11 **Abstract**

12 The porous microenvironment of soil offers various environmental functions which are governed by
13 physical and reactive processes. Understanding reactive transport processes in porous media is essential
14 for many natural systems (soils, aquifers, aquatic sediments or subsurface reservoirs) or technological
15 processes (water treatment, or ceramic and fuel cell technologies). In particular, in the vadose zone of the
16 terrestrial subsurface the spatially and temporally varying saturation of the aqueous and the gas phase
17 leads to systems that involve complex flow and transport processes as well as reactive transformations of
18 chemical compounds in the porous material. To describe these interacting processes and their dynamics at
19 the pore scale requires a well-suited modelling framework accounting for the proper description of all
20 relevant processes at a high spatial resolution. Here we present P3D-BRNS as a new open-source
21 modelling toolbox harnessing the core libraries of OpenFOAM and coupled externally to the
22 Biogeochemical Reaction Network Simulator (BRNS). The native OpenFOAM Volume of Fluid solver is
23 extended to have an improved representation of the fluid-fluid interface. The solvers are further
24 developed to couple the reaction module which can be tailored for a specific reactive transport simulation.
25 P3D-RBNS is benchmarked against three different flow and reactive transport processes; 1) fluid-fluid
26 configuration in a capillary corner, 2) mass transfer across the fluid-fluid interface and 3) microbial
27 growth with a high degree of accuracy. Our model allows for simulation of the spatio-temporal
28 distribution of all bio-chemical species in the porous structure (obtained from μ -CT images), for
29 conditions that are commonly found in the laboratory and environmental systems. With our coupled
30 computational model, we provide a reliable and efficient tool for simulating multiphase, reactive transport
31 in porous media.

32 **1 Introduction**

33 Subsurface environments (soils, aquifers, aqueous sediments) are (typically) porous media host a
34 multitude of biogeochemical processes and interactions and provide different versatile ecosystem
35 functions (e.g. C sequestration, compound degradation, nutrient retention, provision of food, fibers and
36 fuel, habitat for organisms, water retention and purification, etc. (Baveye et al., 2016). These processes
37 are controlled by various biological (e.g., microbial abundance and activity), chemical (e.g., distribution
38 of dissolved and volatile species, mineral composition and surface properties of the solid matrix) and
39 physical (e.g., porous structure and permeability, water saturation) properties of the system. These
40 features create a complex web of interactions, the magnitude and effectiveness of which change
41 dynamically in space and time (Graham et al., 2014). Microbial communities, for example, and their
42 metabolic capacity are considered to be directly related to energy and matter fluxes (Thullner et al., 2007)
43 which are in turn, governed by pore arrangements and their connectivity. Along with other environmental
44 factors this can also modify various properties of the porous media (e.g. by biomass accumulation on pore
45 walls (Thullner, 2010), or mineral dissolution or precipitation (Meakin and Tartakovsky, 2009), which in
46 turn are altering the conditions for biogeochemical processes, too.

47 In soils (or more generally the vadose zone) the dynamically varying distribution of the aqueous and
48 gaseous phase leads to specifically complex and variable constraints for biogeochemical processes. In the
49 past, obtaining (bio)chemical and microbiological information at the pore level was neither economically
50 nor logistically a feasible option (Baveye et al., 2014). Also for the sake of applicability, traditionally,
51 researchers had more tendency to look for macroscale solutions to tackle environmental issues (White and
52 Brantley, 2003). The macroscale view (experimental, theoretical or a mixture of both) serves well the
53 purpose of practical applicability (White and Brantley, 2003), but for example, in the context of
54 microbially mediated degradation processes in the vadose zone, it fails to provide insights on the driving
55 mechanisms, as it overlooks important contributing factors, such as the tortuous porous
56 structure/pathways open to the transport of bio-chemical species, non-uniform distribution of water and
57 air phases as well as nonlinear relation of local biomass concentration and the bulk nutrient concentration.
58 Evidence at microscopic level has shown that biological activity and evolution are more locally organized
59 (Kuzyakov and Blagodatskaya, 2015) where macroscopic studies lead to loss of crucial information. This
60 has motivated the development of sophisticated physics-based models implementing all aspects of
61 hydrological, geochemical and biological processes involved in microbial growth and evolution.

62 Reactive Transport Models (RTMs) are a class of mathematical models that have been applied
63 extensively to study biogeochemical systems for about four decades (Parkhurst and Appelo,
64 1999;Thullner et al., 2005;Thullner and Regnier, 2019;Meile and Scheibe, 2019). There is a long list of
65 principal factors and mechanisms governing biogeochemical reactions at the pore scale. Numerically,

66 these processes can be defined and solved either by fully (global) implicit approaches or by separating
67 and solving different components once at a time. For the continuum scale a wide range of reactive
68 transport models exist which allow for the simulation of biogeochemical processes (Steefel et al., 2015b).
69 In turn, at the pore scale, models combining the simulation of flow, transport and reactive
70 (biogeochemical) processes are scarce, and existing model developments are often driven by specific
71 research questions and/or are subject to severe simplifications in the description of the pore space
72 (Golparvar et al., 2021). Integrated models explicitly capturing simultaneously the structural properties of
73 the soil at the microscale, the resulting multiphase flow and multispecies reactive transport are hardly
74 available (Tian and Wang, 2019).

75 Recently, new frontiers of pore-scale RTMs are emerging with the advances in computational power as
76 well as with huge improvements in imaging techniques (e.g. in static and dynamic scanning of porous
77 structure as well as fluids' distribution (Schlüter et al., 2019) or in detecting bacterial distributions in soil
78 using e.g., catalyzed reporter deposition with fluorescence in situ hybridization (CARD-FISH) technique
79 (Schmidt et al., 2015). Direct Numerical Models (DNMs) are becoming the nexus of next generation of
80 RTMs as they represent the porous structure in a fully explicit manner (directly obtained from soil
81 samples, digitized and fed into RTMs) in addition to offering a more flexible coupling of different
82 components of reactive transport models (Baveye et al., 2018;Raeini et al., 2012;Li et al., 2010;Yan et al.,
83 2016). Another advantage of using DNMs is that they offer a great deal of flexibility in considering
84 settings and conditions that are experimentally impossible to impose (Tian and Wang, 2019).

85 In this work, we introduce the pore-scale RTM package P3D-BRNS explicitly involving the structure and
86 topology of the pore space, the co-existence/co-flow of both the aqueous and the gaseous phase, the
87 advective-diffusive transport of species in each phase, and an arbitrary set of reactive processes controlled
88 by kinetic rate laws or thermodynamic constraints. The fluid flow field is updated via solving the Navier-
89 Stokes (NS) equation (Patankar and Spalding, 1972). The Volume-Of-Fluid (VOF) approach is adopted to
90 account for different phase distribution (Hirt and Nichols, 1981). The transport of chemical species is
91 considered via solving the Advection-Diffusion-Reaction Equation (ADRE), where the concentration
92 jump for soluble/volatile compounds across the fluid/fluid interface is modelled via the Continuous
93 Species Transfer (CST) method (Haroun et al., 2010). Reactive processes are defined and simulated
94 externally via coupling the flow and transport model to the BRNS (Biogeochemical Reactions Network
95 Solver) package (Regnier et al., 2002;Aguilera et al., 2005). The model structure is introduced and the
96 model performance is shown and compared with analytical counterparts. The model capabilities are
97 depicted for a fully three-dimensional case.

98 2 Mathematical Formulation

99 The entire numerical domain (Ω) can be decomposed to two main sub-regions: solid space (Ω_S) and void
100 space (Ω_ϑ). The void space is further divided into aqueous phase ($\Omega_{\vartheta, aq}$) and gaseous phase ($\Omega_{\vartheta, gs}$)
101 which are partitioned by the fluid-fluid interface (Ω_I). The overall domain is bounded externally between
102 inlet (Ω_{in}) and outlet (Ω_{out}) boundaries, which allow for inflow/outflow of different phases and chemical
103 species, as well as no-flux boundaries resembling physical walls, where nothing is allowed to leave or
104 enter the domain (Ω_{wall}). The domain is limited internally by no-flow boundaries where solid space and
105 void space intersect (i.e. solid surface, $\Omega_\vartheta \cap \Omega_S = \Omega_{wall}$).

106 2.1 Fluid Flow: Governing Equations

107 Evolution of a single/multi-phase, isothermal, incompressible, immiscible fluid(s) can be expressed by
108 basic conservation principles. These can be formulated into a single-field formalism (Hirt and Nichols,
109 1981):

$$\nabla \cdot \mathbf{u} = 0 \quad \text{in } \Omega_\vartheta \quad (1)$$

$$\rho \left(\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} \right) = -\nabla P + \nabla \cdot \boldsymbol{\tau} + \rho \mathbf{g} + \mathbf{F}_\sigma \quad \text{in } \Omega_\vartheta \quad (2)$$

110 where \mathbf{u} is the vector of velocity field, ρ is the fluid density, P is the pressure, \mathbf{g} is the gravitational
111 vector, and $\boldsymbol{\tau}$ is the stress tensor which can be defined as $\boldsymbol{\tau} = 2\mu\mathbf{S} = 2\mu(0.5[(\nabla\mathbf{u}) + (\nabla\mathbf{u})^T])$ with μ as
112 the fluid viscosity. \mathbf{F}_σ denotes the interfacial tension force, which is nonzero only when two or more
113 phases (excluding solid) are available.

