13 Abstract.

14 We examine the impact of horizontal resolution and model time step on climate of the OpenIFS version 43R3 atmosphere

15 general circulation model. A series of simulations for the period 1979-2019 are conducted with various horizontal resolutions

16 (i.e., ~100, ~50, and ~25 km) while maintaining the same time step (i.e., 15 minutes) and using different time steps (i.e., 60,

17 30 and 15 minutes) at 100 km horizontal resolution. We find that the surface zonal wind bias reduces significantly over certain

18 regions such as the Southern Ocean, the Northern Hemisphere mid-latitudes, and in tropical and subtropical regions at high

19 horizontal resolution (i.e., ~25 km). Similar improvement is evident too when using a coarse resolution model (~100 km) with

20 a smaller time step (i.e., 30 and 15 minutes). We also find improvements in Rossby wave amplitude and phase speed as well

21 as weather regime patterns when a smaller time step or higher horizontal resolution is used. The improvement in the wind bias

22 when using the shorter time step is mostly due to an increase in shallow and mid-level convection that enhances vertical mixing

23 in the lower troposphere. The enhanced mixing allows frictional effects to influence a deeper layer and reduces wind and wind

24 speed throughout the troposphere. However, precipitation biases generally increase with higher horizontal resolution or smaller

25 time step, whereas the surface-air temperature bias exhibits a small improvement over North America and the Eastern Eurasian

26 continent. We argue that the bias improvement in the highest horizontal resolution (i.e., ~25 km) configuration benefits from

27 a combination of both the enhanced horizontal resolution and the shorter time step. In summary, we demonstrate that by

28 reducing the time step in the coarse resolution (~100 km) OpenIFS model, one can alleviate some climate biases at a lower

29 cost than by increasing the horizontal resolution.

36 1. Introduction

In the last few decades, Atmospheric-Ocean General Circulation Model (AOGCM) simulations from the Coupled Model 37 38 Intercomparison Project (CMIP) have been widely used to study the internal climate variability and the climate response to 39 external forcing such as increasing atmospheric greenhouse gas concentrations causing global warming. These simulations, 40 however, suffer from long-standing biases (Bavr et al., 2018: Flato et al., 2014: Gates et al., 1999: Kim et al., 2014: Zhou 41 et al., 2020), which lead to significant uncertainties in short-term and long-term climate projections and potential ecosystem impacts (Athanasiadis et al., 2022; Couldrey et al., 2021; Meehl and Teng, 2014; Meng et al., 2022). These biases can 42 43 arise from a variety of sources, including inaccurate representation of physical processes, poor initialization of model 44 conditions, or inadequate representation of the Earth's topography and land cover. 45 46 Simulations using Atmospheric General Circulation Models (AGCMs) from the Atmosphere Model Intercomparison Project (AMIP), a part of CMIP, are used to study the internal variability of the atmosphere. The AGCMs are less complex than the 47 AOGCMs as the former are constrained by observed Sea Surface Temperature (SST) and Sea Ice Concentration (SIC). Despite 48 being constrained by the observations, the AGCMs also exhibit biases (e.g., Gates et al., 1999), and some of these biases have 49 50 persisted for over several phases of AMIP (He and Zhou, 2014). The biases in AGCMs are largely due to the fact that many 51 unresolved processes, such as atmospheric convection, precipitation, clouds, cloud-microphysical and aerosol processes, boundary layer processes, and interactions between the land surface and hydrologic processes, have to be included in a 52 parameterized form in the coarse resolution model (Ma et al., 2022). The treatment of unresolved gravity waves and the 53 relatively large model time step also contribute to the biases in AGCMs (Flato et al., 2014; Gates et al., 1999). 54 55 Recently, Liu et al. (2022) analyzed AOGCM simulations and reported that increasing the horizontal resolution of the ocean 56 57 component one can reduce SST and precipitation biases in the equatorial Pacific, whereas increasing the horizontal resolution of the atmospheric component did not have the same effect. However, other studies found that a high-horizontal resolution 58 atmosphere model better simulates the main features of tropical precipitation, tropical atmospheric circulation, and extra-59 tropical cyclones while increasing from 125 km to 40 km horizontal resolution with relatively small improvements for further 60 enhanced horizontal resolution (Branković and Gregory, 2001; Jung et al., 2012; Williamson et al., 1995). Similarly, 61 Roberts et al. (2018) found that there was not much improvement in the Integrated Forecasting System (IFS) from the 62 63 European Centre for Medium-Range Weather Forecasting (ECMWF) when increasing horizontal resolution from 50 to 25 km. 64 Jung et al. (2012) and Roberts et al. (2018) demonstrated a time step sensitivity in the coarse and high horizontal resolution 65

