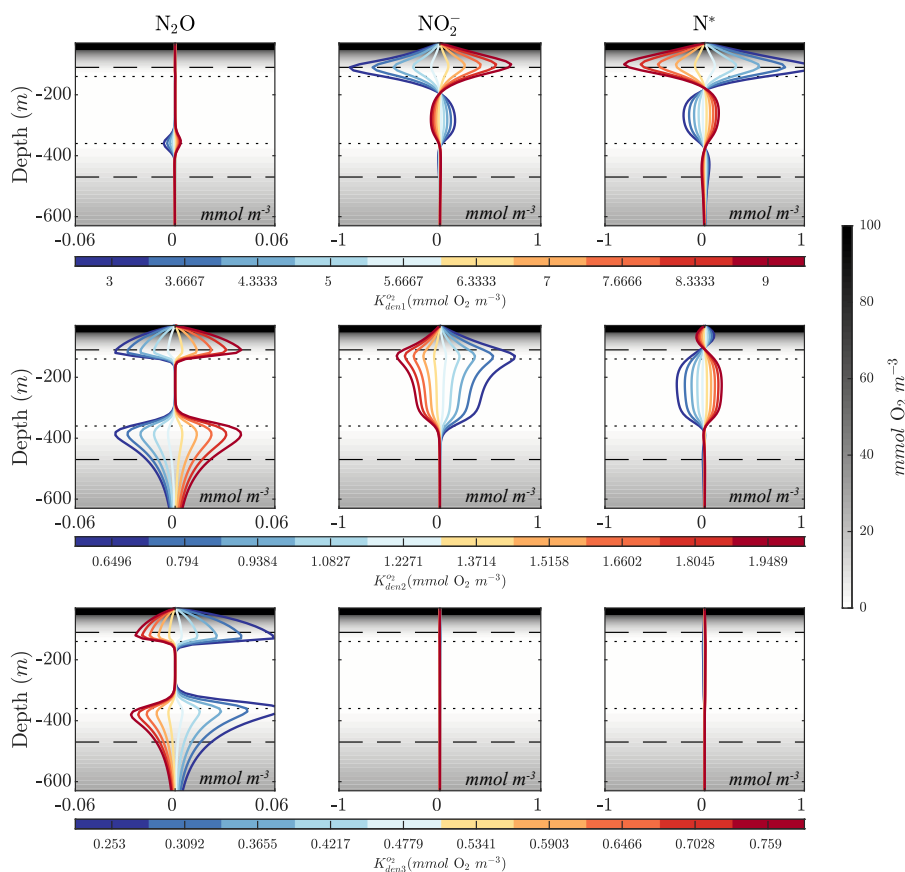

Figure 10. Same as in Fig. 9, but for $\pm 5\%$ variations in the O_2 inhibition constants for NO_3^- , NO_2^- , and N_2O reduction (K_{den1}^{o2} , K_{den2}^{o2} , and K_{den3}^{o2}).

Because the supply of POC to the OMZ controls the overall magnitude of remineralization reactions, including O_2 consumption and denitrification, the model is particularly sensitive to the sinking POC flux at the upper model boundary (Φ_{poc}^{top} , Table B3; Fig. 12, top panel). Increasing Φ_{poc}^{top} causes a greater remineralization rate, which reduces available O_2 , and drives a progressive thickening of the OMZ, with a series of cascading impacts on tracers similar to the ones discussed above. In contrast, decreasing Φ_{poc}^{top} reduces the R_{rem} rates and increases O_2 to the point that anoxic conditions and their signature disappear.

Similar changes can also be driven by variations in the bottom boundary O_2 concentration, which directly controls upward O_2 supply by upwelling (Fig. 12, bottom panel). Increasing bottom O_2 progressively decreases the thickness of the OMZ, shifting it upwards, and eventually eroding the anoxic layer. Conversely, decreasing bottom O_2 leads to a downward expansion of the OMZ and an intensification of anoxic conditions and the resulting anaerobic reactions.

