## 13 **Abstract**

14 The porous microenvironment of soil offers various environmental functions which are governed by  
15 physical and reactive processes. Understanding reactive transport processes in porous media is essential  
16 for many natural systems (soils, aquifers, aquatic sediments or subsurface reservoirs) or technological  
17 processes (water treatment, or ceramic and fuel cell technologies). In particular, in the vadose zone of the  
18 terrestrial subsurface the spatially and temporally varying saturation of the aqueous and the gas phase  
19 leads to systems that involve complex flow and transport processes as well as reactive transformations of  
20 chemical compounds in the porous material. To describe these interacting processes and their dynamics at  
21 the pore scale requires a well-suited modelling framework accounting for the proper description of all  
22 relevant processes at a high spatial resolution. Here we present P3D-BRNS as a new open-source  
23 modelling toolbox harnessing the core libraries of OpenFOAM and coupled externally to the  
24 Biogeochemical Reaction Network Simulator (BRNS). The native OpenFOAM Volume of Fluid solver is  
25 extended to have an improved representation of the fluid-fluid interface. The solvers are further  
26 developed to couple the reaction module which can be tailored for a specific reactive transport simulation.  
27 P3D-RBNS is benchmarked against three different flow and reactive transport processes; 1) fluid-fluid  
28 configuration in a capillary corner, 2) mass transfer across the fluid-fluid interface and 3) microbial  
29 growth with a high degree of accuracy. Our model allows for simulation of the spatio-temporal  
30 distribution of all bio-chemical species in the porous structure (obtained from  $\mu$ -CT images), for  
31 conditions that are commonly found in the laboratory and environmental systems. With our coupled  
32 computational model, we provide a reliable and efficient tool for simulating multiphase, reactive transport  
33 in porous media.

## 34 **1 Introduction**

35 Subsurface environments (soils, aquifers, aqueous sediments) are (typically) porous media host a  
36 multitude of biogeochemical processes and interactions and provide different versatile ecosystem  
37 functions (e.g. C sequestration, compound degradation, nutrient retention, provision of food, fibers and  
38 fuel, habitat for organisms, water retention and purification, etc. (Baveye et al., 2016 ). These processes  
39 are controlled by various biological (e.g., microbial abundance and activity), chemical (e.g., distribution  
40 of dissolved and volatile species, mineral composition and surface properties of the solid matrix) and  
41 physical (e.g., porous structure and permeability, water saturation) properties of the system. These  
42 features create a complex web of interactions, the magnitude and effectiveness of which change  
43 dynamically in space and time (Graham et al., 2014). Microbial communities, for example, and their  
44 metabolic capacity are considered to be directly related to energy and matter fluxes (Thullner et al., 2007)  
45 which are in turn, governed by pore arrangements and their connectivity. Along with other environmental  
46 factors this can also modify various properties of the porous media (e.g. by biomass accumulation on pore  
47 walls (Thullner, 2010), or mineral dissolution or precipitation (Meakin and Tartakovsky, 2009), which in  
48 turn are altering the conditions for biogeochemical processes, too.

49 In soils (or more generally the vadose zone) the dynamically varying distribution of the aqueous and  
50 gaseous phase leads to specifically complex and variable constraints for biogeochemical processes. In the  
51 past, obtaining (bio)chemical and microbiological information at the pore level was neither economically  
52 nor logistically a feasible option (Baveye et al., 2014). Also for the sake of applicability, traditionally,  
53 researchers had more tendency to look for Darcy-scale solutions to tackle environmental issues (White  
54 and Brantley, 2003). The Darcy-scale view (experimental, theoretical or a mixture of both) serves well the  
55 purpose of practical applicability (White and Brantley, 2003), but for example in the context of  
56 microbially mediated degradation processes in the vadose zone, it fails to provide insights on the driving  
57 mechanisms, as it overlooks important contributing factors, such as the tortuous porous  
58 structure/pathways open to the transport of (bio)geochemical species, non-uniform distribution of water  
59 and air phases, as well as the nonlinear dependency between changes of the local nutrient and biomass  
60 concentrations and the bulk concentrations of (bio)geochemical species. Evidence at microscopic level  
61 has shown that biological activity and evolution are more locally organized (Kuzakov and  
62 Blagodatskaya, 2015) where Darcy-scale studies lead to loss of crucial information. This has motivated  
63 the development of sophisticated physics-based models implementing all aspects of hydrological,  
64 geochemical and biological processes involved in microbial growth and evolution.

65 Reactive Transport Models (RTMs) are a class of mathematical models that have been applied  
66 extensively to study biogeochemical systems for about four decades (Parkhurst and Appelo,

67 1999;Thullner et al., 2005;Thullner and Regnier, 2019;Meile and Scheibe, 2019). There is a long list of  
68 principal factors and mechanisms governing biogeochemical reactions at the pore scale. Numerically,  
69 these processes can be defined and solved either by fully (global) implicit approaches or by separating  
70 and solving different components once at a time. For the Darcy scale a wide range of reactive transport  
71 models exist which allow for the simulation of biogeochemical processes (Steeffel et al., 2015b). In turn,  
72 at the pore scale, models combining the simulation of flow, transport and reactive (biogeochemical)  
73 processes are scarce, and existing model developments are often driven by specific research questions  
74 and/or are subject to severe simplifications in the description of the pore space (Golparvar et al., 2021).  
75 Integrated models explicitly capturing simultaneously the structural properties of the soil at the pore  
76 scale, the resulting multiphase flow and multispecies reactive transport are hardly available (Tian and  
77 Wang, 2019).

78 Recently, new frontiers of pore-scale RTMs are emerging with the advances in computational power as  
79 well as with huge improvements in imaging techniques. The latter includes e.g., the static and dynamic  
80 scanning of porous structure as well of as fluids' distribution (Schlüter et al., 2019) or the detection of  
81 bacterial distributions in soil using catalyzed reporter deposition with fluorescence in situ hybridization  
82 (CARD-FISH) technique (Schmidt et al., 2015). Direct Numerical Models (DNMs) are becoming the  
83 nexus of next generation of RTMs as they represent the porous structure in a fully explicit manner  
84 (directly obtained from soil samples, digitized and fed into RTMs) in addition to offering a more flexible  
85 coupling of different components of reactive transport models (Baveye et al., 2018;Raeini et al., 2012;Li  
86 et al., 2010;Yan et al., 2016). Another advantage of using DNMs is that they offer a great deal of  
87 flexibility in considering settings and conditions that are experimentally impossible to impose (Tian and  
88 Wang, 2019).

89 In this work, we introduce the pore-scale RTM package P3D-BRNS explicitly involving the structure and  
90 topology of the pore space, the co-existence/co-flow of both the aqueous and the gaseous phase, the  
91 advective-diffusive transport of species in each phase, and an arbitrary set of reactive processes controlled  
92 by kinetic rate laws or thermodynamic constraints. The fluid flow field is updated via solving the Navier-  
93 Stokes (NS) equations (Patankar and Spalding, 1972). The Volume-Of-Fluid (VOF) approach is adopted  
94 to account for different phase distribution (Hirt and Nichols, 1981). The transport of chemical species is  
95 considered via solving the Advection-Diffusion-Reaction Equation (ADRE), where the concentration  
96 jump for soluble/volatile compounds across the fluid/fluid interface is modelled via the Continuous  
97 Species Transfer (CST) method (Haroun et al., 2010). Reactive processes are defined and simulated  
98 externally via coupling the flow and transport model to the BRNS (Biogeochemical Reactions Network  
99 Solver) package (Regnier et al., 2002;Aguilera et al., 2005). The model structure is introduced and the

100 model performance is shown and compared with analytical counterparts. The model capabilities are  
 101 depicted for a fully three-dimensional case.

## 102 **2 Mathematical Formulation**

103 The entire numerical domain ( $\Omega$ ) can be decomposed to two main sub-regions: solid space ( $\Omega_S$ ) and void  
 104 space ( $\Omega_\vartheta$ ). The void space is further divided into aqueous phase ( $\Omega_{\vartheta,aq}$ ) and gaseous phase ( $\Omega_{\vartheta,gs}$ )  
 105 which are partitioned by the fluid-fluid interface ( $\Omega_I$ ). The overall domain is bounded externally between  
 106 inlet ( $\Omega_{in}$ ) and outlet ( $\Omega_{out}$ ) boundaries, which allow for inflow/outflow of different phases and chemical  
 107 species, as well as no-flux boundaries resembling physical walls, where nothing is allowed to leave or  
 108 enter the domain ( $\Omega_{wall}$ ). The domain is limited internally by no-flow boundaries where solid space and  
 109 void space intersect (i.e. solid surface,  $\Omega_\vartheta \cap \Omega_S = \Omega_{wall}$ ).

### 110 2.1 Fluid Flow: Governing Equations

111 Evolution of a single/multi-phase, isothermal, incompressible, immiscible fluid(s) can be expressed by  
 112 basic conservation principles. These can be formulated into a single-field formalism (Hirt and Nichols,  
 113 1981):

$$114 \quad \nabla \cdot \mathbf{u} = 0 \quad \text{in } \Omega_\vartheta \quad (1)$$

$$115 \quad \rho \left( \frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} \right) = -\nabla P + \nabla \cdot \boldsymbol{\tau} + \rho \mathbf{g} + \mathbf{F}_\sigma \quad \text{in } \Omega_\vartheta \quad (2)$$

114 where  $\mathbf{u}$  is the vector of velocity field,  $\rho$  is the fluid density,  $\mathbf{P}$  is the pressure,  $\mathbf{g}$  is the gravitational  
 115 vector, and  $\boldsymbol{\tau}$  is the stress tensor which can be defined as  $\boldsymbol{\tau} = 2\mu\mathbf{S} = 2\mu(0.5[(\nabla\mathbf{u}) + (\nabla\mathbf{u})^T])$  with  $\mu$  as  
 116 the fluid viscosity.  $\mathbf{F}_\sigma$  denotes the interfacial tension force, which is nonzero only when two or more  
 117 phases (excluding solid) are available. It is safe in using the incompressible form of the Navier-Stokes  
 118 equation for low Mach and Reynolds numbers.