66 model simulations using the JFS model. Jung et al. (2012) found that the precipitation and wind biases were reduced at the

Deleted: are

Deleted: moving

Deleted: moving

Deleted: OpenIFS and

coarse horizontal resolution when shortening the model time step from 60 to 15 minutes. Roberts et al. (2018) did not find 72 73 such a significant improvement when reducing the model time step from 20 to 15 minutes in their high-resolution (~25 km) 74 configuration. However, both studies did not investigate the model's sensitivity to changes in the model time step in detail. While the semi-implicit semi-Lagrangian scheme, as used in OpenIFS, is unconditionally stable and the time step can be 75 76 chosen to be very long, a shorter time step generally leads to a decrease in truncation error in the finite differences and thus a 77 more accurate representation of the model dynamics. The physics parameterisations, which are computed independently of each other in OpenIFS, also benefit from a shorter time step as it will allow the various parameterisations to be coupled at a 78 79 higher frequency (Beljaars et al., 2018). However, model parameters for e.g., convection or diffusion may be tuned for a 80 specific time step and shortening the time step can therefore, in some cases, increase model error. Hence, a shorter model time 81 step is expected to reduce biases in model dynamics, e.g., winds, while the results for parameterised processes, e.g., 82 precipitation, may be mixed.

83

84 In the research community, there is no standard definition for coarse horizontal resolution, as one study considered 200 km as a coarse resolution ($\sim 2^{\circ}$) configuration (**Branković and Gregory**, 2001), whereas another study considered 50 km (0.5°) as a 85 coarse resolution (Roberts et al., 2018). Likewise, there is no unique rule for setting the model time step dependent on model 86 87 resolution. Groups using either the IFS or OpenIFS model at horizontal resolutions of ~100 km have used a relatively long time step of 1 hour (Hazeleger et al., 2012; Kjellsson et al., 2020; Streffing et al., 2022) or 45 minutes (Döscher et al., 88 2022), while other groups using the ARPEGE-Climat with a similar dynamical core use 15 minutes (Voldoire et al., 2019). 89 90 The model's horizontal resolution and time steps are rather chosen on what can be afforded computationally, and their relative 91 contributions to biases in the model's climate are not well documented.

92

93 In this study, we systematically investigate the sensitivity of the OpenIFS model version 43r3v2 to the model time step and 94 horizontal resolution. We mostly focus on the surface zonal winds since they play a crucial role for the ocean circulation in 95 the AOGCMs. We also study the representation of the synoptic-scale variability such as Rossby waves and weather regimes. 96 The paper is structured as follows: section 2 describes the model, experimental design, data and methodology; section 3

97 describes the results and section 4 summarizes the conclusions of this work.

98 2. Model, Experimental design, Data and Methodology

We conducted a series of experiments with the OpenIFS model. The OpenIFS model is derived from the Integrated Forecasting System at the European Centre for Medium-range Weather Forecasting (ECMWF-IFS) cycle 43 release 3 (43r3). The dynamical core is the same as ECMWF-IFS that uses a two-time-level semi-implicit time stepping with semi-Lagrangian advection (Temperton et al., 2001) on a reduced Gaussian grid with a hybrid-sigma vertical coordinate (Simmons and Burridge, 1981). Likewise, the OpenIFS uses the same model physics as the ECMWF-IFS (cf. Forbes and Tompkins, 2011; Hogan and Bozzo, 2018; Tiedtke, 1993) but does not include the tangent-linear code or 4D-VAR capabilities. Our version,
 OpenIFS, is similar to cy43r1 used in Roberts et al., (2018), with the main difference being the new radiation scheme, ecRad
 (Hogan and Bozzo, 2018), introduced in cy43r3.

107

108 Our study is partly motivated by evaluating the suitability of various OpenIFS configurations for coupled climate simulations

109 with FOCI-OpenIFS (Kjellsson et al., 2020) with an atmosphere horizontal resolution higher than that of ECHAM6 Tq63/N48

110 (\sim 200km) in FOCI (Matthes et al., 2020). Our choices thus fall on three different horizontal resolutions: a low-resolution 111 ($T_{co}95$, ~100 km), a medium-resolution ($T_{co}199$, ~50 km), and a high resolution ($T_{co}399$, ~25 km). The Tco95 grid is the lowest 112 acceptable resolution since the supported lower-resolution grids, e.g., Tl95/N48 and Tq42/F32, are either similar to Tq63 in 113 ECHAM6 or coarser. The Tco399 grid was chosen as an upper limit of what is computationally feasible for AMIP integrations 114 and century-long coupled integrations given our computer resources. All the configurations share the same vertical L91 grid. 115 We did not modify any other model parameters when changing the model horizontal resolutions or model time steps, but we 116 note that some parameters such as launch momentum flux for non-orographic gravity waves scales with resolution in the

117 model. We performed 5 experiments in total (**Table 1**). For simplicity, we now refer now OpenIFS as OIFS in the rest of the 118 sections.