114 In case of simultaneous flow of two different phases (e.g. flow of air and water under unsaturated conditions
115 - Figure 1: Illustration of a porous medium at the microscale with one fluid invading the other (on the
116 left). Mathematical representation of the phase saturation in the computational cells around the interface
117 (on the right). The dashed line shows the actual location of the interface while values in each cells show
118 the amount of water saturation relevant to topology of the dashed line. Black dots represent volatile
119 compounds able to cross the fluid-fluid interface; green dots represent non-volatile compounds restricted
120 to the transport in the aqueous phase.), their locations and distribution are represented via introducing an
121 indicator function, α , taking values within the range $[0, 1]$. The first continuous fluid is marked as $\alpha = 1$,
122 the second fluid is denoted as $\beta = 1 - \alpha$ and for the transition from one fluid to the other (i.e. the interface,
123 Ω_I), α varies between 0 and 1. Fluid density and viscosity in each grid cell is then calculated from a linear
124 interpolation of this indicator function:

$$\rho = \alpha\rho_1 + (1 - \alpha)\rho_2 \quad \text{in } \Omega_\theta \quad (3)$$

$$\mu = \alpha\mu_1 + (1 - \alpha)\mu_2 \quad \text{in } \Omega_\theta \quad (4)$$

125 A mass conservative boundary condition at the fluid-fluid interface is written as:

$$\llbracket \rho_i(\mathbf{u}_i - \mathbf{w}) \cdot \mathbf{n}_{\Omega_I} \rrbracket = 0 \quad \text{in } \Omega_I \quad (5)$$

126

Figure 1: Illustration of a porous medium at the microscale with one fluid invading the other (on the left). Mathematical representation of the phase saturation in the computational cells around the interface (on the right). The dashed line shows the actual location of the interface while values in each cells show the amount of water saturation relevant to topology of the dashed line. Black dots represent volatile compounds able to cross the fluid-fluid interface; green dots represent non-volatile compounds restricted to the transport in the aqueous phase.

127 with ρ_i as the density of i^{th} fluid, \mathbf{u}_i as the velocity of i^{th} fluid, \mathbf{w} as the velocity of the interface, \mathbf{n}_{Ω_I} as

128 the normal vector to the interface (Ω_I) pointing from the invading phase to the displaced one and the

129 brackets showing the jump condition at the interface.

130 In the context of the Finite Volume Method (FVM), discretization of the physical domain produces a

131 finite subset of discrete volumes (taking the shape of a polyhedral). The key implication of the Volume of

132 Fluid method is to define and solve for global variables, rather than having one equation for each variable

133 in each phase. Hence, the idea is to transform the integro-differential equations into their global versions

134 by averaging them over each cell volume (Whitaker, 2013). For multiphase systems, after a few steps of

135 linearization and approximation (see Hirt and Nichols (1981) for a detailed derivation), the Volume of

136 Fluid formulation of the momentum equation (2) is obtained as:

$$\rho \left(\frac{\partial \bar{\mathbf{u}}}{\partial t} + \bar{\mathbf{u}} \cdot \nabla \bar{\mathbf{u}} \right) = -\nabla P + \nabla \cdot \mu (\nabla \bar{\mathbf{u}} + (\nabla \bar{\mathbf{u}})^t) + \rho g + F_\sigma \quad \text{in } \Omega_g \quad (6)$$

137 with having $\bar{\mathbf{u}}$ as the global averaged velocity vector. For the sake of simplicity, we drop the “average”
 138 notation from the global velocity vector (i.e. will refer to $\bar{\mathbf{u}}$ as \mathbf{u}), for the rest of this paper.

139 A global, mass conservative, advection equation is used to describe the evolution of the indicator
 140 function:

$$\frac{\partial \alpha}{\partial t} + \nabla \cdot (\alpha \mathbf{u}) + \nabla \cdot (\alpha (1 - \alpha) \mathbf{u}_c) = 0 \quad \text{in } \Omega_g \quad (7)$$

141 where α indicates the volume fraction of phase 1, $\mathbf{u}_c = \mathbf{u}_\alpha - \mathbf{u}_\beta$ is the vector of the compressive velocity
 142 with $\mathbf{u}_{\alpha,\beta}$ as velocity vector of phase α and β right on the edge of the interface (detailed explanation on
 143 deriving eq. (7) can be found in the Supplementary Information **Error! Reference source not found.**).
 144 The latter term in equation (7) is active only in the presence of an interface. It is derived from mass
 145 conservation equation written for phase α , which computationally helps with maintaining stiffness of the
 146 interface. Since we don’t solve for the velocity field of each phase individually, a direct calculation of \mathbf{u}_c
 147 is not possible. However, we can rather take an indirect approach for computing \mathbf{u}_c as follows:

$$\mathbf{u}_c = \min(c_\alpha |\mathbf{u}|, \max(|\mathbf{u}|)) \frac{\nabla \alpha}{|\nabla \alpha|} \quad \text{in } \Omega_I \quad (8)$$

148 In equation (8), c_α is a compression coefficient providing some level of control over how wide the
 149 interface spans. A value of $c_\alpha = 0$ gives no compression of the interface, whereas values of $c_\alpha > 1$
 150 provide an enhanced/sharper interface (Graveleau et al., 2017). In simulation scenarios introduced in this
 151 paper, c_α has been assigned the value of 1, unless otherwise is stated.

152 To calculate the interfacial tension force, \mathbf{F}_σ , Brackbill et al., (1992) have introduced a Continuum
 153 Surface Force (CSF) which requires computing the curvature of the interface:

$$\kappa = \nabla \cdot \mathbf{n}_{\Omega_I} \quad \text{in } \Omega_I \quad (9)$$

154 with having κ as mean interface curvature, and \mathbf{n}_{Ω_I} as the interface unit normal vector defined as:

$$\mathbf{n}_{\Omega_I} = \frac{\nabla \alpha}{|\nabla \alpha|} \quad \text{in } \Omega_I \quad (10)$$

155 Given the curvature, the interfacial tension force can be computed as:

$$\mathbf{F}_\sigma = \sigma \kappa \nabla \alpha \quad \text{in } \Omega_I \quad (11)$$

156 where σ is the surface tension between two fluids.

157 2.2 Reactive Transport: Governing Equations

158 Concentrations of mobile species are affected by advection (i.e. transport with the moving fluid),
159 molecular diffusion and reactive transformation. Also, in case of having two fluids simultaneously in the
160 system, different species can cross the fluid-fluid interface, causing local fluctuations in concentration
161 values. In general to account for all the changes in species concentrations, the ADRE for biogeochemical
162 reactive components can be written as:

$$\frac{\partial C_i}{\partial t} + \nabla \cdot (C_i \mathbf{u}) = -\nabla \cdot (J_{d,i} + J_{m,i}) + R_i \quad \text{in } \Omega_g \quad (12)$$

163 where $J_{d,i}$ is the molecular diffusive flux of component i , $J_{m,i}$ is the mass flux of component i due to mass
164 transfer across the fluid-fluid interface and R_i accounts for the changes in concentration of component i
165 due to reactions. Molecular diffusion follows Fick's law:

$$J_{d,i} = -D_i \nabla (C_i) \quad \text{in } \Omega_g \quad (13)$$

166 where D_i is the diffusion coefficient of species i . At the interface, the assumption of thermodynamic
167 equilibrium implies equality of chemical potentials. Given the condition that liquid concentration of
168 component i is proportional to the partial pressure of the species in the secondary phase (e.g. gas, oil or
169 minerals), a partitioning relationship such as Raoult or Henry's law (Danckwerts and Lannus, 1970) can
170 be established to relate species concentrations on both sides of the interface:

$$C_{i,\beta} = H_i C_{i,\alpha} \quad \text{in } \Omega_I \quad (14)$$

171 with $C_{i,\alpha}$ as concentration of species i in phase α , H_i as Henry's constant of species i and $C_{i,\beta}$ as
172 concentration of species i in phase β . Depending on if a given compound's concentration in the aqueous
173 phase or the gaseous phase is multiplied by the Henry's coefficient, (14), the definition of Henry's
174 constant switches between the solubility or volatility for that compound (i.e. $H_i^{\text{solubility}} = 1/H_i^{\text{volatility}}$)
175 (Sander, 2015). Unless otherwise stated, the volatility concept of Henry's law is adopted in order to
176 define the concentration relationship of a given compound across the fluid-fluid interface (14). The
177 concentration field around the fluid-fluid interface (where $\nabla \alpha \neq 0$) at equilibrium, for any values of $H \neq$
178 1, is discontinuous which imposes the additional flux, $J_{m,i}$, to satisfy the concentration jump across the
179 interface. Hence the mass transfer flux, $J_{m,i}$, can be derived within the VOF framework (i.e. CST) as
180 follows (Haroun et al., 2010):

$$J_{m,i} = -D_i \frac{1 - H_i}{\alpha + (1 - \alpha)H_i} C_i \nabla \alpha \quad \text{in } \Omega_g \quad (15)$$

181 It is noteworthy that few assumptions and volume averaging methods are implemented to derive equation
182 (15), which readers are encouraged to check the references for more details. The diffusion coefficient is
183 calculated from harmonic interpolation:

$$D_i = \frac{1}{\frac{\alpha}{D_{i,A}} + \frac{1-\alpha}{D_{i,B}}} \quad \text{in } \Omega_g \quad (16)$$

184 where $D_{i,\alpha-\beta}$ is the diffusion coefficient of species i in phase α and β respectively.