119 In case of simultaneous flow of two different phases (Figure 1: Illustration of a porous medium at the pore  
 120 scale with one fluid invading the other (on the left). Mathematical representation of the phase saturation  
 121 in the computational cells around the interface (on the right). The dashed line shows the actual location  
 122 of the interface while values in each cells show the amount of water saturation relevant to topology of  
 123 the dashed line. Black dots represent volatile compounds able to cross the fluid-fluid interface; green dots  
 124 represent non-volatile compounds restricted to the transport in the aqueous phase.), their locations and  
 125 distribution are represented via introducing an indicator function,  $\alpha$ , taking values within the range  $[0, 1]$ .  
 126 The first continuous fluid is marked as  $\alpha = 1$ , the second fluid is denoted as  $\beta = 1 - \alpha$  and for the transition

127 from one fluid to the other (i.e. the interface,  $\Omega_I$ ),  $\alpha$  varies between 0 and 1. Fluid density and viscosity in  
 128 each grid cell is then calculated from a linear interpolation of this indicator function:

$$\rho = \alpha\rho_1 + (1 - \alpha)\rho_2 \quad \text{in } \Omega_g \quad (3)$$

$$\mu = \alpha\mu_1 + (1 - \alpha)\mu_2 \quad \text{in } \Omega_g \quad (4)$$

129 A mass conservative boundary condition at the fluid-fluid interface is written as:

$$\llbracket \rho_i(\mathbf{u}_i - \mathbf{w}) \cdot \mathbf{n}_{\Omega_I} \rrbracket = 0 \quad \text{in } \Omega_I \quad (5)$$

130

**Figure 1:** Illustration of a porous medium at the pore scale with one fluid invading the other (on the left). Mathematical representation of the phase saturation in the computational cells around the interface (on the right). The dashed line shows the actual location of the interface while values in each cells show the amount of water saturation relevant to topology of the dashed line. Black dots represent volatile compounds able to cross the fluid-fluid interface; green dots represent non-volatile compounds restricted to the transport in the aqueous phase.

131 with  $\rho_i$  as the density of  $i^{\text{th}}$  fluid,  $\mathbf{u}_i$  as the velocity of  $i^{\text{th}}$  fluid,  $\mathbf{w}$  as the velocity of the interface,  $\mathbf{n}_{\Omega_I}$  as  
 132 the normal vector to the interface ( $\Omega_I$ ) pointing from the invading phase to the displaced one and the  
 133 brackets showing the jump condition at the interface. Individual velocities,  $\mathbf{u}_i$ , and the interface velocity  
 134  $\mathbf{w}$ , are not directly calculated but furthermore averaged to derive the global mass conservation equation  
 135 that is used for numerical discretization (for full derivation, consult with Graveleau et al., 2017).

136 In the context of the Finite Volume Method (FVM), discretization of the physical domain produces a  
 137 finite subset of discrete volumes (taking the shape of a polyhedral). The key implication of the Volume of  
 138 Fluid method is to define and solve for global variables, rather than having one equation for each variable  
 139 in each phase. Hence, the idea is to transform the integro-differential equations into their global versions

140 by averaging them over each cell volume (Whitaker, 2013). For multiphase systems, after a few steps of  
 141 linearization and approximation (see Hirt and Nichols, 1981 for a detailed derivation), the Volume of  
 142 Fluid formulation of the momentum equation (2) is obtained as:

$$\rho \left( \frac{\partial \bar{\mathbf{u}}}{\partial t} + \bar{\mathbf{u}} \cdot \nabla \bar{\mathbf{u}} \right) = -\nabla P + \nabla \cdot \mu (\nabla \bar{\mathbf{u}} + (\nabla \bar{\mathbf{u}})^t) + \rho g + F_\sigma \quad \text{in } \Omega_g \quad (6)$$

143 with having  $\bar{\mathbf{u}}$  as the global averaged velocity vector. For the sake of simplicity, we drop the ‘‘average’’  
 144 notation from the global velocity vector (i.e. will refer to  $\bar{\mathbf{u}}$  as  $\mathbf{u}$ ), for the rest of this paper. The pressure  
 145 gradients (and Reynolds numbers) considered in our simulations are in the range that render changes in  
 146 the gas compressibility negligible.

147 Since we are dealing with only two fluids, index  $i$  in  $\mathbf{u}_i$  takes only two values;  $\alpha$  and  $\beta$  - one for each  
 148 phase. A global, mass conservative, advection equation is used to describe the evolution of the indicator  
 149 function:

$$\frac{\partial \alpha}{\partial t} + \nabla \cdot (\alpha \mathbf{u}) + \nabla \cdot (\alpha(1 - \alpha) \mathbf{u}_c) = 0 \quad \text{in } \Omega_g \quad (7)$$

150 where  $\alpha$  indicates the volume fraction of phase 1,  $\mathbf{u}_c = \mathbf{u}_\alpha - \mathbf{u}_\beta$  is the vector of the compressive velocity  
 151 with  $\mathbf{u}_{\alpha,\beta}$  as velocity vector of phase  $\alpha$  and  $\beta$  right on the edge of the interface (detailed explanation on  
 152 deriving eq. (7) can be found in the Supplementary Information **Error! Reference source not found.**). It  
 153 is derived from mass conservation equation written for phase  $\alpha$ , which computationally helps with  
 154 maintaining stiffness/sharpness of the interface. Sharpening interface means having the interface span  
 155 over a fewer number of computational grids.  $\mathbf{u}_c$  is the vector of compressive velocity on each face of all  
 156 computational grids. Since we don’t solve for the velocity field of each phase individually, a direct  
 157 calculation of  $\mathbf{u}_c$  is not possible. However, we can rather take an indirect approach for computing  $\mathbf{u}_c$  as  
 158 follows:

$$\mathbf{u}_c = \min(c_\alpha |\mathbf{u}|, \max(|\mathbf{u}|)) \frac{\nabla \alpha}{|\nabla \alpha|} \quad \text{in } \Omega_I \quad (8)$$

159 In equation (8),  $c_\alpha$  is a compression coefficient providing some level of control over how wide the  
 160 interface spans. The max function operates on the magnitude of unit velocity vector calculated on all the  
 161 faces of a computational grid. To counteract the numerical diffusion and avoid the spread of interface  
 162 over several computational grids, values of  $c_\alpha > 1$  provide an enhanced/sharper interface whereas a value  
 163 of  $c_\alpha = 0$  gives no compression of the interface (Graveleau et al., 2017). In simulation scenarios  
 164 introduced in this paper,  $c_\alpha$  has been assigned the value of 1, unless stated otherwise.

165 To calculate the interfacial tension force,  $F_\sigma$ , (Brackbill et al., 1992) have introduced a Continuum  
 166 Surface Force (CSF) which requires computing the curvature of the interface:

$$\kappa = \nabla \cdot n_{\Omega_I} \quad \text{in } \Omega_I \quad (9)$$

167 with having  $\kappa$  as mean interface curvature in each computational grid, and  $n_{\Omega_I}$  as the interface unit  
 168 normal vector defined as:

$$n_{\Omega_I} = \frac{\nabla \alpha}{|\nabla \alpha|} \quad \text{in } \Omega_I \quad (10)$$

169 Given the curvature, the interfacial tension force can be approximated as:

$$F_\sigma = \sigma \kappa \nabla \alpha \quad \text{in } \Omega_I \quad (11)$$

170 where  $\sigma$  is the surface tension between two fluids (derivation of this approximation can be found in  
 171 Brackbill et al., 1992).

## 172 2.2 Reactive Transport: Governing Equations

173 Concentrations of mobile species are affected by advection (i.e. transport with the moving fluid),  
 174 molecular diffusion and reactive transformation. Also, in case of having two fluids simultaneously in the  
 175 system, different species can cross the fluid-fluid interface, causing local fluctuations in concentration  
 176 values. In general to account for all the changes in species concentrations, the ADRE for biogeochemical  
 177 reactive components can be written as:

$$\frac{\partial C_i}{\partial t} + \nabla \cdot (C_i \mathbf{u}) = -\nabla \cdot (J_{d,i} + J_{m,i}) + R_i \quad \text{in } \Omega_g \quad (12)$$

178 where  $J_{d,i}$  is the molecular diffusive flux of component  $i$ ,  $J_{m,i}$  is the mass flux of component  $i$  due to mass  
 179 transfer across the fluid-fluid interface and  $R_i$  accounts for the changes in concentration of component  $i$   
 180 due to reactions. Molecular diffusion follows Fick's law:

$$J_{d,i} = -D_i \nabla (C_i) \quad \text{in } \Omega_g \quad (13)$$

181 where  $D_i$  is the diffusion coefficient of species  $i$ . At the interface, the assumption of thermodynamic  
 182 equilibrium implies equality of chemical potentials. Given the condition that liquid concentration of  
 183 component  $i$  is proportional to the partial pressure of the species in the secondary phase (e.g. gas, oil or  
 184 minerals), a partitioning relationship such as Raoult or Henry's law (Danckwerts and Lannus, 1970) can  
 185 be established to relate species concentrations on both sides of the interface:

$$C_{i,\beta} = H_i C_{i,\alpha} \quad \text{in } \Omega_I \quad (14)$$

186 with  $C_{i,\alpha}$  as concentration of species  $i$  in phase  $\alpha$ ,  $H_i$  as Henry's constant of species  $i$  and  $C_{i,\beta}$  as  
 187 concentration of species  $i$  in phase  $\beta$ . Depending on if a given compound's concentration in the aqueous

188 phase or the gaseous phase is multiplied by the Henry's coefficient, (14), the definition of Henry's  
 189 constant switches between the solubility or volatility for that compound (i.e.  $H_i^{solubility} = 1/H_i^{volatility}$ )  
 190 (Sander, 2015). Unless otherwise stated, the volatility concept of Henry's law is adopted in order to  
 191 define the concentration relationship of a given compound across the fluid-fluid interface (14). The  
 192 concentration field around the fluid-fluid interface (where  $\nabla\alpha \neq 0$ ) at equilibrium, for any values of  $H \neq$   
 193 1, is discontinuous which imposes the additional flux,  $J_{m,i}$ , to satisfy the concentration jump across the  
 194 interface. Hence the mass transfer flux,  $J_{m,i}$ , can be derived within the VOF framework (i.e. CST) as  
 195 follows (Haroun et al., 2010):

$$J_{m,i} = -D_i \frac{1 - H_i}{\alpha + (1 - \alpha)H_i} C_i \nabla\alpha \quad \text{in } \Omega_\vartheta \quad (15)$$

196 It is noteworthy that few assumptions and volume averaging methods are implemented to derive equation  
 197 (15), which readers are encouraged to check the references for more details. The diffusion coefficient is  
 198 calculated from harmonic interpolation:

$$D_i = \frac{1}{\frac{\alpha}{D_{i,A}} + \frac{1 - \alpha}{D_{i,B}}} \quad \text{in } \Omega_\vartheta \quad (16)$$

199 where  $D_{i,\alpha-\beta}$  is the diffusion coefficient of species  $i$  in phase  $\alpha$  and  $\beta$  respectively.

200 Simulated reactions include kinetically as well as thermodynamically constrained reactions. For a  
 201 kinetically constrained reaction  $j$  the reaction rate  $r_j = f(C_1, \dots, C_n)$  is needed while for a  
 202 thermodynamically constrained reaction  $k$  the equilibrium conditions defined by a law of mass action  
 203  $M_k = f(C_1, \dots, C_n)$  is needed with  $M_k$  as equilibrium constant. These equations can be of arbitrary form and  
 204 the resulting reaction network defines the term  $R_i$  in equation (12) (Aguilera et al., 2005; Regnier et al.,  
 205 2002). For immobile species concentration changes are only due to reactive processes.

