Abstract. We report on an inconsistency in the latitudinal distribution of aviation emissions between the data products of phases 5 and 6 of the Coupled Model Intercomparison Project (CMIP). Emissions in the CMIP6 data occur at higher latitudes than in the CMIP5 data for all scenarios, years, and emitted species. A comparative simulation with the chemistry-climate model EMAC reveals that the difference in nitrogen oxides emission distribution leads to reduced overall ozone changes due to aviation in the CMIP6 scenarios, because in those scenarios the distribution of emissions is partly shifted towards the chemically less active higher latitudes. The radiative forcing associated with aviation ozone is 7.6% higher for the year 2015 when using the CMIP5 latitudinal distribution of emissions compared to when using the CMIP6 distribution. We do not find a statistically significant difference in the radiative forcing associated with aviation aerosol emissions.

1 Introduction

Emission data are a key contribution to the Coupled Model Intercomparison Project Phase 6 (CMIP6, Eyring et al., 2016). This framework provides both, historical emissions (Hoesly et al., 2018) and emissions for future scenarios (Riahi et al., 2017; Gidden et al., 2019). Several studies have used the aviation emissions provided within the framework of CMIP6 (e.g., Quadros et al., 2020; Righi et al., 2021). The geographical and annual distribution of aviation emissions are identical throughout all historical and scenario data sets in CMIP6, leaving only the total annual emission amounts as variables that are different for each year and each scenario. According to the documentation (Hoesly et al., 2018), the geographical distribution of the CMIP6 aviation emissions is based on that of the CMIP5 aviation emissions (Lamarque et al., 2010), which in turn are derived from the Future Aviation Scenario Tool (FAST, Lee et al., 2005) for the European QUANTIFY project (Hoor et al., 2009), and is not affected by the regridding performed within CMIP6 (Feng et al., 2020). Based on this information we would expect an identical geographical distribution of the aviation emissions in CMIP5 and CMIP6.

Here, we report on an inconsistency in the spatial pattern of aviation emissions between CMIP5 (Lamarque et al., 2010) and CMIP6 (Gidden et al., 2019; Feng et al., 2020). The latitudinal emission distribution differs by an approximate factor of $1.344 \cos \phi$ for historic emissions provided in the Community Emissions Data System (CEDS, Hoesly et al., 2018) and by an

Figure 1. Fraction of total aviation emissions as a function of latitude. The solid blue line is based on the RCP 4.5 scenario for the year 2000 (CMIP5, Lamarque et al., 2010). The dashed blue line is based on historical emissions provided in the CEDS (CMIP6, Hoesly et al., 2018). The dotted blue line is based on the SSP2 4.5 scenario for the year 2015 (CMIP6, Fricko et al., 2017; Gidden et al., 2019). The orange line is based on the REACT4C inventory (Søvde et al., 2014).

approximate factor of $1.912 \cos^2 \phi$ for the Shared Socioeconomic Pathways (SSP) scenarios (Gidden et al., 2019), where ϕ is the latitude (Fig. 1). This difference is particularly noticeable in the North Polar region, where emissions are several times larger in the CMIP6 data sets, but in terms of total amount of emissions, the difference is largest in the regions from $\sim 50^\circ\text{N}$ to $\sim 65^\circ\text{N}$ and from $\sim 25^\circ\text{N}$ to $\sim 40^\circ\text{N}$, where most emissions occur (see also Fig. 2). A comparison with an independent aviation emission inventory derived in the REACT4C project (Søvde et al., 2014) gives a very good match with the CMIP5 data set. The difference is observed for aviation emissions of nitrogen oxides (NO_x), black carbon (BC), and CO_2 . Other emitted species (CO, NH_3 , NMVOC, SO_2 , organic carbon) have an identical geographic distribution to that of NO_x and BC in CMIP6, but were not provided in the CMIP5 data.

The aim of this paper is to investigate the impacts of the differences in the latitudinal distribution of emissions on aviation-induced ozone and aerosols and on their radiative forcing (RF). We do not consider emissions of CO_2 , as it is a well-mixed greenhouse gas with a long lifetime, implying that the spatial distribution of the emissions has a minor effect on the CO_2 -induced climate effect. We also do not consider the potential differences in the contrail climate effect, because the CMIP data do not contain data on flight distance per area, which would be required for their computation.

In Section 2, we introduce the used earth system model and simulation set-up and in Section 3, we present results on the aviation-induced atmospheric ozone concentration and aerosol distributions and differences in radiative fluxes.