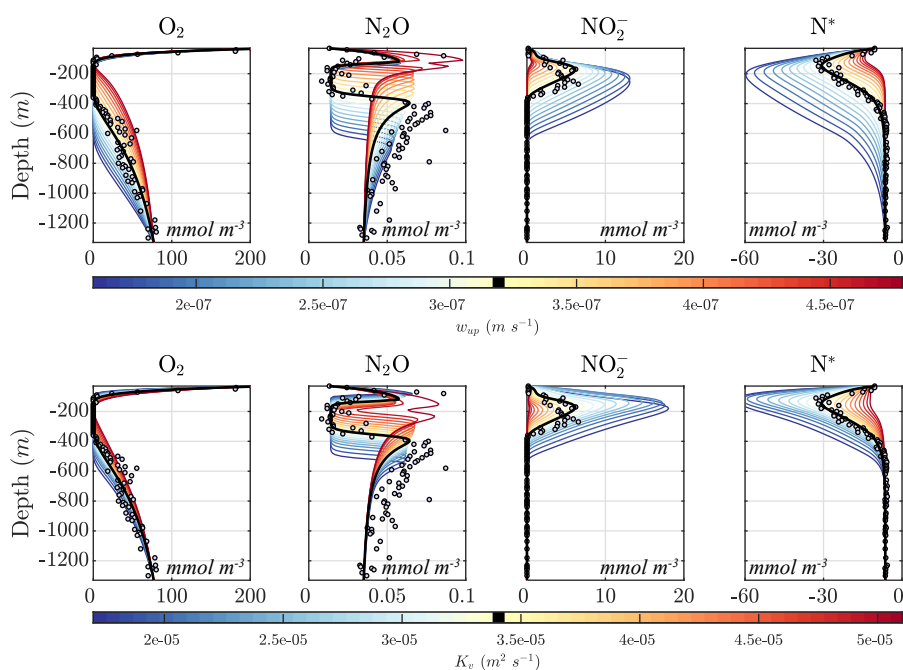

Figure 11. Model sensitivity to physical drivers. (top) Sensitivity of the Opt_{sel} optimized solution to the constant vertical upwelling velocity (w_{up}). (bottom) Sensitivity to the vertical turbulent diffusion coefficient (K_v). The bold black curves indicate original Opt_{sel} values, which are also indicated on their respective colorbars.

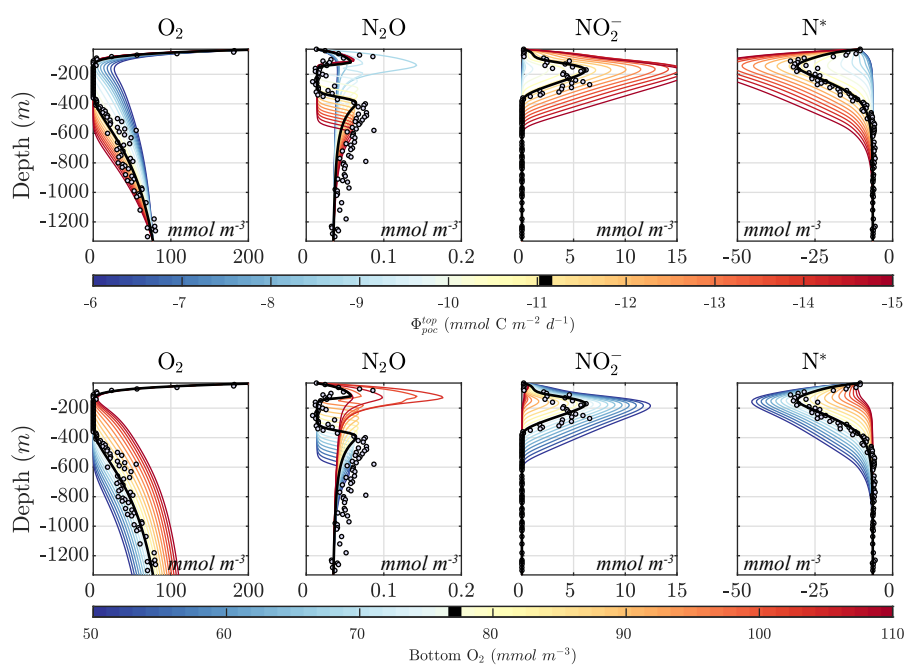

Figure 12. Model sensitivity to biogeochemical drivers. Same as in Fig. 11, but for surface POC flux (Φ_{poc}^{top}) and O_2 concentration at the lower model boundary.