### 206 2.3 Boundary Conditions (BCs)

207 There are various types of boundary conditions, corresponding the real physical conditions, most of which  
 208 can be derived from two basic types:

- 209 • Dirichlet boundary (fixed value) which relates the value of a variable at a given geometric  
 210 location to a constant value; e.g.  $C_i = 1M$  in  $\Omega_{in}$  meaning a constant 1 molar concentration of  
 211 component  $i$  at the boundary,
- 212 • von Neumann boundary (fixed gradient) which provides the value of a variable's gradient at the  
 213 face of the boundary cell; e.g.  $\partial_n p = 0$  in  $\Omega_{wall}$  giving a zero pressure gradient on the wall.

214 In general, our model can apply any of these basic boundary conditions to any scalar or vector variables  
 215 such as pressure, velocity/flux, concentration of volume of fluid fields, but one needs to assure that the  
 216 imposed BC(s) are both compatible and they reflect the correct physical boundary conditions. For  
 217 example, for velocity/flux-pressure coupling, a Dirichlet (i.e. constant) boundary for flux at the inlet can  
 218 be coupled with either 1) fixed discharge velocity/flux and zero gradient (i.e. von Neumann) pressure at  
 219 both inlet and outlet, or 2) a constant pressure head at the inlet and atmospheric pressure at the outlet with  
 220 zero gradient velocity/flux at both ends, or 3) fixed values of pressure and velocity/flux at one end and  
 221 zero gradient at the other end. In the beginning of section 2, typical composition and configuration of an  
 222 arbitrary computational domain is described. Inlet, outlet and impermeable boundaries are amongst the  
 223 most common types that one might face. Inlet BC means for the direction of fluid flux to be pointing  
 224 inwards (i.e. into the domain) while for the outlet, the direction of the flux should be outwards. Also for  
 225 the impermeable wall, zero-orthogonal fluxes need to be satisfied. Either Dirichlet, von Neumann or a  
 226 mixture of both can be used at a particular boundary. Mathematical translation and implementation of  
 227 these boundaries are provided in the next section. Time-dependent BCs (e.g. cyclic or seasonal  
 228 water/species influx) are also readily available to be applied, but never been used in this work. Unless  
 229 otherwise stated, boundary conditions that have been imposed on each section of the computational  
 230 domain are described as follows:

231 **At impermeable boundaries ( $\Omega_{wall}$ ):** Physical wall implies no flux perpendicular to the normal vector  
 232 to its surface. No slip BC is an appropriate BC for the velocity field on the wall. In general, they all can  
 233 be written as:

$$\partial_n \mathbf{C}_i = 0, \quad \mathbf{u}_{x,y,z} = 0, \quad \partial_n \mathbf{p} = 0, \quad \partial_n \alpha = 0 \quad \text{in } \Omega_{wall} \quad (17)$$

234 For the velocity field, on the wall, a slip boundary condition is also available to be applied.

235 **At inlet/outlet boundaries ( $\Omega_{in}, \Omega_{out}$ ):** Concentration of reactants, products and inert tracers are set to  
 236 fixed values at inlet, while they are allowed to leave the domain at outlet with zero gradient boundary  
 237 condition. Constant flowrate with zero pressure gradient is applied at inlet and an atmospheric pressure  
 238 (fixed value) with zero velocity gradient is set at outlet. Also in case of two-phase flow, the invading  
 239 phase is set to enter from inlet at fixed value and exits from outlet with zero gradient BC. Mathematically,  
 240 they can be expressed as:

$$C_i \geq 0, \quad \mathbf{u} = const., \quad \partial_n \mathbf{p} = 0, \quad \alpha = const. \quad \text{in } \Omega_{in} \quad (18)$$

241 together with:

$$\partial_n \mathbf{C}_i = 0, \quad \partial_n \mathbf{u}_n = 0, \quad \mathbf{p} = 0, \quad \partial_n \alpha = 0 \quad \text{in } \Omega_{out} \quad (19)$$

242 with  $u_n$  as the normal velocity vector. While we have mostly applied equations (18) and (19) for  
 243 designing an inlet/outlet duo, other formats, such as defining a pressure head (plus zero gradient velocity)  
 244 on the inlet in combination with either constant exit pressure or constant discharge rate, are readily  
 245 available to implement as well.

246 **At the fluid-fluid-solid contact line** ( $\Omega_{l3}$ ): At the fluid-fluid-solid contact line, in case of no interactions  
 247 or no reaction of any chemical species with the solid, the boundary condition at the triple point is derived  
 248 to be:

$$\nabla C_i \cdot \mathbf{n}_s = \frac{H_i - 1}{\alpha H_i + (1 - \alpha)} C_i \nabla \alpha \cdot \mathbf{n}_s \quad \text{in } \Omega_l \quad (20)$$

249 with  $\mathbf{n}_s$  as the normal vector to the solid surface (Graveleau et al., 2017). Also, the concept of contact  
 250 angle is applied by making the following modification to the interface normal vector:

$$\mathbf{n}_{\Omega_{l3}} = \cos\theta \mathbf{n}_s + \sin\theta \mathbf{t}_s \quad \text{in } \Omega_{l3} \quad (21)$$

251 where  $\mathbf{n}_s$  is the normal vector and  $\mathbf{t}_s$  is the tangential vector to the solid surface (Brackbill et al., 1992).  
 252 At the triple point, i.e. fluid-fluid-solid interface,  $\mathbf{n}_{\Omega_{l3}}$  is used for normal vector to the interface. CSF,  
 253 though, has been reportedly generating non-physical spurious currents (Scardovelli and Zaleski, 1999).  
 254 For this, many have tried to eliminate/mitigate this issue by explicit representation of the interface either  
 255 via using the Geometric VOF method (Popinet, 2009) or coupled Level-set (LS) VOF functions  
 256 (Albadawi et al., 2013). Geometric VOF is quite suitable for structured grids, but for porous structures  
 257 with highly unstructured grids, the calculations can become quite complicated. Alternatively, Raeini et al.  
 258 (2012) suggested filtering the capillary forces parallel to the interface, which can significantly reduce the  
 259 non-physical velocities. In short, the modifications they proposed and which are used here are: 1)  
 260 smoothing the indicator function to have a better measure of the interface curvature, 2) sharpening the  
 261 indicator function for computation of the interfacial tension force, 3) filtering the capillary pressure force  
 262 parallel to the interface, and 4) filtering capillary fluxes based on the capillary pressure gradient (for full  
 263 description of each point, please consult with Raeini et al., 2012). The correction introduced for filtering  
 264 capillary forces helps with eliminating some of the parasitic velocities parallel to the interface.  
 265 To sum up what has been presented so far, we integrated a) the original *interFoam* solver from the  
 266 OpenFOAM library that only solves for the advection-diffusion transport of two phase flow, with b) the  
 267 improved-interface-resolver library from Raeini et al. (2012), and c) added a scalar transport solver on top  
 268 of them. Finally, the full-scale advection-diffusion-reaction model of the biogeochemical species is  
 269 attained by coupling this to an external reaction-network solver, which is explained in the section 2.4  
 270 below.

271 2.4 Numerical Formulation

272 The mass conservation (eq. (1), momentum (NS - eq. (2) and indicator function (eq. (7) equations are all  
 273 implemented within the open source computational fluid dynamics (CFD) package, OpenFOAM  
 274 (Greenshields, 2015). OpenFOAM utilizes the finite volume methodology (FVM), a common choice for  
 275 CFD problems as FVM works only with conservative flux evaluation at each computational cell's  
 276 boundaries, making it robust in handling nonlinear transport problems. Also all the differential equations  
 277 mentioned before are first written in their integral form over each cell volume and then converted to the  
 278 surface summations using Green's Theorem.

279 The original two-phase (VOF) flow solver, i.e. *interFoam*, is modified to construct our biogeochemical  
 280 reactive transport package. The momentum equation (2) is linearized in a semi-discrete form as:

$$A_d \mathbf{u} = \mathbf{H}(\mathbf{u}) - \nabla P + \mathbf{F}, \quad (22)$$

281 where  $A_d$  holds the diagonal elements of the coefficient matrix,  $\mathbf{H}(\mathbf{u})$  contains off-diagonal elements of  
 282 the coefficient matrix including all source terms, and  $\mathbf{F}$  entails any body forces (interfacial tension force  
 283 only in this case). Temporal discretization is handled via the first order Euler method while spatial  
 284 discretization is managed via second order finite volume schemes. Convection terms of the momentum  
 285 equation and indicator function (7) are computed using a bounded self-filtered central differencing  
 286 (SFCD) scheme (based on Gauss's theorem). Rearranging equation (22) for velocity and imposing the  
 287 continuity equation (1), the following linear pressure equation can be obtained:

$$\sum_f \frac{S_f}{\langle A_d \rangle_f} \nabla_f^\perp P = \sum_f \left( \left\langle \frac{\mathbf{H}(\mathbf{u})}{A_d} \right\rangle_f \cdot |S_f| + \frac{\varphi_{F,f}}{\langle A_d \rangle_f} \right). \quad (23)$$

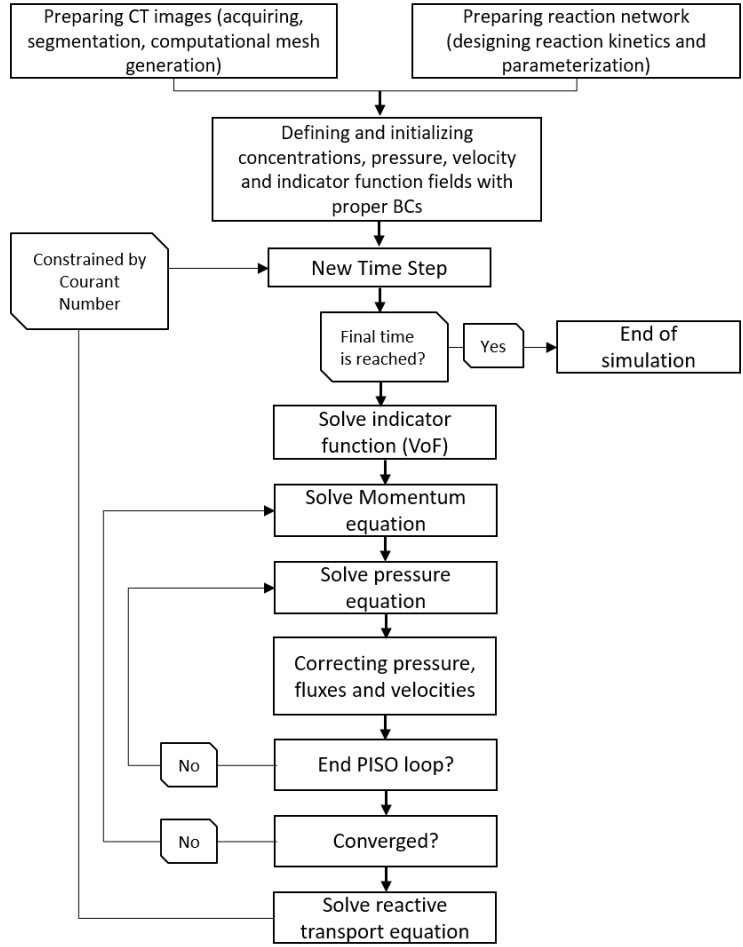

288  $S_f$  in equation (23) denotes the outward area-vector of face  $f$ , the notation  $\nabla_f^\perp$  shows face normal  
 289 gradients calculated right on the face centers,  $\langle \rangle_f$  shows the interpolated values of a face-centered  
 290 parameter from its cell-centered counterpart, and  $\varphi_{F,f}$  is the interfacial force flux term.