185 Simulated reactions include kinetically as well as thermodynamically constrained reactions. For a
186 kinetically constrained reaction j the reaction rate $r_j = f(C_1, \dots, C_n)$ is needed while for a
187 thermodynamically constrained reaction k the equilibrium conditions defined by a law of mass action
188 $M_k = f(C_1, \dots, C_n)$ is needed with M_k as equilibrium constant. These equations can be of arbitrary form and
189 the resulting reaction network defines the term R_i in equation (12) (Aguilera et al., 2005; Regnier et al.,
190 2002). For immobile species concentration changes are only due to reactive processes.

191 2.3 Boundary Conditions (BCs)

192 There are various types of boundary conditions, corresponding the real physical conditions, most of which
193 can be derived from two basic types:

- 194 • Dirichlet boundary (fixed value) which relates the value of a variable at a given geometric
195 location to a constant value; e.g. $C_i = 1M$ in Ω_{in} meaning a constant 1 molar concentration of
196 component i at the boundary,
- 197 • von Neumann boundary (fixed gradient) which provides the value of a variable's gradient at the
198 face of the boundary cell; e.g. $\partial_n p = 0$ in Ω_{wall} giving a zero pressure gradient on the wall.

199 In general, our model can apply any of these basic boundary conditions to any scalar or vector variables
200 such as pressure, velocity/flux, concentration of volume of fluid fields, but one needs to assure that the
201 imposed BC(s) are both compatible and they reflect the correct physical boundary conditions. For
202 example, for velocity/flux-pressure coupling, a Dirichlet (i.e. constant) boundary for flux at the inlet can
203 be coupled with either 1) fixed discharge velocity/flux and zero gradient (i.e. von Neumann) pressure at
204 both inlet and outlet, or 2) a constant pressure head at the inlet and atmospheric pressure at the outlet with
205 zero gradient velocity/flux at both ends, or 3) fixed values of pressure and velocity/flux at one end and
206 zero gradient at the other end. In the beginning of section 2, typical composition and configuration of an
207 arbitrary computational domain is described. Inlet, outlet and impermeable boundaries are amongst the
208 most common types that one might face. Inlet BC means for the direction of fluid flux to be pointing
209 inwards (i.e. into the domain) while for the outlet, the direction of the flux should be outwards. Also for

210 the impermeable wall, zero-orthogonal fluxes need to be satisfied. Either Dirichlet, von Neumann or a
211 mixture of both can be used at a particular boundary. Mathematical translation and implementation of
212 these boundaries are provided in the next section. Time-dependent BCs (e.g. cyclic or seasonal
213 water/species influx) are also readily available to be applied, but never been used in this work. Unless
214 otherwise stated, boundary conditions that have been imposed on each section of the computational
215 domain are described as follows:

216 **At impermeable boundaries (Ω_{wall}):** Physical wall implies no flux perpendicular to the normal vector
217 to its surface. No slip BC is an appropriate BC for the velocity field on the wall. In general, they all can
218 be written as:

$$\partial_n C_i = 0, \quad \mathbf{u}_{x,y,z} = 0, \quad \partial_n \mathbf{p} = 0, \quad \partial_n \alpha = 0 \quad \text{in } \Omega_{wall} \quad (17)$$

219 For the velocity field, on the wall, a slip boundary condition is also available to be applied.

220 **At inlet/outlet boundaries ($\Omega_{in}, \Omega_{out}$):** Concentration of reactants, products and inert tracers are set to
221 fixed values at inlet, while they are allowed to leave the domain at outlet with zero gradient boundary
222 condition. Constant flowrate with zero pressure gradient is applied at inlet and an atmospheric pressure
223 (fixed value) with zero velocity gradient is set at outlet. Also in case of two-phase flow, the invading
224 phase is set to enter from inlet at fixed value and exits from outlet with zero gradient BC. Mathematically,
225 they can be expressed as:

$$C_i \geq 0, \quad \mathbf{u} = const., \quad \partial_n \mathbf{p} = 0, \quad \alpha = const. \quad \text{in } \Omega_{in} \quad (18)$$

226 together with:

$$\partial_n C_i = 0, \quad \partial_n \mathbf{u}_n = 0, \quad \mathbf{p} = 0, \quad \partial_n \alpha = 0 \quad \text{in } \Omega_{out} \quad (19)$$

227 While we have mostly applied equations (18) and (19) for designing an inlet/outlet duo, other formats,
228 such as defining a pressure head (plus zero gradient velocity) on the inlet in combination with either
229 constant exit pressure or constant discharge rate, are readily available to implement as well.

230 **At the fluid-fluid-solid contact line (Ω_{f3}):** At the fluid-fluid-solid contact line, in case of no interactions
231 or no reaction of any chemical species with the solid, the boundary condition at the triple point is derived
232 to be:

$$\nabla C_i \cdot \mathbf{n}_s = \frac{H_i - 1}{\alpha H_i + (1 - \alpha)} C_i \nabla \alpha \cdot \mathbf{n}_s \quad \text{in } \Omega_f \quad (20)$$

233 with \mathbf{n}_s as the normal vector to the solid surface (Graveleau et al., 2017). Also, the concept of contact
234 angle is applied by making the following modification to the interface normal vector:

$$n_{\Omega_i^3} = \cos\theta \mathbf{n}_s + \sin\theta \mathbf{t}_s \quad \text{in } \Omega_i^3 \quad (21)$$

235 where \mathbf{n}_s is normal vector and \mathbf{t}_s is the tangential vector to the solid surface (Brackbill et al., 1992). CSF,
236 though, has been reportedly generating non-physical spurious currents (Scardovelli and Zaleski, 1999).
237 For this, many have tried to eliminate/mitigate this issue by explicit representation of the interface either
238 via using the Geometric VOF method (Popinet, 2009) or coupled Level-set (LS) VOF functions
239 (Albadawi et al., 2013). Geometric VOF is quite suitable for structured grids, but for porous structures
240 with highly unstructured grids, the calculations can become quite complicated. Alternatively, Raeini et al.
241 (2012) suggested filtering the capillary forces parallel to the interface, which can significantly reduce the
242 non-physical velocities. In short, the modifications they proposed and which are used here are: 1)
243 smoothing the indicator function to have a better measure of the interface curvature, 2) sharpening the
244 indicator function for computation of the interfacial tension force, 3) filtering the capillary pressure force
245 parallel to the interface, and 4) filtering capillary fluxes based on the capillary pressure gradient.

246 2.4 Numerical Formulation

247 The mass conservation (eq. (1), momentum (NS - eq. (2) and indicator function (eq. (7) equations are all
248 implemented within the open source computational fluid dynamics (CFD) package, OpenFOAM
249 (Greenshields, 2015). OpenFOAM utilizes the finite volume methodology (FVM), a common choice for
250 CFD problems as FVM works only with conservative flux evaluation at each computational cell's
251 boundaries, making it robust in handling nonlinear transport problems. Also all the differential equations
252 mentioned before are first written in their integral form over each cell volume and then converted to the
253 surface summations using Green's Theorem.

254 In this work, the original two-phase (VOF) flow solver, i.e. *interFoam*, is modified to construct our
255 biogeochemical reactive transport package. The momentum equation (2) is linearized in a semi-discrete
256 form as:

$$A_d \mathbf{u} = \mathbf{H}(\mathbf{u}) - \nabla P + \mathbf{F}, \quad (22)$$

257 where A_d holds the diagonal elements of the coefficient matrix, $\mathbf{H}(\mathbf{u})$ contains off-diagonal elements of
258 the coefficient matrix including all source terms, and \mathbf{F} entails any body forces (interfacial tension force
259 only in this case). Temporal discretization is handled via the first order Euler method while spatial
260 discretization is managed via second order finite volume schemes. Convection terms of the momentum
261 equation and indicator function (7) are computed using a bounded self-filtered central differencing
262 (SFCD) scheme (based on Gauss's theorem). Rearranging equation (22) for velocity and imposing the
263 continuity equation (1), the following linear pressure equation can be obtained:

$$\sum_f \frac{S_f}{\langle A_d \rangle_f} \nabla_f^\perp P = \sum_f \left(\left\langle \frac{\mathbf{H}(\mathbf{u})}{A_d} \right\rangle_f \cdot |S_f| + \frac{\varphi_{F,f}}{\langle A_d \rangle_f} \right). \quad (23)$$

264 S_f in equation (23) denotes the outward area-vector of face f , the notation ∇_f^\perp shows face normal
265 gradients calculated right on the face centers, $\langle \rangle_f$ shows the interpolated values of a face-centered
266 parameter from its cell-centered counterpart, and $\varphi_{F,f}$ is the interfacial force flux term.