6 Discussion and conclusions

We developed a model of the N cycle in low O_2 waters, and optimized it to reproduce observations from the ETSP OMZ. The model is able to simulate the distribution of multiple N cycle tracers, including NO_2^- and N_2O , and their transformation rates, capturing the underlying dynamics and environmental sensitivity of the underlying reactions (Fig. 5). In general, the model reproduces observed tracer concentration profiles more accurately than transformation rates. Mismatches with transformation rates may point to processes that need improvement in the model, but also underscore limitations in rate measurements, which rely on shipboard incubation experiments that are usually more uncertain and limited in number than tracer measurements, and may not perfectly reflect *in situ* conditions. However, by matching observed reaction rates to a reasonable degree, the model reproduces tracer distributions by capturing the correct underlying dynamics. Co-located tracer and rate measurements for multiple processes are thus an effective way to constrain the model representation of the anaerobic N cycle.

The optimization indicates that multiple parameter sets can produce equally good fits to tracer and rate profiles (Fig. 5). This is expected given the non-linear nature of the model, and limitations in the observations. Even when rate measurements are used to constrain the model, an ensemble of equally good solutions is thus possible. This optimized ensemble shows that significant variability and trade-offs can exist between specific parameters (Fig. 4), suggesting that compensation between different processes can lead to similar profiles of tracers and transformation rates. Further refinements to the criteria used to optimize the model, i.e., additional constraints in the definition of the cost function, could allow to further narrow down plausible sets of parameters. For example, to evaluate the model sensitivity (Fig. 8-10), we select a parameter set from our optimization ensemble that better captures the magnitude of the secondary N_2O maximum, while reproducing other observational features equally well. While we adopt a relatively simple definition for the optimization cost function, additional constraints such as this one could be explicitly built into its formulation and weighted more heavily to further refine parameter selection.

A better characterization of environmental sensitivities to substrate concentrations (e.g., half saturation constant for substrate uptake) and O_2 sensitivities would also help parameter selection, for example by narrowing down their prior (and posterior) range of values. To this end, rate measurements under a range of O_2 and substrate concentrations are especially helpful. Similarly, simultaneous optimization of the model to reproduce observations across multiple regions of an OMZ characterized by different conditions, e.g., the core and the boundaries, or across different OMZ and oceanographic regimes, would likely result in more robust optimizations.

Despite the variability in parameter values, analysis of the optimal ensemble suggests emerging features that appear robust across multiple optimizations. For example, the sensitivity of denitrification processes to O_2 shows systematic variations, with weaker O_2 inhibition for NO_3^- reduction, and stronger for N_2O reduction (Fig. 6). Accordingly, NO_3^- reduction to NO_2^- tends to occur at higher O_2 concentrations than NO_2^- reduction to N_2O , which in turns occurs at higher O_2 concentrations than N_2O reduction to N_2 . In the model, this O_2 sensitivity offset supports an O_2 -dependent production window for N_2O , which allows net accumulation of N_2O at the margins of the OMZ core, i.e., along the upper and lower oxyclines. This, and other systematic relationships between parameters and features of the solutions, as revealed by a sensitivity analysis (Fig. 8-10), shed light on

485 specific balances in the N cycle, and can be exploited as a powerful tool to fine-tuning the model, both in the 1D setup used here, and in more complex and resource-intensive 3D implementations where a formal optimization would be unfeasible.

Because the model is based on a mechanistic representation of N transformations, it is suitable to investigate the response of the N cycle to environmental variability and other perturbations (Fig. 11,12). For example, the model could be used to investigate the effects of eddy variability near the boundaries of OMZs, or the effects of OMZ expansion under global change. With
490 these goals in mind, the model is designed to be coupled to the biogeochemical component of the current generation of Earth System Models, enabling accurate simulation of NO_2^- and N_2O dynamics, with minimal interference with the representation of the cycles of oxygen, nutrients, carbon, and organic matter.