291 The velocity-pressure coupling of equations (1) and (2) are solved using Pressure Implicit with Splitting  
 292 of Operators (PISO) (Issa, 1986). PISO embodies a predictor-corrector strategy to simultaneously update  
 293 pressure and velocity within each time step. The resultant system of equations are solved on the cell faces  
 294 and then interpolated back to calculate velocities and pressure at the cell centers. The coupling of  
 295 indicator function (eq. (7)) and momentum equation is explicitly defined and solved right after the PISO  
 296 step is finished. Within the same time step, transport and reaction of different species are then solved  
 297 sequentially – using a Sequential Non-Iterative Algorithm (Steeffel et al., 2015a; Steeffel and MacQuarrie,  
 298 1996). Time step size is controlled by introducing a Courant number. Time is discretized using either

299 Euler or Crank-Nicholson methods and spatial discretization is performed using the Van Leer second  
300 order Total Variation Diminishing scheme (TVD) (van Leer, 1979).

301 The reaction network is built separately and externally solved within the BRNS package - which employs  
302 first order Taylor series expansion terms and uses Newton-Raphson method to iteratively solve the  
303 system of linear equations (Regnier et al., 2002). BRNS utilizes MAPLE programming language to  
304 construct the Jacobian matrix (which contains the partial derivatives of unknown parameters, i.e.  
305 concentrations) and other problem-related data such as rate parameters and translating them to a  
306 FORTRAN package. The FORTRAN code is then compiled to generate shared object (\*.so file) that can  
307 be dynamically called later from the transport solver (Centler et al., 2010). The significance of having  
308 dynamically shared object file is more apparent when running computationally-demanding  
309 cases/scenarios while decomposing and running the application in parallel. BRNS is invoked once the  
310 new concentrations are computed from the transport solver. The updated concentrations from the BRNS  
311 library (i.e. updating concentrations from redox reactions) are then fed back into the transport solver  
312 before moving to the next time step. This process repeats until the final time is reached. This coupling  
313 scheme has been successfully used for other RTM approaches before (Centler et al., 2010;Gharasoo et al.,  
314 2012;Nick et al., 2013). As the reactions are localized, the reaction solver is modular, and OpenFOAM  
315 inherently provides parallelized simulations (via domain decomposition), the P3D-BRNS can easily be  
316 used to model larger systems. To achieve higher performance, it is recommended to utilize physical cores  
317 than using hyper-threading. The parallelization of our model strengthens its scalability in the sense of the  
318 size (pore scale or Darcy scale) of the simulated system. However, in terms of upscaling (e.g., from the  
319 pore scale to the Darcy scale) an intermediate step would be required depending on the complexity of the  
320 processes that are involved and on the size of the domain.

321 Prior to run simulations, the physical settings of the domain are required to be specified; i.e. the physical  
322 geometry of the pore space with proper boundaries and the meshing scheme should be designed.  
323 OpenFOAM provides a basic utility for defining boundaries as well as mesh generation which are  
324 translatable by the OpenFOAM engine. Any other meshing software/freeware can be freely used as long  
325 as an OpenFOAM-compatible format for the meshed file can be created. The overall workflow required  
326 to build and run a case/scenario is summarized in Figure 2.

327

328

**Figure 2:** Full solution procedure to simulate a reactive transport process at its fullest complexity.

329 **3 Model Performance**

330 The presented reactive transport model is designed 1) to capture real world pore structures in up to three  
 331 dimensions, 2) to explicitly simulate the transient distribution of a gas and a liquid phase within the entire  
 332 pore space and 3) to simulate a full set of advection-diffusion-reaction mechanisms. Capturing the correct  
 333 curvature of the interface depends heavily on the grid resolution. For a fixed velocity magnitude, higher  
 334 grid resolution, enforces shorter time-step size (from Courant number) for the numerical simulations to  
 335 converge. Also to validate different features of the model various simplified scenarios were used which  
 336 allow the use of analytical expressions as reference for the numerical results. We here show three  
 337 representative test scenarios addressing different features of the model (two-phase flow, mass transfer  
 338 across the fluid-fluid interface and reactive transport) individually. Subsequently, the model capabilities  
 339 are depicted in a final biodegradation scenario making use of the various model features simultaneously.

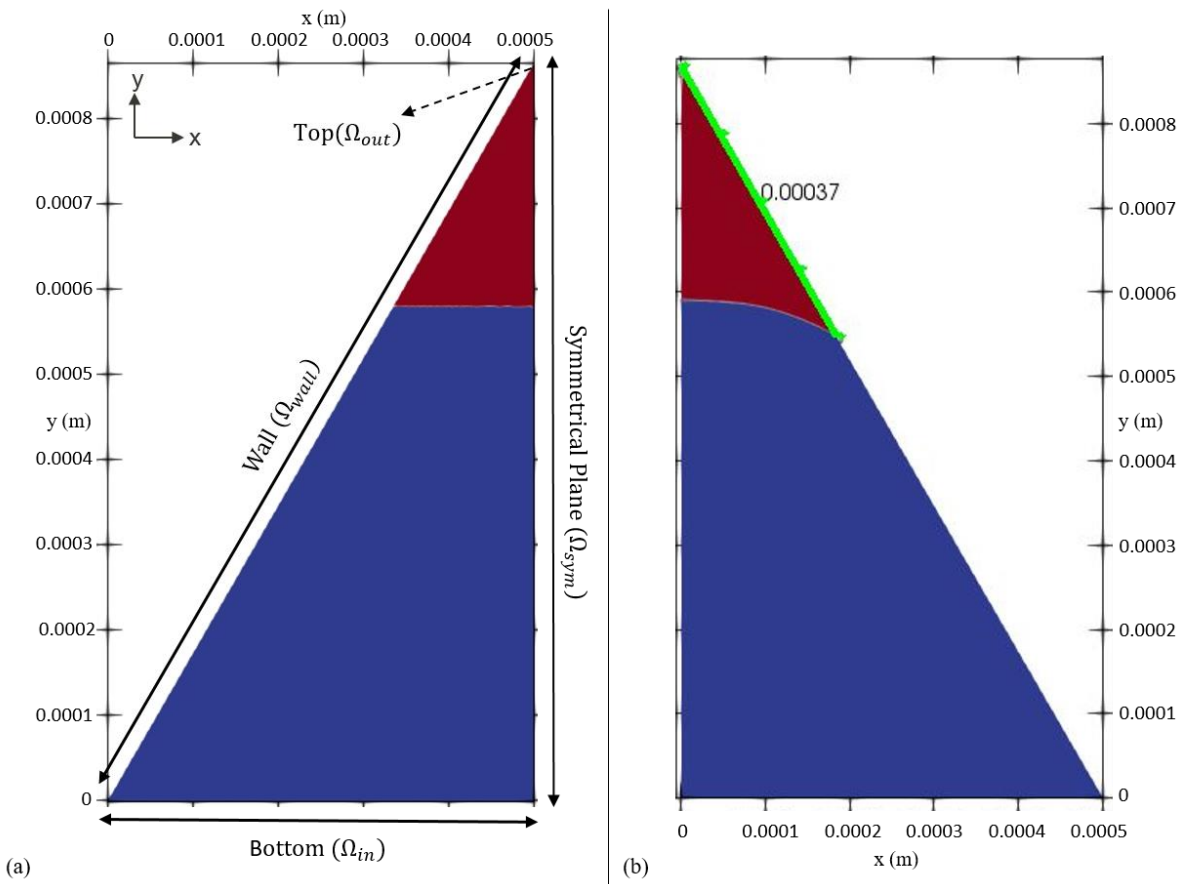

### 340 3.1 Fluid Configurations

341 In order to test our model's performance in simulating two-phase flow, we have zoomed into a two-  
 342 dimensional porous structure and isolated only one single corner taking the shape of an equilateral  
 343 triangle. A triangulated mesh is adopted that naturally conforms to the overall shape of the domain.  
 344 Initially, two immiscible fluids (one wetting, and one non-wetting, e.g. water and air) are placed in such a  
 345 way that their interface forms a straight line (Figure 3, a). The side length of the triangle is 1 mm with a  
 346 mesh size of 1  $\mu\text{m}$ . Under thermodynamic equilibrium conditions, the force exerted by the pressure  
 347 difference between two phases is countered by the interfacial tension force. This, along with the contact  
 348 angle of the non-wetting phase at the wall surface in presence of the wetting phase (e.g. water),  
 349 determines the topology of the fluid-fluid interface. For a given corner half-angle, the distance that  
 350 wetting phase spreads over the solid surface from the corner vertices (the highlighted section with green  
 351 color on Figure 3, b),  $b$ , can be calculated as:

$$b = r \frac{\cos(\theta + \beta)}{\sin(\beta)} \quad (24)$$

352 with  $r$  as the radius of the interface's curvature,  $\theta$  as the contact angle and  $\beta$  as the corner half-angle  
 353 (Blunt, 2017). In order to reach thermodynamic equilibrium, we performed transient, two-phase flow  
 354 simulations to compute velocity, pressure and indicator function fields until the triple contact line ( $\Omega_{\Gamma^3}$ ) is  
 355 static. For this, we first divided the equilateral triangle in half, as the problem is symmetrical along the  
 356 height of the triangle. The symmetrical plane implies that there is no gradient (of any scalar or vector  
 357 field) perpendicular to its surface while the tangential components (of all fields) remain the same. To find  
 358 the fluid configuration at equilibrium, we simulated the two-phase flow scenario in two steps. First, we  
 359 applied a closed boundary condition on the bottom domain by setting  $\mathbf{u} = 0$  together with  $\partial_n p = 0$ . Also  
 360 a closed boundary is imposed on the topmost part of the domain which follows the same BC as the  
 361 bottom. This way, the interface is able to reconfigure and reorient itself in order to recreate the imposed  
 362 contact angle with the wall, and at the same time, pressure is allowed to build up in both phases to support  
 363 the shape of the interface. Then, in order to obtain an equilibrium curvature for the interface, bottom and  
 364 top domains are opened. This is achieved by setting the 1) pressure in  $\Omega_{in}$  to the average pressure within  
 365 the non-wetting phase, 2) pressure in  $\Omega_{out}$  to the average pressure within wetting phase together with 3)  
 366  $\partial_n \mathbf{u} = 0$  on both  $\Omega_{in}$  and  $\Omega_{out}$ . At this stage, we applied a special BC for the indicator function to allow  
 367 the fluids to enter or leave the domain at both ends, so that the interface can freely transition to its static  
 368 shape. At the inlet ( $\Omega_{in}$ ), the BC for  $\alpha$  is set to switch between  $\partial_n \alpha = 0$ , if the fluid flux is pointing  
 369 outwards, and  $\alpha = 0$  if the fluid flux is directed into the domain. Also at the outlet ( $\Omega_{out}$ ), the BC for  $\alpha$   
 370 switches between  $\alpha = 1$ , if the fluid flux is inwards, and  $\partial_n \alpha = 0$ , if the fluid flux is outwards. This