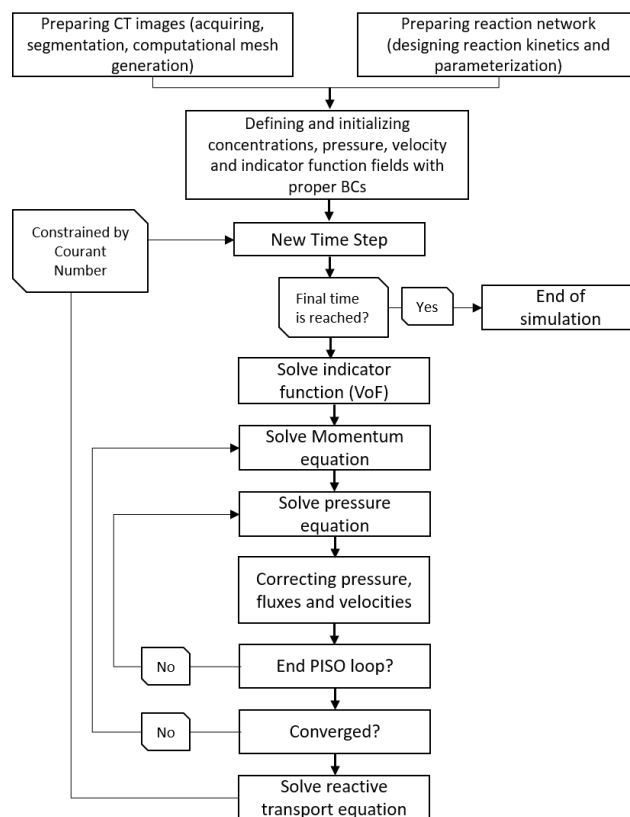

267 The velocity-pressure coupling of equations (1) and (2) are solved using Pressure Implicit with Splitting
268 of Operators (PISO) (Issa, 1986). PISO embodies a predictor-corrector strategy to simultaneously update
269 pressure and velocity within each time step. The resultant system of equations are solved on the cell faces
270 and then interpolated back to calculate velocities and pressure at the cell centers. The coupling of
271 indicator function (eq. (7)) and momentum equation is explicitly defined and solved right after the PISO
272 step is finished. Within the same time step, transport and reaction of different species are then solved
273 sequentially – using a Sequential Non-Iterative Algorithm (Steeffel et al., 2015a; Steeffel and MacQuarrie,
274 1996). Time step size is controlled by introducing a Courant number. Time is discretized using either
275 Euler or Crank-Nicholson methods and spatial discretization is performed using the Van Leer second
276 order Total Variation Diminishing scheme (TVD) (van Leer, 1979).

277 The reaction network is built separately and externally solved within the BRNS package - which employs
278 first order Taylor series expansion terms and uses Newton-Raphson method to iteratively solve the
279 system of linear equations (Regnier et al., 2002). BRNS utilizes MAPLE programming language to
280 construct the Jacobian matrix (which contains the partial derivatives of unknown parameters, i.e.
281 concentrations) and other problem-related data such as rate parameters and translating them to a
282 FORTRAN package. The FORTRAN code is then compiled to generate shared object (*.so file) that can
283 be dynamically called later from the transport solver (Centler et al., 2010). The significance of having
284 dynamically shared object file is more apparent when running computationally-demanding
285 cases/scenarios while decomposing and running the application in parallel. BRNS is invoked once the
286 new concentrations are computed from the transport solver. The updated concentrations from the BRNS
287 library (i.e. updating concentrations from redox reactions) are then fed back into the transport solver
288 before moving to the next time step. This process repeats until the final time is reached. This coupling
289 scheme has been successfully used for other RTM approaches before (Centler et al., 2010; Gharasoo et al.,
290 2012; Nick et al., 2013).

291 Prior to run simulations, the physical settings of the domain are required to be specified; i.e. the physical
292 geometry of the pore space with proper boundaries and the meshing scheme should be designed.
293 OpenFOAM provides a basic utility for defining boundaries as well as mesh generation which are

294 translatable by the OpenFOAM engine. Any other meshing software/freeware can be freely used as long
295 as an OpenFOAM-compatible format for the meshed file can be created. The overall workflow required
296 to build and run a case/scenario is summarized in Figure 2.

297

298 **Figure 2:** Full solution procedure to simulate a reactive transport process at its fullest complexity.

299 3 Model Performance

300 The presented reactive transport model is designed 1) to capture real world pore structures in up to three
301 dimensions, 2) to explicitly simulate the transient distribution of a gas and a liquid phase within the entire
302 pore space and 3) to simulate a full set of advection-diffusion-reaction mechanisms. To validate different
303 features of the model various simplified scenarios were used which allow the use of analytical
304 expressions as reference for the numerical results. We here show three representative test scenarios
305 addressing different features of the model (two-phase flow, mass transfer across the fluid-fluid interface
306 and reactive transport) individually. Subsequently, the model capabilities are depicted in a final
307 biodegradation scenario making use of the various model features simultaneously.

308 3.1 Fluid Configurations

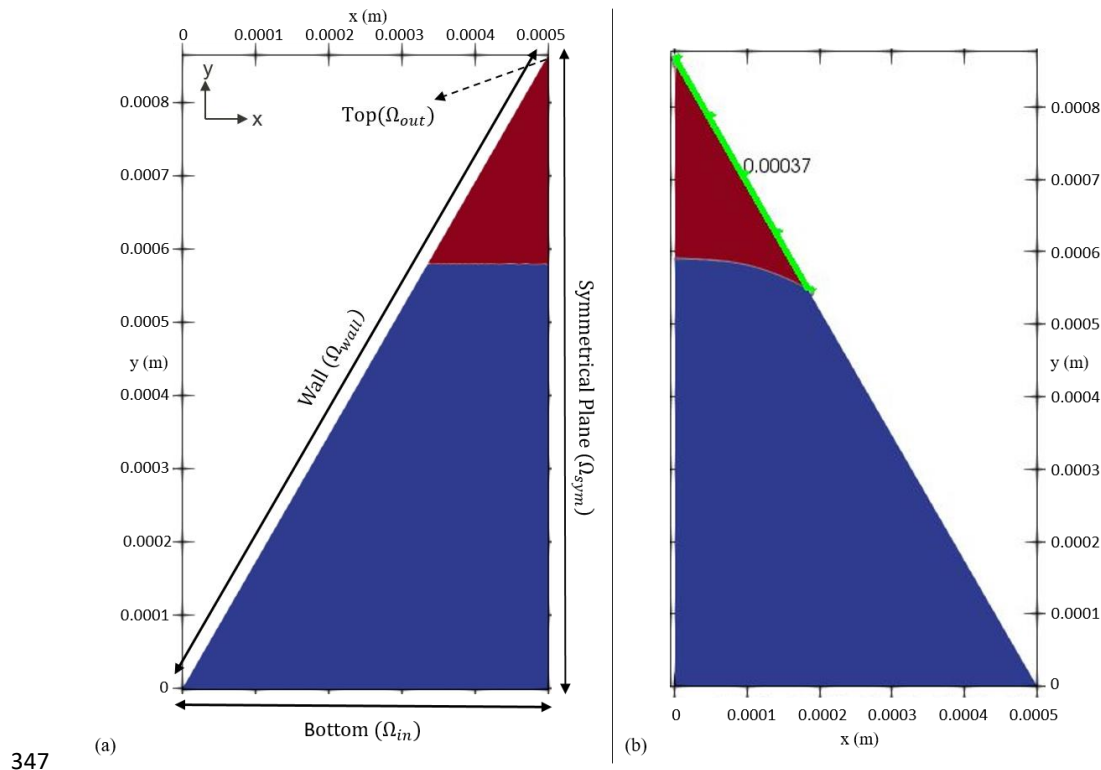

309 In order to test our model's performance in simulating two-phase flow, we have zoomed into a two-
310 dimensional porous structure and isolated only one single corner taking the shape of an equilateral
311 triangle. Initially, two immiscible fluids (one wetting, and one non-wetting, e.g. water and air) are placed
312 in such a way that their interface forms a straight line (Figure 3, a). The side length of the triangle is 1 mm
313 with a mesh size of 1 μm . Under thermodynamic equilibrium conditions, the force exerted by the pressure
314 difference between two phases is countered by the interfacial tension force. This, along with the contact
315 angle of the non-wetting phase at the wall surface in presence of the wetting phase (e.g. water),
316 determines the topology of the fluid-fluid interface. For a given corner half-angle, the distance that
317 wetting phase spreads over the solid surface from the corner vertices (the highlighted section with green
318 color on Figure 3, b), b , can be calculated as:

$$b = r \frac{\cos(\theta + \beta)}{\sin(\beta)} \quad (24)$$

319 with r as the radius of the interface's curvature, θ as the contact angle and β as the corner half-angle
320 (Blunt, 2017). In order to reach thermodynamic equilibrium, we performed transient, two-phase flow
321 simulations to compute velocity, pressure and indicator function fields until the triple contact line (Ω_{i3}) is
322 static. For this, we first divided the equilateral triangle in half, as the problem is symmetrical along the
323 height of the triangle. The symmetrical plane implies that there is no gradient (of any scalar or vector
324 field) perpendicular to its surface while the tangential components (of all fields) remain the same. To find
325 the fluid configuration at equilibrium, we simulated the two-phase flow scenario in two steps. First, we
326 applied a closed boundary condition on the bottom domain by setting $\mathbf{u} = 0$ together with $\partial_n p = 0$. Also
327 a closed boundary is imposed on the topmost part of the domain which follows the same BC as the
328 bottom. This way, the interface is able to reconfigure and reorient itself in order to recreate the imposed
329 contact angle with the wall, and at the same time, pressure is allowed to build up in both phases to support
330 the shape of the interface. Then, in order to obtain an equilibrium curvature for the interface, bottom and
331 top domains are opened. This is achieved by setting the 1) pressure in Ω_{in} to the average pressure within
332 the non-wetting phase, 2) pressure in Ω_{out} to the average pressure within wetting phase together with 3)
333 $\partial_n \mathbf{u} = 0$ on both Ω_{in} and Ω_{out} . At this stage, we applied a special BC for the indicator function to allow
334 the fluids to enter or leave the domain at both ends, so that the interface can freely transition to its static
335 shape. At the inlet (Ω_{in}), the BC for α is set to switch between $\partial_n \alpha = 0$, if the fluid flux is pointing
336 outwards, and $\alpha = 0$ if the fluid flux is directed into the domain. Also at the outlet (Ω_{out}), the BC for α
337 switches between $\alpha = 1$, if the fluid flux is inwards, and $\partial_n \alpha = 0$, if the fluid flux is outwards. This
338 ensured that appropriate fluids entered the domain from either inlet or outlet boundaries. The radius of

339 curvature can be also evaluated from the Young-Laplace equation ($P_c = \frac{\sigma}{r}$). With a pressure difference of
 340 255.33 ($\text{kg m}^{-1} \text{s}^{-2}$) obtained from the last step and a surface tension of 0.07 (kg s^{-2}), the radius of
 341 curvature is calculated to be $2.17\text{e-}4$ m. In a different approach, once the interface attains stationarity, we
 342 calculated r for equation (24) as the reciprocal of the interface's mean curvature ($2.77\text{e-}4$ m). For a
 343 contact angle of 10° and a corner half-angle of 30° , the analytically calculated value for the length, b , of
 344 the section in contact with the wetting phase is $375 \mu\text{m}$, while the numerical solution yields $370 \mu\text{m}$.
 345 With a relative error of 1.21% this shows a reasonable match between numerical and analytical solutions
 346 in modelling two-phase flow.

348 **Figure 3:** Initial condition (a) versus final arrangement (b) of the two phases in the fluid configurations scenario. The blue color
 349 indicates the non-wetting and the red color shows the wetting phases respectively. The dashed arrow shows the location of the
 350 outlet, while the solid-line arrows depict the extent of others boundaries. Once equilibrium is reached (figure b), the curvature of
 351 the interface corresponds to the force balance between pressure difference across the interface and the surface tension which can
 352 be used to verify the model's sanity. The distance of the contact point (i.e. the point/line where all three phases – water, air and
 353 solid – meets) from the corner vertex (highlighted as green), also provides another measure for checking the accuracy of the
 354 numerical model.

355 3.2 Mass Transfer across the Fluid-Fluid Interface

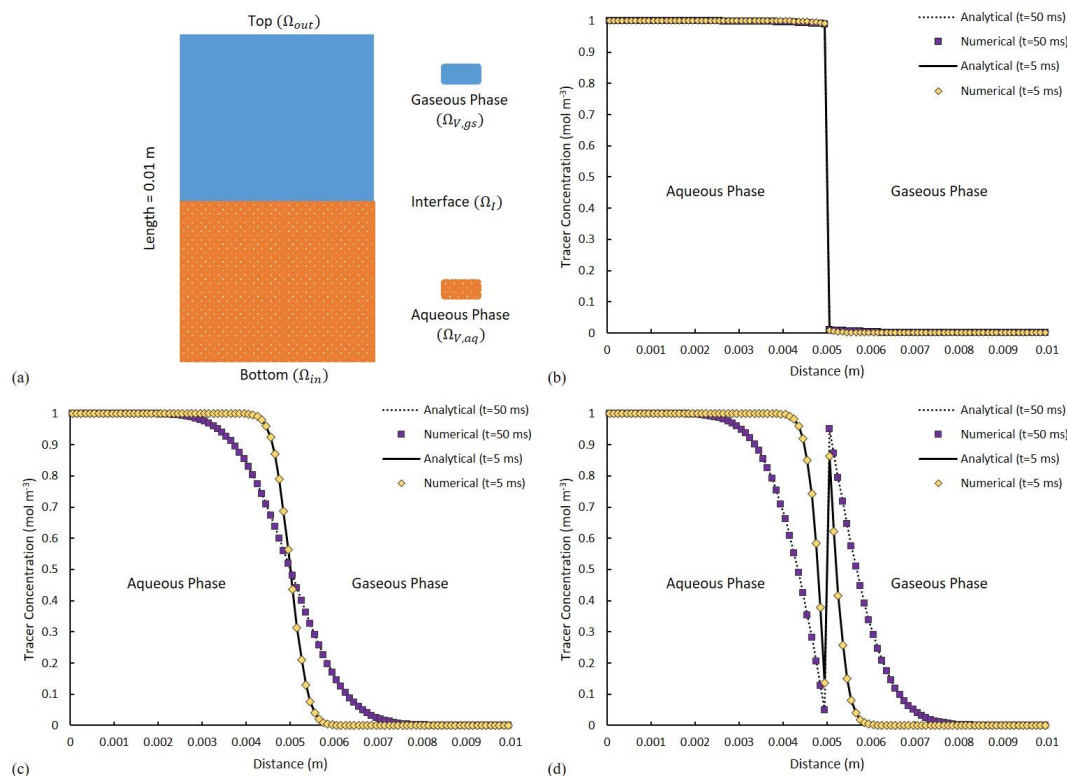

356 Mass transfer of dissolved species between different phases, is particularly of importance for various
357 biogeochemical processes in unsaturated subsurface environment as e.g., oxygen or volatile organic
358 carbon compounds are found in the liquid and the gas phase, yet their transport and reaction conditions
359 differ highly between these two phase

360 Model performance in simulating mass flux across the fluid-fluid interface is validated via a numerical
361 experiment in which two immiscible stationary fluids (an aqueous - α - and a gaseous - β - phase, $\mathbf{u} = 0$ in
362 Ω_ϑ) are horizontally (to remove buoyancy effects) residing on a one dimensional tube of 10 mm length
363 with mesh size of 100 μm . The general partial differential equation (PDE) of equation (12) takes the form
364 of a simple diffusive transport as:

$$\frac{\partial C_{tr,i}}{\partial t} - D_{tr,i} \nabla(C_{tr,i}) = 0 \quad i = aq, gs$$
$$BC - 1: \quad C_{tr,aq} \times H = C_{tr,gs} \quad \text{in } \Omega_I \quad (25)$$
$$BC - 2: \quad D_{tr,aq} \frac{\partial C_{tr,aq}}{\partial x} = D_{tr,gs} \frac{\partial C_{tr,gs}}{\partial x} \quad \text{in } \Omega_I$$

365 with C_{tr} as the concentration of a volatile tracer and $D_{tr,i}$ as the diffusivity of the tracer in phase i . Each
366 phase is set to occupy half of the total volume (Figure 4-a). The system is initialized with a volatile
367 chemical species of concentration of 1 mol m^{-3} in $\Omega_{\vartheta,aq}$, and 0 mol m^{-3} in $\Omega_{\vartheta,gs}$. At the inlet and the outlet
368 boundary, tracer concentration equals that of the nearest solution such that, in short simulation time, it
369 yields no concentration gradient into or out of the domain. The tendency of the dissolved chemical
370 component to cross the fluid-fluid interface is expressed using a constant Henry coefficient. Tracer
371 diffusivity is set to be 1e-5 $\text{m}^2 \text{s}^{-1}$ in both phases. The analytical solution for equation (25) can be found in
372 Bird (Bird, 2002).