While the model reflects our current understanding of the N cycle, its assumptions can be re-evaluated as new N transformation processes and aspects of microbial dynamics are uncovered. Because of its modular design, the model can be naturally
495 expanded to represent additional processes that, while thought to be relevant in OMZ, are still uncertain. These include: (1) Alternative oxidation pathways, for example NO_2^- oxidation with iodate, or NO_2^- disproportionation reactions (Babbin et al., 2020; Sun et al., 2021a); (2) Coupling of N tracers with the cycles of other elements, e.g. carbon, sulfur and iron, such as chemolithotrophic denitrification coupled to hydrogen sulfide (H_2S) oxidation, or anaerobic NO_2^- -based methane (CH_4) oxidation (Azhar et al., 2014; Scholz et al., 2016; Thamdrup et al., 2019; Callbeck et al., 2021); (3) Explicit representation of
500 chemolithotrophy and its effects on organic matter fixation (Swan et al., 2011); (4) Explicit coupling to the inorganic carbon cycle, by inclusion of CO_2 and alkalinity changes associated with N cycle reactions; (5) The cycling of nitric oxide (NO), a very reactive intermediate in N transformations that is generally not considered in models (Ward and Zafriou, 1988; Lutterbeck et al., 2018); (6) A more detailed representation of the microbial dynamics of underlying the N cycle, with inclusion of explicit populations and processes such as growth, competition, mortality, and metabolite exchanges (Louca et al., 2016; Zakem et al.,
505 2018; Penn et al., 2019).

Code and data availability. The current version of NitrOMZv1.0 is available from the project website: <https://doi.org/10.5281/zenodo.7106213>. The exact version of the model used to produce the results used in this paper is archived on Zenodo (Daniele Bianchi, Simon Yang, and Daniel McCoy. (2022). NitrOMZv1.0 Model Code (1.0). Zenodo. <https://doi.org/10.5281/zenodo.7106213>), as are input data and scripts to run the model and produce the plots for all the simulations presented in this paper (Bianchi et al., 2022).

510 *Author contributions.* DB conceptualized the formulation of the model; DB and SY developed the model code, including optimization procedures; DB and SY organized the validation data; DB and DM designed the analyses; DM prepared the tables and visualization of data; DB and DM prepared the manuscript with contributions from SY.

Competing interests. The authors declare that they have no conflict of interest.

Sloan Foundation, and computational support by the Extreme Science and Engineering Discovery Environment (XSEDE) through allocation TG-OCE17001. The Authors wish to thank A. Babbín, A. Santoro, C. Kelly for helpful discussion.

Appendix A: NitrOMZ Equations

A1 Heterotrophic rate equations

$$R_{rem} = k_{rem} \cdot \frac{O_2}{K_{rem}^{O_2} + O_2} \cdot POC \quad (A1)$$

$$R_{den1} = k_{den1} \cdot \frac{NO_3^-}{K_{den1}^{NO_3} + NO_3^-} \cdot e^{\frac{-O_2}{K_{den1}^{O_2}}} \cdot POC \quad (A2)$$

$$R_{den2} = k_{den2} \cdot \frac{NO_2^-}{K_{den2}^{NO_2} + NO_2^-} \cdot e^{\frac{-O_2}{K_{den2}^{O_2}}} \cdot POC \quad (A3)$$

$$R_{den3} = k_{den3} \cdot \frac{N_2O}{K_{den3}^{N_2O} + N_2O} \cdot e^{\frac{-O_2}{K_{den3}^{O_2}}} \cdot POC \quad (A4)$$

A2 Chemolithotrophic rate equations

$$R_{ao} = k_{ao} \cdot \frac{O_2}{K_{ao}^{O_2} + O_2} \cdot \frac{NH_4^+}{K_{ao}^{NH_4} + NH_4^+} \quad (A5)$$

$$R_{no} = k_{no} \cdot \frac{O_2}{K_{no}^{O_2} + O_2} \cdot \frac{NO_2^-}{K_{no}^{NO_2} + NO_2^-} \quad (A6)$$

$$R_{ax} = k_{ax} \cdot \frac{NH_4^+}{K_{ax}^{NH_4} + NH_4^+} \cdot \frac{NO_2^-}{K_{ax}^{NO_2} + NO_2^-} \cdot e^{\frac{-O_2}{K_{ax}^{O_2}}} \quad (A7)$$

520 A3 Aerobic N₂O production

Production of N₂O via the nitrification pathway in NitrOMZ (pathway 2b in Fig. 1) is modelled as a by-product of R_{ao} with enhanced yields at lower O₂ concentrations. The partitioning between N₂O and NO₂⁻ production from R_{ao} is calculated using the function proposed by Nevison et al. (2003), which was derived by fitting measured N₂O and NO₂⁻ yields ($Y_{ao}^{N_2O}$ and $Y_{ao}^{NO_2}$, respectively) to oxygen concentrations (Goreau et al., 1980), and re-fit by multiple observations in the Eastern Tropical North