371 ensured that appropriate fluids entered the domain from either inlet or outlet boundaries. The radius of  
 372 curvature can be also evaluated from the Young-Laplace equation ( $P_c = \frac{\sigma}{r}$ ). With a pressure difference of  
 373 255.33 ( $\text{kg m}^{-1} \text{s}^{-2}$ ) obtained from the last step and a surface tension of 0.07 ( $\text{kg s}^{-2}$ ), the radius of  
 374 curvature is calculated to be  $2.17\text{e-}4$  m. In a different approach, once the interface attains stationarity, we  
 375 calculated  $r$  for equation (24) as the reciprocal of the interface's mean curvature ( $2.77\text{e-}4$  m). For a  
 376 contact angle of  $10^\circ$  and a corner half-angle of  $30^\circ$ , the analytically calculated value for the length,  $b$ , of  
 377 the section in contact with the wetting phase is  $375 \mu\text{m}$ , while the numerical solution yields  $370 \mu\text{m}$ .  
 378 With a relative error of 1.21% this shows a reasonable match between numerical and analytical solutions  
 379 in modelling two-phase flow.

380

381 **Figure 3:** Initial condition (a) versus final arrangement (b) of the two phases in the fluid configurations scenario. The blue color  
 382 indicates the non-wetting and the red color shows the wetting phases respectively. The dashed arrow shows the location of the  
 383 outlet, while the solid-line arrows depict the extent of others boundaries. Once equilibrium is reached (figure b), the curvature of  
 384 the interface corresponds to the force balance between pressure difference across the interface and the surface tension which can  
 385 be used to verify the model's sanity. The distance of the contact point (i.e. the point/line where all three phases – water, air and  
 386 solid – meets) from the corner vertex (highlighted as green), also provides another measure for checking the accuracy of the  
 387 numerical model.

### 388 3.2 Mass Transfer across the Fluid-Fluid Interface

389 Mass transfer of dissolved species between different phases is particularly of importance for various  
390 biogeochemical processes in unsaturated subsurface environments.

391 Model performance in simulating mass flux across the fluid-fluid interface is validated via a numerical  
392 experiment in which two immiscible stationary fluids (an aqueous -  $\alpha$  - and a gaseous -  $\beta$  - phase,  $\mathbf{u} = 0$  in  
393  $\Omega_\vartheta$ ) are horizontally (to remove buoyancy effects) residing on a one dimensional tube of 10 mm length  
394 with mesh size of 100  $\mu\text{m}$ . The general partial differential equation (PDE) of equation (12) takes the form  
395 of a simple diffusive transport as:

$$\frac{\partial C_{tr,i}}{\partial t} - D_{tr,i} \nabla(C_{tr,i}) = 0 \quad i = aq, gs$$

$$BC - 1: \quad C_{tr,aq} \times H = C_{tr,gs} \quad in \Omega_I \quad (25)$$

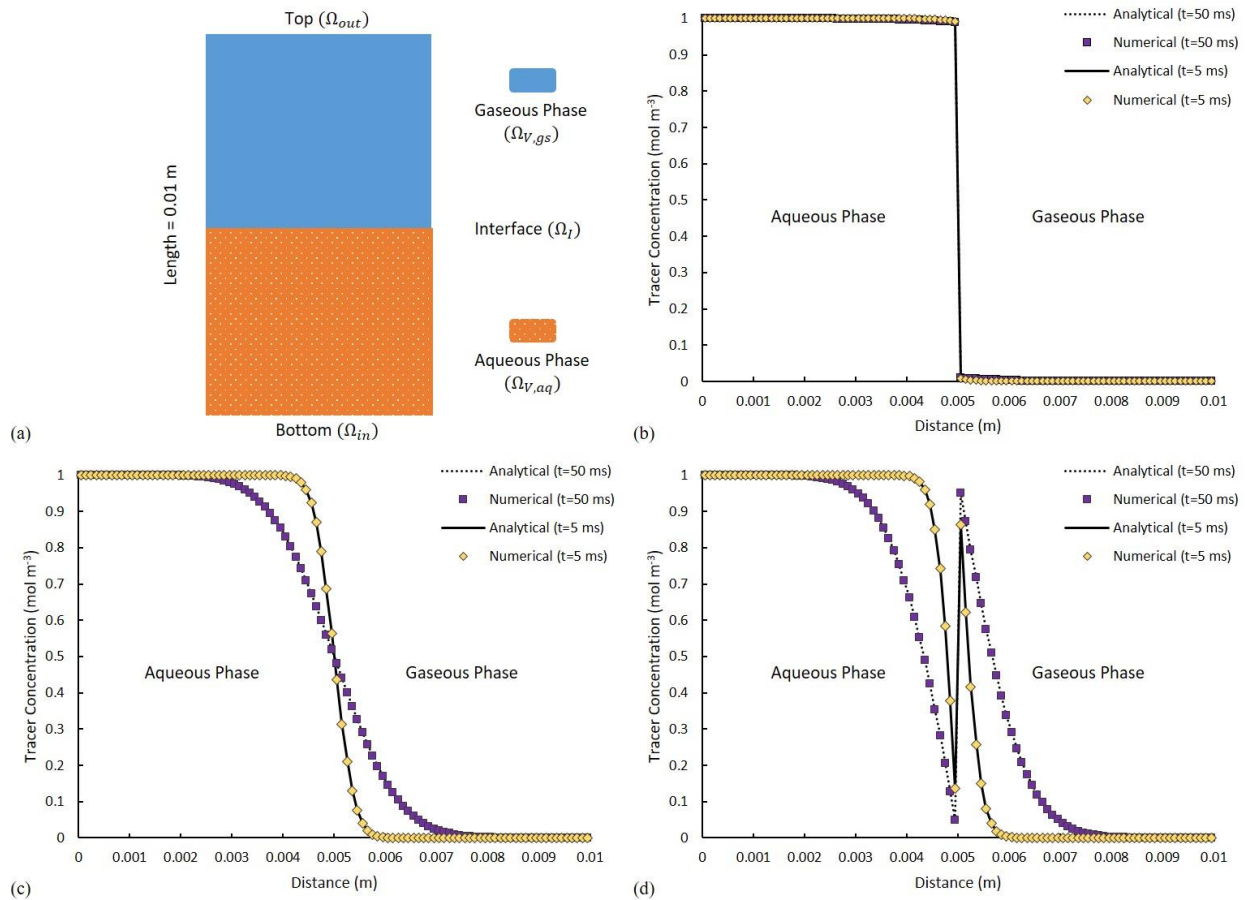

$$BC - 2: \quad D_{tr,aq} \frac{\partial C_{tr,aq}}{\partial x} = D_{tr,gs} \frac{\partial C_{tr,gs}}{\partial x} \quad in \Omega_I$$

396 with  $C_{tr}$  as the concentration of a volatile tracer and  $D_{tr,i}$  as the diffusivity of the tracer in phase  $i$ . Each  
397 phase is set to occupy half of the total volume (Figure 4-a). The system is initialized with a volatile  
398 chemical species of concentration of 1 mol  $\text{m}^{-3}$  in  $\Omega_{\vartheta,aq}$ , and 0 mol  $\text{m}^{-3}$  in  $\Omega_{\vartheta,gs}$ . At the inlet and the outlet  
399 boundary, tracer concentration equals that of the nearest solution such that, in short simulation time, it  
400 yields no concentration gradient into or out of the domain. The tendency of the dissolved chemical  
401 component to cross the fluid-fluid interface is expressed using a constant Henry coefficient. Tracer  
402 diffusivity is set to be  $1\text{e-}5 \text{ m}^2 \text{ s}^{-1}$  in both phases. The analytical solution for equation (25) can be found in  
403 Bird (Bird, 2002).

404 Three scenarios with low, neutral, and high affinity of the volatile compound towards the gaseous phase  
405 are considered with corresponding Henry coefficients of 0.01 (low volatility, similar to naphthalene), 1  
406 (moderate volatility, e.g., vinyl chloride) and 100 respectively (high volatility, e.g. heptane). For a low  
407 value of  $H$  ( $H = 0.01$  – Figure 4-b) little (almost no) tracer is crossing the interface, while at neutral  
408 condition ( $H = 1$  – Figure 4-c), tracer diffusion is invariant to the phase it is occupying. Evidently for  
409 high values of  $H$  ( $H = 100$  – Figure 4-d), significant reduction in the tracer amount within the liquid  
410 phase can be detected, which is accompanied by a notable change in concentration across the interface.  
411 This complies fully with the concentration jump for such highly volatile component between the liquid  
412 and the gas phase. The numerical results are ubiquitously identical to the results of the analytical solution  
413 (Figure 4-b, c, d). The effect of grid size/resolution is also investigated for this scenario. With 10 times  
414 higher grid resolution, the total CPU-elapsed time is increased from  $\sim 650$  seconds to  $\sim 3500$  seconds. The

415 concentration profile remains unchanged, but, the average residuals of the numerical solution of the  
 416 concentration field, calculated at the end of the simulation, is increased from  $3.1 \times 10^{-10}$  to  $6.5 \times 10^{-10}$  (meaning  
 417 increasing resolution does not necessarily helps with numerical convergence).

418

419 **Figure 4:** (a) A schematic of the fluid distributions at initial condition. The solid and dotted lines show the analytical solutions  
 420 with purple and yellow squares depicting the numerical solutions. Comparison of the analytical and numerical solutions of tracer  
 421 distribution at two distinct time points of  $t_1=5\text{ms}$  and  $t_2=50\text{ms}$  for (b)  $H = 0.01$ , (c)  $H = 1$ , and (d)  $H = 100$ .