373 Three scenarios with low, neutral, and high affinity of the volatile compound towards the gaseous phase
374 are considered with corresponding Henry coefficients of 0.01 (low volatility, similar to naphthalene), 1
375 (moderate volatility, e.g., vinyl chloride) and 100 respectively (high volatility, e.g. heptane). For a low
376 value of H ($H = 0.01$ – Figure 4-b) little (almost no) tracer is crossing the interface, while at neutral
377 condition ($H = 1$ – Figure 4-c), tracer diffusion is invariant to the phase it is occupying. Evidently for
378 high values of H ($H = 100$ – Figure 4-d), strong depletion of the tracer in aqueous phase as well as the
379 concentration jump across the interface are observed. The numerical results are ubiquitously identical to
380 the results of the analytical solution (Figure 4-b, c, d).

381

382 **Figure 4:** (a) A schematic of the fluid distributions at initial condition. The solid and dotted lines show the analytical solutions
 383 with purple and yellow squares depicting the numerical solutions. Comparison of the analytical and numerical solutions of tracer
 384 distribution at two distinct time points of $t_1=5\text{ms}$ and $t_2=50\text{ms}$ for (b) $H = 0.01$, (c) $H = 1$, and (d) $H = 100$.

385

386 3.3 Microbial Growth and Reactive Transport

387 Our modelling framework can parameterize any type of reactions, we put the main focus in this
 388 subsection on microbially driven redox transformations (i.e. a type of reactions commonly encountered in
 389 soils and other porous media environments) and on the implementation of the corresponding
 390 mathematical formulation. To validate our model with a scenario in which bacterial biomass is allowed to
 391 evolve (i.e. to grow and to decay) we adapted a conceptual biodegradation scenario from Cirpka and
 392 Valocchi (2007b) in which a fully-water-saturated, two-dimensional domain is subjected to a constant
 393 flux of two different components; ED (electron donor – e.g. hydrocarbon) and EA (electron acceptor –
 394 e.g. oxygen). The bacteria residing in the channel, facilitate the reaction between ED and EA, which can
 395 be written in an abstract form as $f_a ED + f_b EA \xrightarrow{\text{biomass}} f_c Prod$, where *biomass* is the microbial
 396 biomass, *Prod* is the product(s) (e.g. metabolites such as carbon dioxide) and f_a, f_b and f_c are

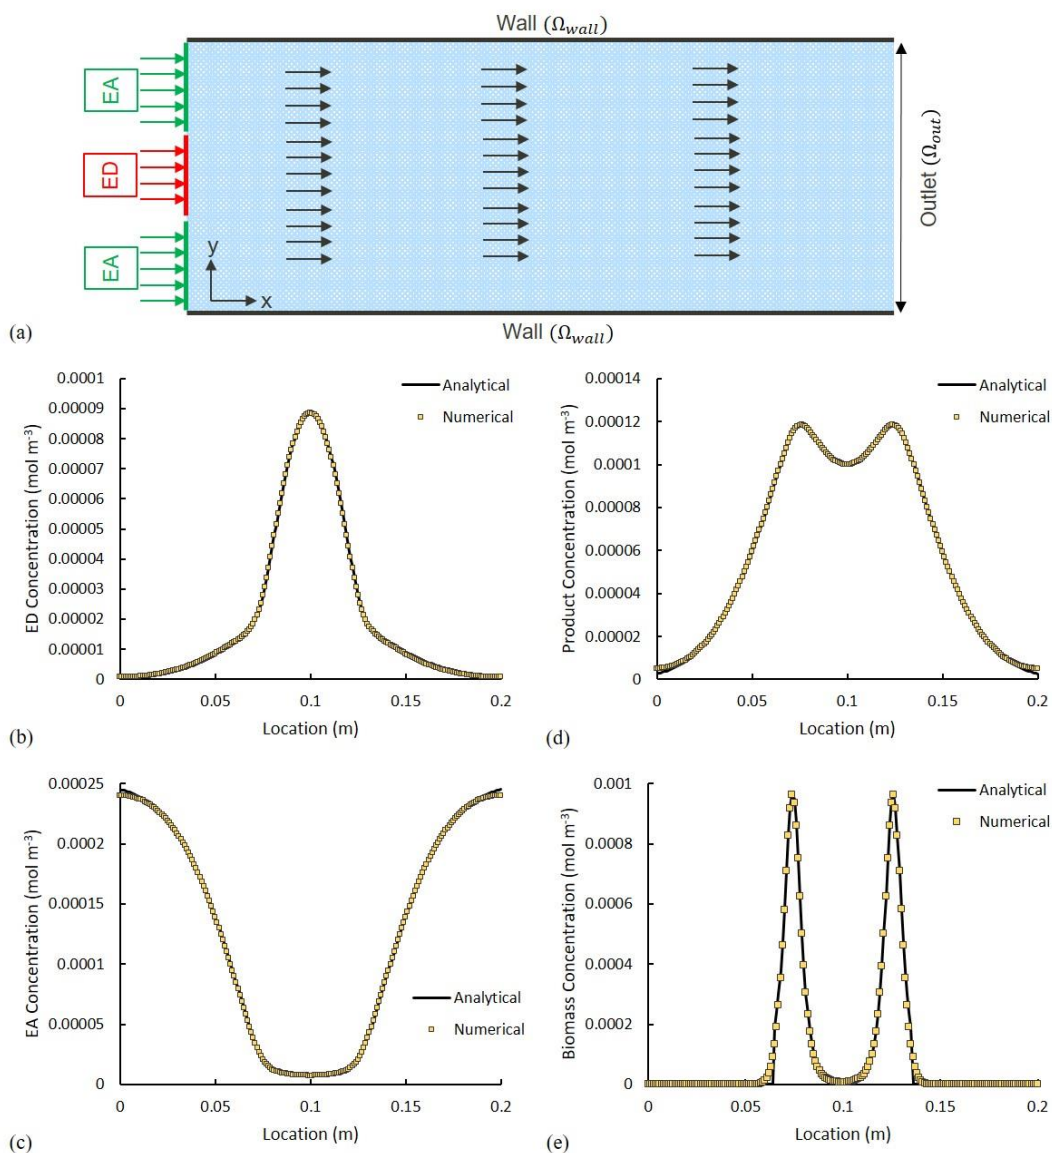

397 stoichiometric coefficients. Assuming a double-Monod kinetics for expressing microbial growth and the
 398 microbially driven reaction rates, as well as assuming none of the reactants nor products are involved in
 399 secondary reactions, the ADRE (eq. (12)) for each chemical species can then be written as:

$$\begin{aligned}
 \frac{\partial C_{ED}}{\partial t} + \mathbf{u} \frac{\partial C_{ED}}{\partial x} - D_t \frac{\partial^2 C_{ED}}{\partial y^2} &= -\frac{C_{ED}}{C_{ED} + K_{ED}} \frac{C_{EA}}{C_{EA} + K_{EA}} \frac{\mu_{max}}{Y} f_a C_{bio} & \text{in } \Omega_\theta \\
 \frac{\partial C_{EA}}{\partial t} + \mathbf{u} \frac{\partial C_{EA}}{\partial x} - D_t \frac{\partial^2 C_{EA}}{\partial y^2} &= -\frac{C_{ED}}{C_{ED} + K_{ED}} \frac{C_{EA}}{C_{EA} + K_{EA}} \frac{\mu_{max}}{Y} f_b C_{bio} & \text{in } \Omega_\theta \\
 \frac{\partial C_{Prod}}{\partial t} + \mathbf{u} \frac{\partial C_{Prod}}{\partial x} - D_t \frac{\partial^2 C_{Prod}}{\partial y^2} &= \frac{C_{ED}}{C_{ED} + K_{ED}} \frac{C_{EA}}{C_{EA} + K_{EA}} \frac{\mu_{max}}{Y} f_c C_{bio} & \text{in } \Omega_\theta \\
 \frac{\partial C_{bio}}{\partial t} &= \frac{C_{ED}}{C_{ED} + K_{ED}} \frac{C_{EA}}{C_{EA} + K_{EA}} \mu_{max} C_{bio} - \lambda C_{bio} & \text{in } \Omega_\theta
 \end{aligned} \tag{26}$$

400 where \mathbf{u} is the velocity (which has only a constant x -component), D_t is the transverse dispersivity,
 401 C_{ED} , C_{EA} , C_{Met} and C_{bio} are concentrations of ED , EA , $Prod$ and $biomass$ respectively; K_{ED} and K_{EA} are
 402 half saturation constants for respective compounds in the biomass growth term, Y is the yield coefficient,
 403 μ_{max} is the maximum bacterial growth rate, and λ is the bacterial decay rate. Using these equations
 404 Cirpka and Valocchi (2007a) developed an analytical solution for steady-state conditions, which in the
 405 version of Cirpka and Valocchi (2009) is used as reference for the numerical results.