525 and South Pacific OMZ (Ji et al., 2015a, 2018; Santoro et al., 2021):

$$\frac{Y_{ao}^{N_2O}}{Y_{ao}^{NO_2}} = \left(\frac{Ji_a}{[O_2]} + Ji_b \right) \cdot 0.01 \quad (A8)$$

Nitrification-derived NO₂⁻ and N₂O production rates ($R_{ao}^{NO_2}$ and $R_{ao}^{N_2O}$ respectively, pathways 2a and 2b in Fig. 1) are therefore represented as:

$$R_{ao}^{N_2O} = R_{ao} \cdot Y_{ao}^{N_2O}, \quad (A9)$$

$$R_{ao}^{NO_2} = R_{ao} \cdot Y_{ao}^{NO_2}. \quad (A10)$$

A4 Stoichiometry

The stoichiometry of heterotrophic redox reactions assumes that organic matter (POC) follows the average oceanic ratios from
 530 Anderson and Sarmiento (1994): C₁₀₆H₁₇₅O₄₂N₁₆P. This chemical composition can be adjusted in NitrOMZ. The NH₄⁺ to C

and PO_4^{3-} to C ratios during aerobic respiration are therefore represented as:

$$Q_{rem}^{N:C} = \frac{16}{106}, \quad (\text{A11})$$

$$Q_{rem}^{P:C} = \frac{1}{106}. \quad (\text{A12})$$

As a result of the POC composition, a total of 472 electrons are required to oxidize POC to CO_2 . With 4 electrons required to reduce O_2 to H_2O , the oxygen to carbon remineralization ratio for aerobic respiration is represented as:

$$Q_{rem}^{O:C} = \frac{472}{106 \cdot 4}, \quad (\text{A13})$$

For denitrification, 2 electrons are required for each respective reduction step (NO_3^- to NO_2^- , NO_2^- to N_2O , and N_2O to N_2),
 535 thus the corresponding ratios can be represented as:

$$Q_{den}^{N:C} = \frac{472}{106 \cdot 2} \quad (\text{A14})$$

The above ratios are then applied to the tracer equations in Sect. A5.

A5 Tracer sources-minus-sinks equations

$$\frac{d[\text{POC}]}{dt} = -(R_{rem} + R_{den1} + R_{den2} + R_{den3}) \quad (\text{A15})$$

$$\frac{d[\text{O}_2]}{dt} = (Q_{rem}^{O:C} \cdot R_{rem}) - (1.5 \cdot R_{ao}) - (0.5 \cdot R_{no}) \quad (\text{A16})$$

$$\frac{d[\text{NO}_3^-]}{dt} = R_{no} - (Q_{den}^{N:C} \cdot R_{den1}) \quad (\text{A17})$$

$$\frac{d[\text{PO}_4^{3-}]}{dt} = Q_{rem}^{P:C} \cdot (R_{rem} + R_{den1} + R_{den2} + R_{den3}) \quad (\text{A18})$$

$$\frac{d[\text{NH}_4^+]}{dt} = Q_{rem}^{N:C} \cdot (R_{rem} + R_{den1} + R_{den2} + R_{den3}) - (R_{ao} + R_{ax}) \quad (\text{A19})$$

$$\frac{d[\text{NO}_2^-]}{dt} = R_{ao}^{no2} + Q_{den}^{N:C} \cdot (R_{den1} - R_{den2}) - (R_{no} + R_{ax}) \quad (\text{A20})$$

$$\frac{d[\text{N}_2\text{O}]}{dt} = 0.5 \cdot (R_{ao}^{n2o} + Q_{den}^{N:C} \cdot R_{den2}) - (Q_{N:C}^{den} \cdot R_{den3}) \quad (\text{A21})$$

$$\frac{d[\text{N}_2]}{dt} = (Q_{den}^{N:C} \cdot R_{den3}) + R_{ax} \quad (\text{A22})$$

$$(\text{A23})$$

Appendix B: NitrOMZ Parameters and Configurations

Table B1. NitrOMZ nitrogen cycle parameters and CMA-ES optimization ranges.

Parameter	Description	Units	CMA-ES Min Value	CMA-ES Max Value	Opt _{sel} ETSP
J_{ia}	Nevison et al. (2003) 'a' parameter	N/A	0.0500	0.4000	0.4000