422

### 423 3.3 Microbial Growth and Reactive Transport

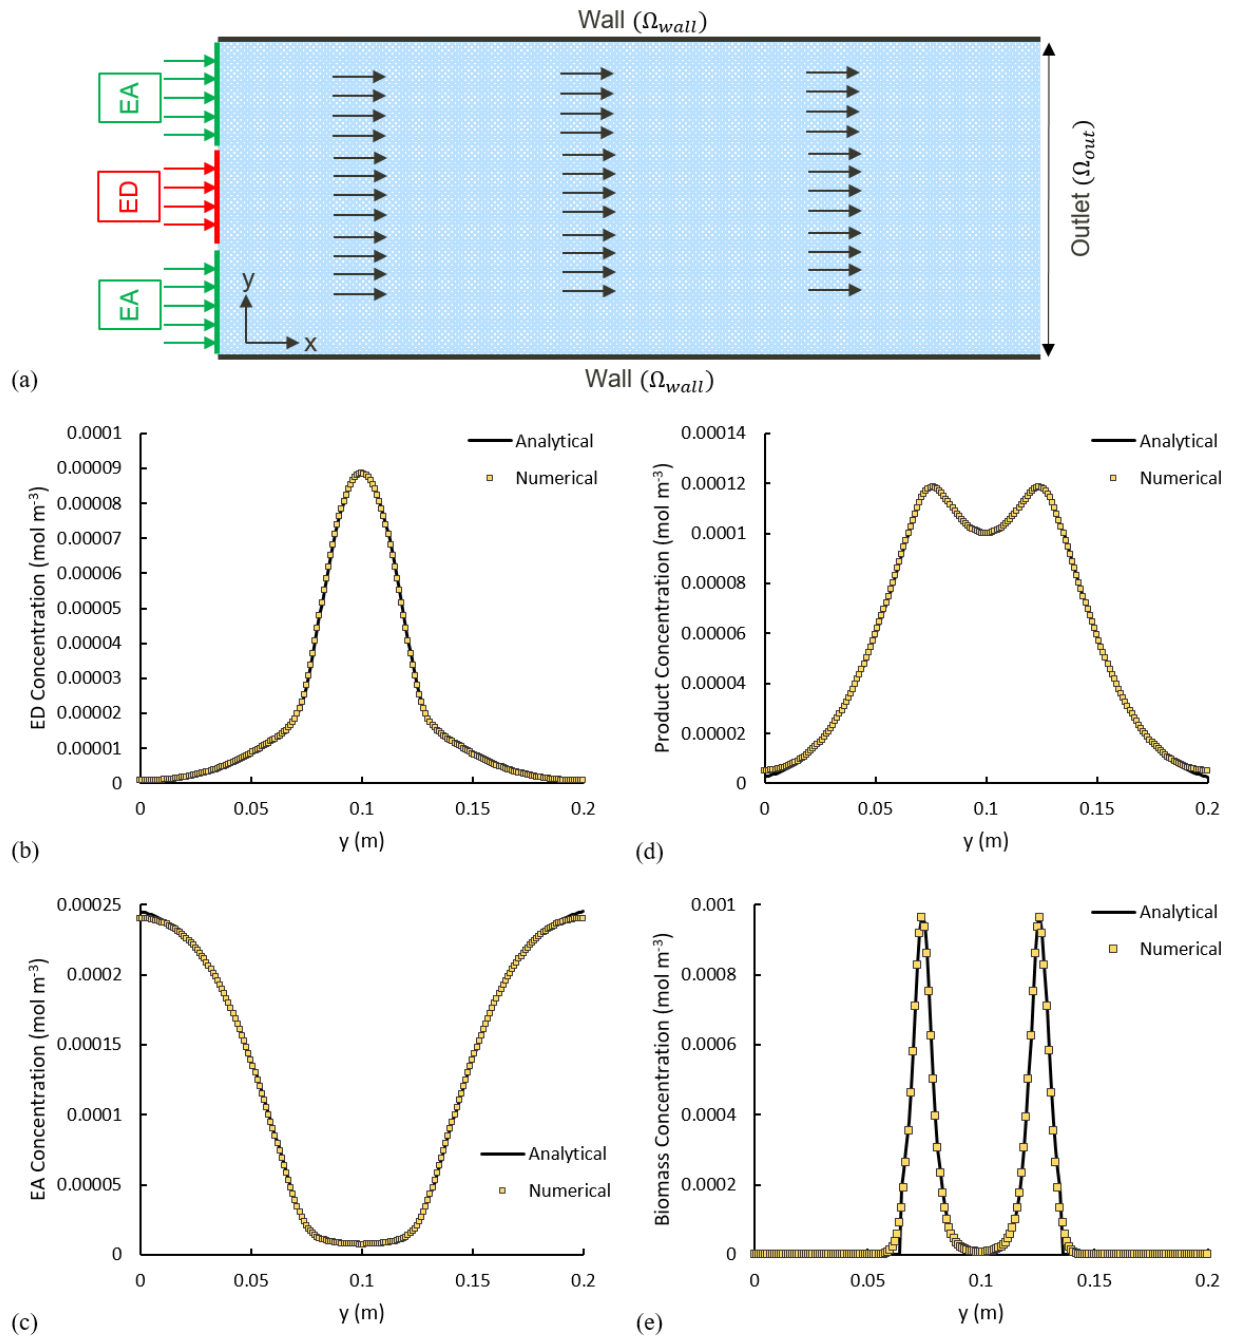

424 Our modelling framework can parameterize any type of reactions, we put the main focus in this  
 425 subsection on microbially driven redox transformations (i.e. a type of reactions commonly encountered in  
 426 soils and other porous media environments) and on the implementation of the corresponding  
 427 mathematical formulation. To validate our model with a scenario in which bacterial biomass is allowed to  
 428 evolve (i.e. to grow and to decay) we adapted a conceptual biodegradation scenario from (Cirpka and  
 429 Valocchi, 2007b) in which a fully-water-saturated, two-dimensional channel is subjected to a constant  
 430 flux of two different components; ED (electron donor – e.g. hydrocarbon) and EA (electron acceptor –

431 e.g. oxygen). The imposed uniform flow field is assumed to be constant over time and has only the x-  
 432 component. The bacteria residing in the channel, facilitate the reaction between ED and EA, which can be  
 433 written in an abstract form as  $f_a ED + f_b EA \xrightarrow{\text{biomass}} f_c Prod$ , where *biomass* is the microbial biomass,  
 434 *Prod* is the product(s) (e.g. metabolites such as carbon dioxide) and  $f_a, f_b$  and  $f_c$  are stoichiometric  
 435 coefficients. Assuming a double-Monod kinetics for expressing microbial growth and the microbially  
 436 driven reaction rates, as well as assuming none of the reactants nor products are involved in secondary  
 437 reactions, the ADRE (eq. (12)) for each chemical species can then be written as:

$$\begin{aligned}
 \frac{\partial C_{ED}}{\partial t} + \mathbf{u} \frac{\partial C_{ED}}{\partial x} - D_t \frac{\partial^2 C_{ED}}{\partial y^2} &= - \frac{C_{ED}}{C_{ED} + K_{ED}} \frac{C_{EA}}{C_{EA} + K_{EA}} \frac{\mu_{max}}{Y} f_a C_{bio} & \text{in } \Omega_\vartheta \\
 \frac{\partial C_{EA}}{\partial t} + \mathbf{u} \frac{\partial C_{EA}}{\partial x} - D_t \frac{\partial^2 C_{EA}}{\partial y^2} &= - \frac{C_{ED}}{C_{ED} + K_{ED}} \frac{C_{EA}}{C_{EA} + K_{EA}} \frac{\mu_{max}}{Y} f_b C_{bio} & \text{in } \Omega_\vartheta \\
 \frac{\partial C_{Prod}}{\partial t} + \mathbf{u} \frac{\partial C_{Prod}}{\partial x} - D_t \frac{\partial^2 C_{Prod}}{\partial y^2} &= \frac{C_{ED}}{C_{ED} + K_{ED}} \frac{C_{EA}}{C_{EA} + K_{EA}} \frac{\mu_{max}}{Y} f_c C_{bio} & \text{in } \Omega_\vartheta \\
 \frac{\partial C_{bio}}{\partial t} &= \frac{C_{ED}}{C_{ED} + K_{ED}} \frac{C_{EA}}{C_{EA} + K_{EA}} \mu_{max} C_{bio} - \lambda C_{bio} & \text{in } \Omega_\vartheta
 \end{aligned} \tag{26}$$

438 where  $\mathbf{u}$  is the velocity (which has only a constant  $x$ -component),  $D_t$  is the transverse dispersivity,  
 439  $C_{ED}, C_{EA}, C_{Met}$  and  $C_{bio}$  are concentrations of *ED, EA, Prod* and *biomass* respectively;  $K_{ED}$  and  $K_{EA}$  are  
 440 half saturation constants for respective compounds in the biomass growth term,  $Y$  is the yield coefficient,  
 441  $\mu_{max}$  is the maximum bacterial growth rate, and  $\lambda$  is the bacterial decay rate. Using these equations  
 442 Cirpka and Valocchi (2007a) developed an analytical solution for steady-state conditions, which in the  
 443 version of Cirpka and Valocchi (2009) is used as reference for the numerical results.

444 The numerical experiment is designed to have ED and EA, occupying 25% and 75% of the inlet  
 445 repectively, and, simultaneously, invading the domain under a constant uniform velocity field, with  
 446 concentration of  $C_{ED}^{inlet}$  and  $C_{EA}^{inlet}$ . In a real-world scenario, this can be seen as a plume of a contaminant  
 447 (i.e. a hydrocarbon as *ED*) being carried into the domain within an oxygenated stream and essentially we  
 448 are interested in knowing the final concentration/distribution of all bio-chemical species within the  
 449 domain. The parameters used in this scenario are summerized in Table 1. Transient reactive transport  
 450 simulations are performed until a steady state is achieved. For validation, we analyze all concentration  
 451 profiles along the  $y$ -axis at a fixed distance of  $x = 2$  m and compare them with the analytical solutions.  
 452 The analytical and numerical results show an almost perfect agreement (Figure 5, b-e).

453

454 **Figure 5:** (a) Model set up. The arrows show the direction of the flow field. Solid lines show the analytical solution and the  
 455 yellow squares illustrate the numerical results. (b-e) Comparison of the analytical and numerical solutions  $x=2\text{m}$   
 456 concentration of (b) *Electron Donor*, (c) *Electron Acceptor*, (d) *Product*, and (e) *Biomass*.

457

458

Table 1: Parameter values used for simulating microbial growth.