406 The numerical experiment is designed to have ED and EA , occupying 25% and 75% of the inlet
 407 respectively, and, simultaneously, invading the domain under a constant uniform velocity field, with
 408 concentration of C_{ED}^{inlet} and C_{EA}^{inlet} . In a real-world scenario, this can be seen as a plume of a contaminant
 409 (i.e. a hydrocarbon as ED) being carried into the domain within an oxygenated stream and essentially we
 410 are interested in knowing the final concentration/distribution of all bio-chemical species within the
 411 domain. The parameters used in this scenario are summarized in Table 1. Transient reactive transport
 412 simulations are performed until a steady state is achieved. For validation, we analyze all concentration
 413 profiles along the y -axis at a fixed distance of $x = 2$ m and compare them with the analytical solutions.
 414 The analytical and numerical results show an almost perfect agreement (Figure 5, b-e).

415

416 **Figure 5:** (a) Model set up. The arrows show the direction of the flow field. Solid lines show the analytical solution and the
 417 yellow squares illustrate the numerical results. (b-e) Comparison of the analytical and numerical solutions $x=2\text{m}$
 418 concentration of (b) *Electron Donor*, (c) *Electron Acceptor*, (d) *Product*, and (e) *Biomass*.

419

420

421

Table 1: Parameter values used for simulating microbial growth.

Parameter	Value	Unit	Parameter	Value	Unit
\mathbf{u}	100	$cm\ d^{-1}$	μ_{max}	1	d^{-1}
Domain width	20	cm	Domain length	500	cm
D_t	2.5	$cm^2\ d^{-1}$	λ	0.1	d^{-1}
f_a, f_b, f_c	1	-	K_{ED}	8.33e-2	mM
C_{ED}^{inlet}	0.33	mM	K_{EA}	3.13e-2	mM
C_{EA}^{inlet}	0.25	mM	Y	1	-
Mesh size	0.2	mm			

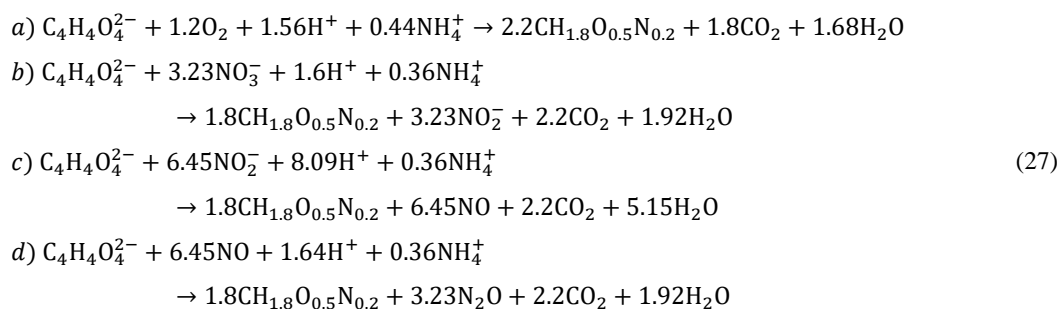

422

423 3.4 Theme: Demonstrating Model Capabilities

424 The scenarios described above are designed to serve as the sole purpose of creating a baseline for
425 validating the numerical toolbox – simple enough where analytical solutions could exist. Unlike the
426 simplicity introduced in previous sections, simulating soil processes with all of the complexities, though,
427 would require having all the modelling elements to be present. We thus present here a scenario with an
428 unsaturated soil hosting the facultative anaerobic bacteria *Agrobacterium tumefaciens*, which performs
429 aerobic respiration under oxic condition, but switches to denitrification using nitrate, nitrite or nitric oxide
430 under anoxic condition (Kampschreur et al., 2012). This example allows us to show our model
431 capabilities, as it involves 1) the actual micro structure of the soil, 2) unsaturated conditions, and 3) an
432 enzymatic reaction network with limiting/inhibition terms. The microstructure is obtained via
433 subsampling from a larger μ -CT image with voxel size of 6 micron (see Supplementary Information). A
434 two-phase simulation is then performed on the voxelized subsample to obtain the fluxes and phase
435 distribution of air and water within the pore space. For this, the entire domain is initially filled with water
436 and subject to injecting air from the top boundary with constant flux of $0.013\ ml\ h^{-1}$. An important note to
437 make here is with a relatively high influx, advection transport acts as the bottleneck for numerical time
438 steps. Hence, reactions are performed at a quite slower pace (i.e. larger time steps). This separation of
439 processes helps improve the overall run-time of the simulations. Fluids are allowed to leave the domain
440 from the bottom part (kept at atmospheric pressure) while all the remaining sides are set to be
441 impermeable walls. Once fluid configurations in the domain are stationary, their distribution along with
442 the velocity profile are used as basis for the reactive transport simulations (phase distributions can be
443 found in the Supplementary Information). Using succinate ($C_4H_4O_4^{2-}$) as organic carbon substrate to be
444 degraded, a metabolic reaction network is constructed with four microbial degradation pathways each

445 following Monod-type kinetics: 1) aerobic respiration with a nitric oxide (NO) inhibitory term, 2) nitrate
 446 (NO_3^-) reduction, 3) nitrite (NO_2^-) reduction and 4) NO reduction, with having oxygen (O_2) as inhibitory
 447 element for all denitrification conversions (eq. (27)). Also three additional equations are considered for the
 448 synthesis of the three different enzymes required for degradation processes (eq. (28)). We consider only
 449 one single strain of bacteria (*Agrobacterium tumefaciens*) which has the benefits of performing both
 450 aerobic respiration and denitrification. Bacteria are considered to be non-motile with an initial
 451 concentration of 0.25 mol m^{-2} and uniformly covering the entire grain surface area. Succinate has its
 452 initial concentration in the aqueous phase set at 0.2 mM (0 mM in the gaseous phase), while all other
 453 species have their initial concentrations of 0 mM in both aqueous and gaseous phases. Boundary condition
 454 for all concentration fields on all boundaries is set to zero gradient except for the inlet boundary (fully
 455 saturated with air) - where for oxygen it is set to 0.03567 mM , and for all others is set to 0 mM . In order to
 456 avoid depletion of the nitrate in the system, a nitrate concentration of $0.1 \mu\text{M}$ (as initial condition) is
 457 provided. The complete reaction network can be written as follows (Kampschreur et al., 2012):

458 Several assumptions are made for preparing the kinetics of the reactions: 1) reaction rates are limited by
 459 the maximum specific uptake rate of succinate and are hence independent of its concentration (Beun et
 460 al., 2000), 2) sufficient amount of buffer is added to the solution to keep the pH level constant, 3) three
 461 nitrogen reductase enzymes ($\xi_{sat,NOR}$ for NO reduction, $\xi_{sat,NIR}$ for nitrite reduction and $\xi_{sat,NAP}$ for
 462 nitrate reduction) can have saturation values varying between 0 (i.e. non-existing) and 1 in a bacterial cell,
 463 and 4) inhibitory oxygen limits the reduction of NO , NO_2^- and NO_3^- . Reaction rates are designed to have a
 464 dependency on the enzymes' level and biomass concentration with proper limiting/inhibiting terms.
 465 Equation (12) is used to describe the evolution of each biochemical species. The final system of
 466 advective-diffusive-reactive equations is adapted from (Kampschreur et al., 2012):

$$\begin{aligned}
 \frac{\partial C_i}{\partial t} + \nabla \cdot (C_i \mathbf{u}) &= -\nabla \cdot \left(D_i \nabla C_i - D_i \frac{1 - H_i}{\alpha + (1 - \alpha)H_i} C_i \nabla \alpha \right) + R_i, \\
 i &= suc, O_2, NO_3^-, NO_2^-, NO, N_2O \quad \text{in } \Omega_g
 \end{aligned} \quad (28)$$