2 Method

To investigate the effect of the difference in latitudinal distribution of aviation emissions on ozone, aerosols, and the related radiative forcings, we perform simulations with the chemistry-climate model ECHAM/MESSy Atmospheric Chemistry (EMAC), using each of the geographical distributions, but identical total amounts of emissions. The EMAC model is a numerical chem-

istry and climate simulation system that includes sub-models describing tropospheric and middle atmosphere processes and their interaction with oceans, land and human influences (Jöckel et al., 2010). It uses the second version of the Modular Earth Submodel System (MESSy2) to link multi-institutional computer codes. The core atmospheric model is the 5th generation
45 European Centre Hamburg general circulation model (ECHAM5, Roeckner et al., 2006). The physics subroutines of the original ECHAM code have been modularized and reimplemented as MESSy sub-models and have been continuously been further developed. Only the spectral transform dynamical core, the flux-form semi-Lagrangian large scale advection scheme, and the nudging routines for Newtonian relaxation are remaining from ECHAM.

For the simulations of aviation-induced ozone changes in the present study, we applied EMAC (MESSy version 2.54.0.3)
50 in the T42L90MA-resolution, i.e. with a spherical truncation of T42 (corresponding to a quadratic Gaussian grid of approx. 2.8 by 2.8 degrees in latitude and longitude) with 90 vertical hybrid pressure levels up to 0.01 hPa. The applied model setup comprised RF calculations based on the sub-model RAD (Dietmüller et al., 2016) and the sub-model TAGGING (version 1.1, Grewe et al., 2017; Rieger et al., 2018) for the attribution of RF to emissions from the aviation sector (Mertens et al., 2018). The simulations use specified dynamics and the set-up is very similar to the one of the simulation RC1SD-base-10a
55 described in detail by Jöckel et al. (2016) (see also Mertens et al., 2022). For one simulation we use the unaltered CMIP6 aviation emissions of the SSP2 4.5 scenario (Fricko et al., 2017) for the year 2015, whereas for a second simulation we use the CMIP6 aviation emissions with their latitudinal distribution changed to be equal to that of the CMIP5 emissions. Other simulation settings are identical. The presented results are obtained as a 5-year mean after a spin-up period of 6 months in quasi-chemical transport model (QCTM) mode (Deckert et al., 2011), where feedback between chemistry and dynamics is
60 suppressed, and using meteorology data reaching from 2013 to 2017 and specified dynamics by Newtonian relaxation towards ECMWF ERA-Interim reanalysis data (Dee et al., 2011). For the spin-up period, we use meteorology data from the second half of 2012. The simulations were initialized from a previous 1.5-year simulation including TAGGING for the spin-up of the TAGGING tracers. This spin-up simulation itself was initialized from the long-term (since 1950) SC1SD-base-01 simulation which is similar to the RC1SD-base-10a simulation (Jöckel et al., 2016).

For the simulations of the aviation-induced aerosol effect, we used EMAC with the aerosol submodel MADE3 (Modular
65 Aerosol Dynamics model for Europe, adapted for global applications, third generation; Kaiser et al., 2014, 2019) in the configuration described by Righi et al. (2020). With respect to the version adopted for the ozone changes, the EMAC-MADE3 setup for aerosol uses a lower vertical resolution with 41 layers, mostly covering the troposphere and the lower stratosphere, and a simplified chemistry scheme, only including the reactions relevant for the aerosol processes. The aerosol simulations
70 cover a period of 13 years, from 2006 to 2018, with nudged meteorology using the ECMWF ERA-Interim reanalysis data. The QCTM mode and the tagging method cannot be applied for investigating the aerosol effects, due to the role of the cloud feedback and the complexity of the liquid-phase chemistry for sulfate, respectively. Hence, the statistical significance of the changes in the aerosol RF between the original and the corrected emission dataset is evaluated using a paired sample *t* test at the 95% confidence level.

Figure 2. Differences (CMIP5 - CMIP6) of NO_x emissions (solid line), O₃ burden (dashed line), and radiative flux (dotted line) from two simulations with identical total amount of aviation emissions, but different latitudinal distributions, as a function of latitude.

75 3 Results

Our analysis for the SSP scenarios shows that regional emission amounts from aviation differ substantially in the northern mid-latitudes (Fig. 2). Emissions of NO_x north of 45°N are 36.8% lower and emissions south of 45°N are 31.9% higher when using the CMIP5 latitudinal distribution of emissions compared to when using the unaltered CMIP6 emissions. The mean emission latitude shifts from 41.3°N for the CMIP6 latitudinal distribution to 34.3°N for the CMIP5 latitudinal distribution.

80 The difference in the ozone distribution between the two QCTM simulations reflects the latitudinal difference in aviation emissions (dashed and solid lines in Fig. 2, respectively). However, atmospheric dynamics and the larger chemical activity in tropical latitudes lead to a southward shift of the ozone burden difference with respect to the emission difference. The increased NO_x emissions southwards of 45°N cause a positive ozone burden whose value (2.13 Tg) is larger than the absolute value of the negative ozone burden caused by the decreased NO_x emissions northwards of 45°N (-1.18 Tg). In total, using the CMIP5
85 latitudinal pattern of emissions increases the atmospheric ozone burden by 0.95 Tg, corresponding to an increase of 3.4% in the total ozone burden attributed to aviation.