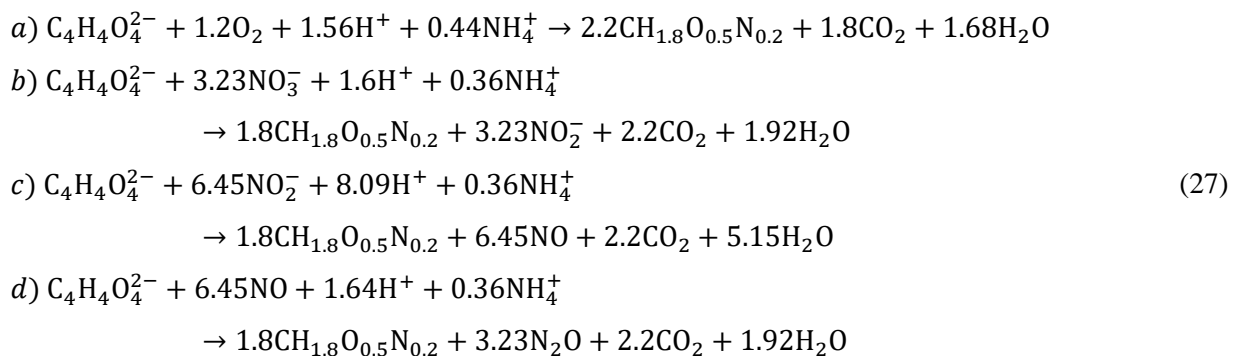

Parameter	Value	Unit	Parameter	Value	Unit
$u$	100	$cm\ d^{-1}$	$\mu_{max}$	1	$d^{-1}$
Domain width	20	$cm$	Domain length	500	$cm$
$D_t$	2.5	$cm^2\ d^{-1}$	$\lambda$	0.1	$d^{-1}$
$f_a, f_b, f_c$	1	-	$K_{ED}$	8.33e-2	$mM$
$C_{ED}^{inlet}$	0.33	$mM$	$K_{EA}$	3.13e-2	$mM$
$C_{EA}^{inlet}$	0.25	$mM$	Y	1	-
Mesh size	0.2	mm			

460

## 461 3.4 Theme: Demonstrating Model Capabilities

462 The scenarios described above are designed to serve as the sole purpose of creating a baseline for  
463 validating the numerical toolbox – simple enough where analytical solutions could exist. Unlike the  
464 simplicity introduced in previous sections, simulating soil processes with all of the complexities, though,  
465 would require having all the modelling elements to be present. We thus present here a scenario with an  
466 unsaturated soil hosting the facultative anaerobic bacteria *Agrobacterium tumefaciens*, which performs  
467 aerobic respiration under oxic condition, but switches to denitrification using nitrate, nitrite or nitric oxide  
468 under anoxic condition (Kampschreur et al., 2012). This example allows us to show our model  
469 capabilities, as it involves 1) the actual micro structure of the soil, 2) unsaturated conditions, and 3) an  
470 enzymatic reaction network with limiting/inhibition terms. The microstructure is obtained via  
471 subsampling from a larger  $\mu$ -CT image with voxel size of 6 micron (see Supplementary Information). A  
472 two-phase simulation is then performed on the voxelized subsample to obtain the fluxes and phase  
473 distribution of air and water within the pore space. For this, the entire domain is initially filled with water  
474 and subject to injecting air from the top boundary with constant flux of  $0.013\ ml\ h^{-1}$ . An important note to  
475 make here is with a relatively high influx, advection transport acts as the bottleneck for numerical time  
476 steps. Hence, reactions are performed at a quite slower pace (i.e. larger time steps roughly estimated  
477 around 10 hrs). This separation of processes helps improve the overall run-time of the simulations.  
478 Generally, the time step sizes are automatically enforced by the Courant number from the transient  
479 advective-diffusive transport equation (with order of  $10^{-5}$  seconds). The biomass is assumed to be non-  
480 motile meaning it sticks to the solid surface and shows no planktonic behavior. Fluids are allowed to  
481 leave the domain from the bottom part (kept at atmospheric pressure) while all the remaining sides are set  
482 to be impermeable walls. Once fluid configurations in the domain are stationary, their distribution along

483 with the velocity profile are used as basis for the reactive transport simulations (phase distributions can be  
484 found in the Supplementary Information). Using succinate ( $C_4H_4O_4^{2-}$ ) as organic carbon substrate to be  
485 degraded, a metabolic reaction network is constructed with four microbial degradation pathways each  
486 following Monod-type kinetics: 1) aerobic respiration with a nitric oxide ( $NO$ ) inhibitory term, 2) nitrate  
487 ( $NO_3^-$ ) reduction, 3) nitrite ( $NO_2^-$ ) reduction and 4)  $NO$  reduction, with having oxygen ( $O_2$ ) as inhibitory  
488 element for all denitrification conversions (eq. (27)). Also three additional equations are considered for the  
489 synthesis of the three different enzymes required for degradation processes (eq. (28)). We consider only  
490 one single strain of bacteria (*Agrobacterium tumefaciens*) which has the benefits of performing both  
491 aerobic respiration and denitrification. Bacteria are considered to be non-motile with an initial  
492 concentration of  $0.25 \text{ mol m}^{-2}$  and uniformly covering the entire grain surface area. Succinate has its  
493 initial concentration in the aqueous phase set at  $0.2 \text{ mM}$  ( $0 \text{ mM}$  in the gaseous phase), while all other  
494 species have their initial concentrations of  $0 \text{ mM}$  in both aqueous and gaseous phases. Boundary condition  
495 for all concentration fields on all boundaries is set to zero gradient except for the inlet boundary (fully  
496 saturated with air) - where for oxygen it is set to  $0.03567 \text{ mM}$ , and for all others is set to  $0 \text{ mM}$ . In order to  
497 avoid depletion of the nitrate in the system, a nitrate concentration of  $0.1 \text{ }\mu\text{M}$  (as initial condition) is  
498 provided. The complete reaction network can be written as follows (Kampschreur et al., 2012):

499 Several assumptions are made for preparing the kinetics of the reactions: 1) reaction rates are limited by  
500 the maximum specific uptake rate of succinate and are hence independent of its concentration (Beun et  
501 al., 2000), 2) sufficient amount of buffer is added to the solution to keep the pH level constant, 3) three  
502 nitrogen reductase enzymes ( $\xi_{sat,NOR}$  for  $NO$  reduction,  $\xi_{sat,NIR}$  for nitrite reduction and  $\xi_{sat,NAP}$  for  
503 nitrate reduction) can have saturation values varying between 0 (i.e. non-existing) and 1 in a bacterial cell,  
504 and 4) inhibitory oxygen limits the reduction of  $NO$ ,  $NO_2^-$  and  $NO_3^-$ . Reaction rates are designed to have a  
505 dependency on the enzymes' level and biomass concentration with proper limiting/inhibiting terms.  
506 Equation (12) is used to describe the evolution of each biochemical species. The final system of  
507 advective-diffusive-reactive equations is adapted from (Kampschreur et al., 2012):

$$\begin{aligned}
\frac{\partial C_i}{\partial t} + \nabla \cdot (C_i \mathbf{u}) &= -\nabla \cdot \left( D_i \nabla C_i - D_i \frac{1 - H_i}{\alpha + (1 - \alpha) H_i} C_i \nabla \alpha \right) + R_i, \\
i &= suc, O_2, NO_3^-, NO_2^-, NO, N_2O && \text{in } \Omega_g \\
R_{suc} &= -(r_{suc,O_2} + r_{suc,NAP} + r_{suc,NIR} + r_{suc,NOR}) \\
R_{O_2} &= -1.2r_{suc,O_2} \\
R_{NO_3^-} &= -3.23r_{suc,NAP} \\
R_{NO_2^-} &= 3.23r_{suc,NAP} - 6.45r_{suc,NIR} \\
R_{NO} &= 6.45r_{suc,NIR} - 6.45r_{suc,NOR} \\
R_{N_2O} &= 3.23r_{suc,NOR} \\
r_{suc,O_2} &= \mu_{max} C_{bio} \frac{C_{O_2}}{K_{O_2} \left( 1 + \frac{C_{NO}}{K_{I,NO,O_2}} \right) + C_{O_2}} \\
r_{suc,NAP} &= \mu_{max} C_{bio} \xi_{sat,NAP} \frac{C_{NO_3}}{K_{NO_3} + C_{NO_3}} \frac{K_{I,O_2,NAP}^{nNAP}}{K_{I,O_2,NAP}^{nNAP} + C_{O_2}^{nNAP}} \\
r_{suc,NIR} &= \mu_{max} C_{bio} \xi_{sat,NIR} \frac{C_{NO_2}}{K_{NO_2} + C_{NO_2}} \frac{K_{I,O_2,NIR}^{nNIR}}{K_{I,O_2,NIR}^{nNIR} + C_{O_2}^{nNIR}} \\
r_{suc,NOR} &= \mu_{max} C_{bio} \xi_{sat,NOR} \frac{C_{NO}^2}{\left[ C_{NO} \left( 1 + \frac{C_{NO}}{K_{I,NO}} \right) + K_{NO} \right]^2} \frac{K_{I,O_2,NOR}}{K_{I,O_2,NOR} + C_{O_2}} \\
\frac{d\xi_{sat,NAP}}{dt} &= v_{m,NAP} \frac{C_{NO_3}}{K_{NO_3,NAP} + C_{NO_3}} \frac{K_{I,O_2,NAP}}{K_{I,O_2,NAP} + C_{O_2}} (1 - \xi_{sat,NAP}) \\
\frac{d\xi_{sat,NIR}}{dt} &= v_{m,NIR} \frac{C_{NO_2}}{K_{NO_2,NIR} + C_{NO_2}} (1 - \xi_{sat,NIR}) \\
\frac{d\xi_{sat,NOR}}{dt} &= v_{m,NOR} \frac{C_{NO}}{K_{NO,NOR} + C_{NO}} (1 - \xi_{sat,NOR}) \\
\frac{dC_{bio}}{dt} &= 2.2r_{suc,O_2} + 1.8(r_{suc,NAP} + r_{suc,NIR} + r_{suc,NOR})
\end{aligned} \tag{28}$$