$$\begin{aligned}
 R_{suc} &= -(r_{suc,O_2} + r_{suc,NAP} + r_{suc,NIR} + r_{suc,NOR}) \\
 R_{O_2} &= -1.2r_{suc,O_2} \\
 R_{NO_3^-} &= -3.23r_{suc,NAP} \\
 R_{NO_2^-} &= 3.23r_{suc,NAP} - 6.45r_{suc,NIR} \\
 R_{NO} &= 6.45r_{suc,NIR} - 6.45r_{suc,NOR} \\
 R_{N_2O} &= 3.23r_{suc,NOR} \\
 r_{suc,O_2} &= \mu_{max} C_{bio} \frac{C_{O_2}}{K_{O_2} \left(1 + \frac{C_{NO}}{K_{I,NO,O_2}}\right) + C_{O_2}} \\
 r_{suc,NAP} &= \mu_{max} C_{bio} \xi_{sat,NAP} \frac{C_{NO_3}}{K_{NO_3} + C_{NO_3}} \frac{K_{I,O_2,NAP}^{nNAP}}{K_{I,O_2,NAP}^{nNAP} + C_{O_2}^{nNAP}} \\
 r_{suc,NIR} &= \mu_{max} C_{bio} \xi_{sat,NIR} \frac{C_{NO_2}}{K_{NO_2} + C_{NO_2}} \frac{K_{I,O_2,NIR}^{nNIR}}{K_{I,O_2,NIR}^{nNIR} + C_{O_2}^{nNIR}} \\
 r_{suc,NOR} &= \mu_{max} C_{bio} \xi_{sat,NOR} \frac{C_{NO}^2}{\left[C_{NO} \left(1 + \frac{C_{NO}}{K_{I,NO}}\right) + K_{NO}\right]^2} \frac{K_{I,O_2,NOR}}{K_{I,O_2,NOR} + C_{O_2}} \\
 \frac{d\xi_{sat,NAP}}{dt} &= v_{m,NAP} \frac{C_{NO_3}}{K_{NO_3,NAP} + C_{NO_3}} \frac{K_{I,O_2,NAP}}{K_{I,O_2,NAP} + C_{O_2}} (1 - \xi_{sat,NAP}) \\
 \frac{d\xi_{sat,NIR}}{dt} &= v_{m,NIR} \frac{C_{NO_2}}{K_{NO_2,NIR} + C_{NO_2}} (1 - \xi_{sat,NIR}) \\
 \frac{d\xi_{sat,NOR}}{dt} &= v_{m,NOR} \frac{C_{NO}}{K_{NO,NOR} + C_{NO}} (1 - \xi_{sat,NOR}) \\
 \frac{dC_{bio}}{dt} &= 2.2r_{suc,O_2} + 1.8(r_{suc,NAP} + r_{suc,NIR} + r_{suc,NOR})
 \end{aligned}$$

467 The full list of modelling parameters used for this study can be found in **Error! Reference source not**
 468 **found.** (see Supplementary Information).

469 Reactive transport simulations were performed until a quasi-steady state was achieved. This was
 470 characterized by all chemical species concentrations reaching a steady-state as determined by the
 471 degradation activity of the given distribution of microorganisms. Since microbial growth takes place at
 472 much larger time scales than the pore-scale transport processes no significant growth takes place during
 473 the simulated time period. Simulation results show that the presence of air in this two-phase system
 474 affects the distribution of biochemical species. Air, as the non-wetting phase, occupies the central part of
 475 the pore space while the aqueous phase is expected to cover the corners and crevices (Figure 6, a). For

476 oxygen with $H_{O_2} = 31$ a higher concentration is observed in the air compared to that of the adjacent
477 aqueous phase (Figure 6, d). An analysis of how the volatility of a tracer compound may affect its
478 residence time in the porous medium is given in the Supplementary Information. Since the biomass is
479 only present on the grain surfaces (Figure 6, b), oxygen, nitrate and succinate deplete as the microbially-
480 mediated reactions only at these micro-locations. Fresh oxygen and nitrate thus need to diffuse from the
481 bulk (either from the aqueous phase or the air) to the reactive sites. The regions with high (i.e. not
482 degraded) succinate concentrations are compatible with low concentration regions of oxygen and nitrate,
483 i.e. the reactions are limited by the bioavailable oxygen and nitrate (Figure 6, b-e). Finally, all three
484 enzymes have an increased abundance in anaerobic regions with an active biomass (saturation map of
485 nitrate reductase enzyme is shown in Figure 6, e). While the saturation of nitrate reductase enzyme grows
486 linearly with time (until 0.25 s), the rate at which the nitrite and NO reductase enzymes ($\xi_{sat,NIR}$ and
487 $\xi_{sat,NOR}$ respectively) growth is rather slow for the very beginning of the simulation (until ~0.2 s), but it
488 surges exponentially afterward. A spatially integrated assessment of the degradation processes showed
489 that for the presented example 99% of the total succinate degradation is attributed to aerobic respiration
490 while a trivial amount is attributed to the three anaerobic processes (nitrate reduction, nitrite reduction and
491 NO reductions).

492 The presented results highlight the ability of the model to combine a high-resolution simulation of multi-
493 phase flow and transport processes with the simulation of complex biogeochemical processes. This allows
494 for a realistic simulation of the micro-scale distribution of reactive processes and for the derivation of an
495 accurate aggregated description of these processes.

496

497 Figure 6: Cross-sectional view of the three dimensional porous medium. The opaque grayish background represents the 3D
498 porous structure that is extracted and digitized from a μ -CT image. The colored surfaces are obtained by running a cutting plane
499 through the middle of the sample and perpendicular to the z-axis. The distribution of (a) water saturation (i.e. water volume
500 fraction), (b) biomass, (c) succinate, (d) oxygen, (e) nitrate and (f) nitrate reductase enzyme are respectively depicted with having
501 yellow color indicating highest value and light blue as the lowest value. With air as the non-wetting phase, it is expected to fill
502 the middle of the pore space where capillary pressure is lower while water, as the wetting phase, is expected to occupy the
503 corners (figure a). A high volatility constant for oxygen enforces to have higher concentrations of oxygen in the air compared to
504 that of aqueous phase adjacent to the water-air interface.

505 As it can be seen from Figure 6, our model can be used (among other options) to identify clusters in
506 which succinate is most and least depleted. This would ease the process of analyzing the results by
507 isolating the parameters that are boosting/limiting the degradation of the carbon source. 3D visualization
508 of the oxygen and succinate distributions can be found in Golparvar et al. (2022).

509 **4. Conclusion and future remarks**

510 In this paper, we have presented a newly developed modelling framework for simulating reactive
511 transport processes in real porous soil structures obtained from μ -CT images under unsaturated
512 conditions. The successful application of various benchmark test showed the model's accuracy in the
513 simulation of 1) the movement of water and air phase in variably saturated conditions via the enhanced
514 algebraic Volume of Fluid method (Raeini et al., 2012) coupled with the Navier Stokes equation, 2) the
515 transport of different species in both phases by the full advective-diffusive transport equation, and finally
516 3) using the operator splitting technique, an arbitrary set of biogeochemical reactions solved externally by
517 the Biogeochemical Reaction Network Simulator and communicated back into the main solver.

518 The presented model provides a novel and unique combination of pore-scale simulations of two-phase
519 flow, transport of dissolved and volatile species and their reactive transformations. This makes it an
520 accurate and powerful tool for the simulation of soil systems or other unsaturated porous media and of the
521 reactive transport processes therein. While developed with the aim for simulating biogeochemical
522 processes in soils the model is equally applicable for simulating other abiotic reactive processes coupled
523 to the dynamics of flow and transport in variably saturated pore structures of arbitrary geometry. Our
524 modelling framework is properly designed for simulating biogeochemical processes such as carbon-
525 nitrogen-sulfur-phosphorus cycles in soil as well as mixing and migration of contaminants in both
526 unsaturated soil and water aquifers. It comes with the benefit of explicit recognition of the soil structure,
527 phase dynamics/distributions and the capability of designing the complete redox reactions necessary for a
528 given process in a straightforward fashion. It is best suitable for running pre-pilot tests as feasibility
529 scenarios where the stakes for the success of the project are high. Also our model provides the best tool
530 for designing hypothetical experiments that are hard (if not impossible) to implement experimentally (e.g.
531 a specific distribution of biomass/reactants within the domain, or variation of specific properties of
532 reactive compound and/or the porous matrix). Furthermore, the high resolution modelling results
533 provided by this model support the upscaling of reactive-transport process description from the pore to
534 the continuum scale and from the process to the observation scale, respectively.

535 Although the current version of our numerical model is already covering a wide range of bio-physio-
536 chemical properties of the soil constituents, for having more realistic representation of multiphase,

537 multicomponent reactive transport in partially saturated porous media, few more factors still might be
538 considered in future developments of the model: 1) shrinkage/expanding of the air/aqueous phase due to
539 mass transfer of chemical species across fluid-fluid interface, 2) accounting for gas compressibility by
540 adding an equation of state for tracking changes of air volume/density under flowing condition, 3)
541 translating accumulated biomass on the grain surfaces into new flow-resistance components which would
542 potentially change the velocity streamlines (i.e. bioclogging), 4) changes of the grain surface structures
543 and of the associated solid-liquid interface due to mineral precipitation/dilution or due to
544 accumulation/depletion of solid organic material and 5) chemotactic behavior of the microbial species.

545 **5. Acknowledgements**

546 This work was funded by the Helmholtz Association via the integrated project “Controlling Chemicals
547 Fate.”

548 **6. Code and data availability**

549 The source codes, benchmark and demonstration cases along with instruction for installing and running
550 each case that are presented in this paper, are archived at <https://github.com/amirgolp/P3D-BRNS> DOI:
551 [10.5281/zenodo.6301317](https://doi.org/10.5281/zenodo.6301317).

552 **7. Author contributions**

553 AR was responsible for model/software curation, validation and visualization. Conceptualization and
554 methodology development were managed by AR, MK, and MT. Writing the original manuscript was
555 handled by AR while all authors contributed to the revision and curation of the final draft. The entire
556 work is supervised by MT.

557 **8. Competing interests**

558 The authors declare that they have no conflict of interest.