We also compute the stratospherically adjusted radiative flux at the tropopause resulting from these differences in the ozone concentration distribution. The pattern of the radiative flux difference between the two simulations closely follows the pattern of the ozone burden difference, but the radiative flux decrease at high northern latitudes is more pronounced than the corresponding ozone decrease (Fig. 2). We show radiative flux instead of radiative forcing to keep all quantities in Fig. 2 independent
90 of the area for better comparability. The radiative forcing attributed to aviation emissions is 30.82 mW m⁻² in the simulation with unaltered CMIP6 emissions and 33.16 mW m⁻² in the simulation using the CMIP5 emission pattern, corresponding to a difference of 2.34 mW m⁻² or 7.6%. The difference in total RF between the two simulations is 2.08 mW m⁻². The total difference is smaller due to the non-linearity between nitrogen oxide emissions and ozone changes. Emissions from other sectors
95 cause weaker radiative effects in a more polluted atmosphere, partly compensating for a larger aviation RF.

Transport emissions also influence the lifetime of methane, with aviation emissions generally leading to a lifetime decrease (Mertens et al., 2022). In the simulation using the CMIP5 emission pattern, we found a 5.7% larger decrease of lifetime for aviation. All these changes are statistically significant because they are 5 to 6 times larger than their standard deviation over the 5-year simulation period. For context, aviation emissions have consistently increased over time, with a decadal increase ranging from 10-25%, depending on the time period (O'Rourke et al., 2021). This points to the importance of accurately quantifying not only the magnitude and spatial distribution of aviation emissions, but their changes over time.

We also investigate the difference in aerosol RF between the two simulations, but cannot detect a significant difference: For the simulations with the CMIP5 and unaltered CMIP6 emissions we quantify a RF of -46.0 mW m^{-2} and -54.7 mW m^{-2} , respectively, i.e. a difference of 8.7 mW m^{-2} (15.9%), but with a low statistical significance of 79.8%. This is related to the large variability associated with aerosol RF compared to those associated with ozone RF, especially due to the role of aerosol-cloud interactions (see, e.g., Righi et al., 2013).

4 Conclusions

In summary, the inconsistency in the latitudinal distribution of aviation emissions between CMIP5 and CMIP6 leads to differences not only in the latitudinal distributions and regional emission amounts, but also in the total amounts of resulting ozone changes, methane lifetime changes, and RF attributed to aviation. The usage of the CMIP6 latitudinal distribution of emissions leads to an overall lower climate effect of aviation emissions, even though the same total global amount of emissions was assumed in the simulations. The difference of 2.34 mW m^{-2} reported in this study for the SSP2 4.5 scenario is small in the context of anthropogenic climate change, but constitutes 7.6% of the RF attributed to aviation ozone in our model. We therefore recommend that scholars studying the effects of aviation emissions on ozone and climate consider the inconsistency in the latitudinal distribution of aviation emissions reported here. We also investigated the effect of the inconsistency on aerosol RF, but could not detect a significant difference. Furthermore, the results emphasize the importance of a correct and realistic geographic distribution of emissions when studying their effects on atmospheric composition and climate. Future aviation emission datasets should also consider temporal changes in the spatial distribution of emissions. No spatial changes over time were incorporated in either the CMIP5 or CMIP6 aviation datasets because such changes have not been estimated by the research community. The spatial distribution of aviation emissions have certainly changed over time, however. For example, from 1990 to 2017 the share of estimated NO_x emissions from flights originating in (roughly) the northern hemisphere (here Former Soviet Union, Europe, China, and North America) declined from 73% to 62%, implying a shift in aviation emissions away from the northern mid-latitudes (O'Rourke et al., 2021).

Code and data availability. The Modular Earth Submodel System (MESSy) is continuously further developed and applied by a consortium of institutions. The usage of MESSy and access to the source code is licensed to all affiliates of institutions which are members of the MESSy Consortium. Institutions can become a member of the MESSy Consortium by signing the MESSy Memorandum of Understanding.

130 More information can be found on the MESSy Consortium website (<http://www.messy-interface.org>, last access: 10 October 2022). The simulations presented here have been performed with a release of MESSy based on version d2.54.0.3-pre2.55-02. All changes are available in the official release (version 2.55). The namelist setups used for the simulations and the scripts used for the creation of the figures are given in Thor (2022).

Author contributions. R. N. T. discovered the inconsistency. S. M. and V. G. conceptualized the study. M. M., R. N. T., and M. R. carried out the simulations. M. R., S. B., P. G., and P. J. prepared the modified CMIP6 input emission data for the model simulation to be consistent with the CMIP5 spatial emission pattern. S. B. calculated the methane lifetime. M. R. and J. H. calculated the aerosol RF. R. N. T. created all figures and wrote the manuscript with the help of all co-authors.