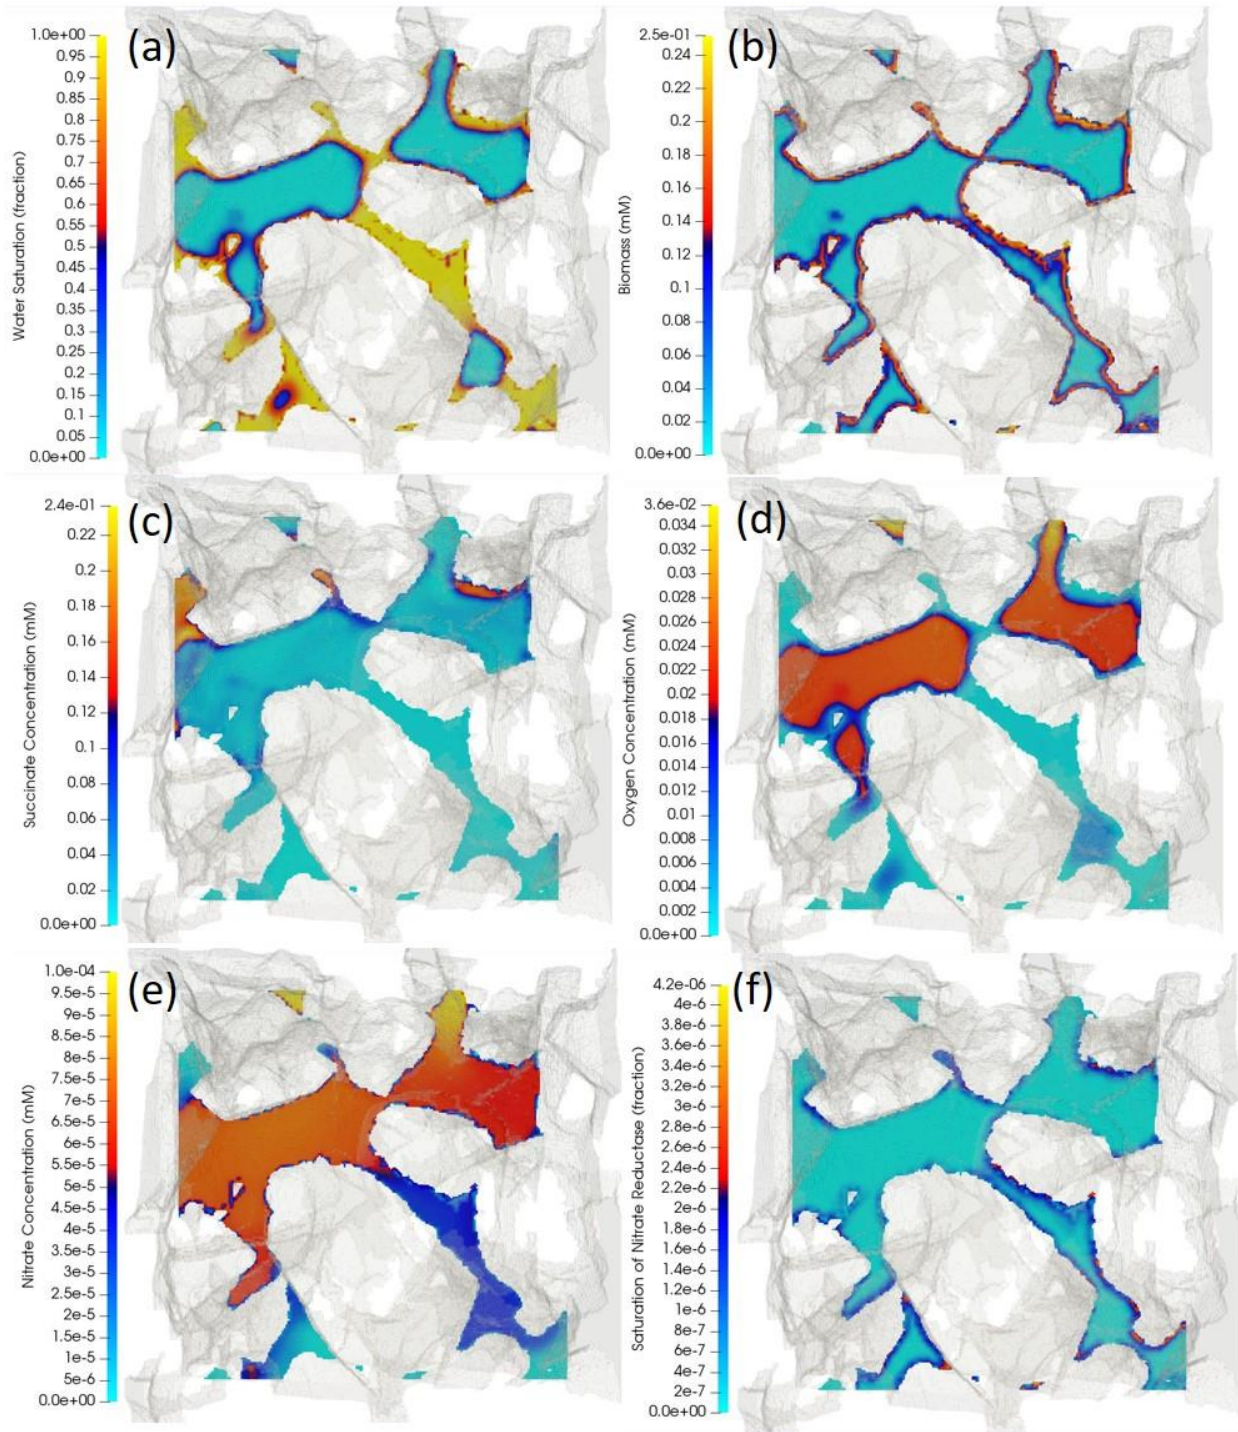

508 The full list of modelling parameters used for this study can be found in the Supplementary Information.

509 Reactive transport simulations were performed until a quasi-steady state was achieved. This was  
510 characterized by all chemical species concentrations reaching a steady-state as determined by the  
511 degradation activity of the given distribution of microorganisms. Since microbial growth takes place at  
512 much larger time scales than the pore-scale transport processes no significant growth takes place during  
513 the simulated time period and shown results are nearly identical to the initial conditions. Simulation  
514 results show that the presence of air in this two-phase system affects the distribution of biochemical

515 species. Air, as the non-wetting phase, occupies the central part of the pore space while the aqueous phase  
516 is expected to cover the corners and crevices (Figure 6, a). For oxygen with  $H_{O_2} = 31$  a higher  
517 concentration is observed in the air compared to that of the adjacent aqueous phase (Figure 6, d). An  
518 analysis of how the volatility of a tracer compound may affect its residence time in the porous medium is  
519 given in the Supplementary Information. Since the biomass is only present on the grain surfaces (Figure  
520 6, b), oxygen, nitrate and succinate deplete as the microbially-mediated reactions only at these micro-  
521 locations. Fresh oxygen and nitrate thus need to diffuse from the bulk (either from the aqueous phase or  
522 the air) to the reactive sites. The regions with high (i.e. not degraded) succinate concentrations are  
523 compatible with low concentration regions of oxygen and nitrate, i.e. the reactions are limited by the  
524 bioavailable oxygen and nitrate (Figure 6, b-e). Finally, all three enzymes have an increased abundance in  
525 anaerobic regions with an active biomass (saturation map of nitrate reductase enzyme is shown in Figure  
526 6, e). While the saturation of nitrate reductase enzyme grows linearly with time (until 0.25 s), the rate at  
527 which the nitrite and NO reductase enzymes ( $\xi_{sat,NIR}$  and  $\xi_{sat,NOR}$  respectively) grow is rather slow for  
528 the very beginning of the simulation (until ~0.2 s), but it surges exponentially afterward. A spatially  
529 integrated assessment of the degradation processes showed that for the presented example 99% of the  
530 total succinate degradation is attributed to aerobic respiration while a trivial amount is attributed to the  
531 three anaerobic processes (nitrate reduction, nitrite reduction and NO reductions).

532 The presented results highlight the ability of the model to combine a high-resolution simulation of multi-  
533 phase flow and transport processes with the simulation of complex biogeochemical processes. This allows  
534 for a realistic simulation of the pore-scale distribution of reactive processes and for the derivation of an  
535 accurate aggregated description of these processes.

536

537 Figure 6: Cross-sectional view of the three dimensional porous medium. The cutting plane is arbitrary cutting through the middle  
 538 of the porous structure, meaning at some locations, the phases are continuous perpendicular to the plane. The opaque grayish  
 539 background represents the 3D porous structure that is extracted and digitized from a  $\mu$ -CT image. The colored surfaces are  
 540 obtained by running a cutting plane through the middle of the sample and perpendicular to the z-axis. The distribution of (a)  
 541 water-content fraction (i.e. water volume fraction), (b) biomass, (c) succinate, (d) oxygen, (e) nitrate and (f) nitrate reductase  
 542 enzyme are respectively depicted with having yellow color indicating highest value and light blue as the lowest value. With air as  
 543 the non-wetting phase, it is expected to fill in the middle of the pore space where capillary pressure is lower while water, as the  
 544 wetting phase, is expected to occupy the corners (figure a). A high volatility constant for oxygen enforces to have higher  
 545 concentrations of oxygen in the air compared to that of aqueous phase adjacent to the water-air interface.

546 As it can be seen from Figure 6, our model can be used (among other options) to identify clusters in  
547 which succinate is most and least depleted. This would ease the process of analyzing the results by  
548 isolating the parameters that are boosting/limiting the degradation of the carbon source. 3D visualization  
549 of the oxygen and succinate distributions can be found in Golparvar, 2022.

#### 550 **4. Conclusion and future remarks**

551 In this paper, we have presented a newly developed modelling framework for simulating reactive  
552 transport processes in real porous soil structures obtained from  $\mu$ -CT images under unsaturated  
553 conditions. The successful application of various benchmark test showed the model's accuracy in the  
554 simulation of 1) the movement of water and air phase in variably saturated conditions via the enhanced  
555 algebraic Volume of Fluid method (Raeini et al., 2012) coupled with the Navier Stokes equation, 2) the  
556 transport of different species in both phases by the full advective-diffusive transport equation, and finally  
557 3) using the operator splitting technique, an arbitrary set of biogeochemical reactions solved externally by  
558 the Biogeochemical Reaction Network Simulator and communicated back into the main solver.

559 The presented model provides a novel and unique combination of pore-scale simulations of two-phase  
560 flow, transport of dissolved and volatile species and their reactive transformations. This makes it an  
561 accurate and powerful tool for the simulation of soil systems or other unsaturated porous media and of the  
562 reactive transport processes therein. While developed with the aim for simulating biogeochemical  
563 processes in soils the model is equally applicable for simulating other abiotic reactive processes coupled  
564 to the dynamics of flow and transport in variably saturated pore structures of arbitrary geometry. Our  
565 modelling framework is properly designed for simulating biogeochemical processes such as carbon-  
566 nitrogen-sulfur-phosphorus cycles in soil as well as mixing and migration of contaminants in both  
567 unsaturated soil and water aquifers. It comes with the benefit of explicit recognition of the soil structure  
568 (i.e. using the 3D structure as close to the original shape as possible with the least amount of  
569 simplifications/modifications), phase dynamics/distributions and the capability of designing the complete  
570 redox reactions necessary for a given process in a straightforward fashion. It is best suitable for running  
571 pre-pilot tests as feasibility scenarios where the stakes for the success of the project are high. Also, our  
572 model provides the best tool for designing hypothetical experiments that are hard (if not impossible) to  
573 implement experimentally (e.g. a specific distribution of biomass/reactants within the domain, or  
574 variation of specific properties of reactive compound and/or the porous matrix). Furthermore, the high  
575 resolution modelling results provided by this model support the upscaling of reactive-transport process  
576 description from the pore to the Darcy scale and from the process to the observation scale, respectively.

577 Although the current version of our numerical model is already covering a wide range of bio-physio-  
578 chemical properties of the soil constituents, for having more realistic representation of multiphase,  
579 multicomponent reactive transport in partially saturated porous media, few more factors still might be  
580 considered in future developments of the model: 1) shrinkage/expanding of the air/aqueous phase due to  
581 mass transfer of chemical species across fluid-fluid interface, 2) accounting for gas compressibility by  
582 adding an equation of state for tracking changes of air volume/density under flowing condition, 3)  
583 translating accumulated biomass on the grain surfaces into new flow-resistance components which would  
584 potentially change the velocity streamlines (i.e. bioclogging), 4) changes of the grain surface structures  
585 and of the associated solid-liquid interface due to mineral precipitation/dilution or due to  
586 accumulation/depletion of solid organic material, 5) chemotactic behavior of the microbial species, and 6)  
587 osmotic forces and electro-migration. Due to its modular structure, such features can be relatively easily  
588 included into future upgrades of our model.