119

120 The lower boundary conditions, i.e., SST and SIC, are taken the from Atmospheric Model Intercomparison Project (AMIP) version 1.1.6 (Evring et al., 2016; Taylor et al., 2012), which are available as monthly means on a 1°x1° horizontal grid. The 121 122 external forcing is identical to that used in the CMIP6 AMIP simulations except for the aerosol and ozone concentrations, 123 which are taken from monthly mean climatology. SST and SIC are interpolated from monthly to daily frequency and from 124 1ºx1º horizontal resolution to the OIFS horizontal grid using bilinear interpolation. All the simulations are run for the period 125 1979-2019. We extend the simulations beyond the AMIP protocol for 1979-2014 up to 2019 by using SST and SIC from the 126 ERA5 reanalysis and the Shared Socioeconomic Pathways 5 (SSP5-8.5) emission scenario. Ozone concentrations are taken from monthly photochemical equilibrium state and aerosol concentrations from monthly CAMS climatology of 11 species. 127 128

129 Amplitude and phase speed of Rossby wave were computed by performing a Fourier decomposition analysis on 300 hPa daily meridional winds. First, we interpolated both ERA5 and OIFS simulation datasets onto a 2.5° x 2.5° grid using bilinear 130 131 interpolation. We then applied the Fourier decomposition analysis to determine amplitude and position for each Rossby wave 132 number at each latitude as a function of time. Phase speed is computed as the difference in the daily position of each wave, 133 and stored at the midpoints in the time dimension. For consistency, wave amplitudes are interpolated to the midpoints in time 134 as well. Lastly, seasonal averages are computed from the daily data for the boreal and austral winter seasons over the time 135 period 1979-2019. In the case of phase speed, it is weighed by the corresponding daily (midpoint) amplitude squared when 136 computing the seasonal averages in order to account for the impact of higher-amplitude events. The results are presented in

137 wavenumber-latitude diagrams similar to previous studies (e.g., Pilch Kedzierski et al., 2020; Wolf and Wirth, 2017). Our

Deleted: The Rossby-wave amplitude and phase speed were computed for the boreal and austral winter seasons respectively using daily values of amplitude and phase speed over the time period 1979–2019. The phase speed is weighed by daily amplitude squared when computing the seasonal averages

144 wavenumber-latitude analysis is not directly comparable to both studies mentioned above, because we did not apply any high-145 pass filtering in time before the Fourier decomposition. While the previous literature had similar diagrams with varying 146 measures of wave amplitude, our detailed analysis of phase speed in such a manner is novel in literature to our knowledge and 147 a strong addition as a model performance diagnostic.

148

149 The Weather Regime Patterns (WRPs) were calculated using daily 500-hPa geopotential height (z500) anomalies over the Euro-Atlantic region (30°-90 °N, 80 °W-40 °E) for the boreal winter season during the period 1979-2019. The daily z500 150 daily anomalies were computed by subtracting the daily climatology smoothed by a 20-day running mean from the raw z500 151 152 data. We calculated the first four Empirical Orthogonal Functions (EOFs) from the ERA5 dataset. In the next step, the OIFS-153 simulated z500 anomalies were projected on the ERA5 EOFs to obtain Pseudo-Principal Components (Pseudo-PCs). We then applied a K-means clustering algorithm to the individual model pseudo-PCs and observation PCs using four clusters. We chose 154 155 four clusters because these give the most of the significant clustering. Spatial WRPs are obtained by compositing over all daily z500 anomalies for each regime. More information about the methodology can be found in Fabiano et al. (2020), section 3.1. 156 In order to evaluate the WRPs simulated by the OIFS across configurations more quantitatively, we have additionally estimated 157 the Pearson's Pattern Correlation Coefficient (PCC) between the WRPs identified in the model and ERA5. 158

159

We compare the climate of OIFS to observational and reanalysis datasets. Precipitation is validated against the Global Precipitation Climatology Project (GPCP; Huffman et al., 1997), and the surface air temperature (SAT) against the CRUTEM4 (Harris et al., 2014; Osborn and Jones, 2014). We have used the ERA5 reanalysis (Hersbach et al., 2020) to evaluate 10-meter surface wind as well as the zonal wind at 300 hPa for the Rossby wave analysis. We use z500 from ERA5 to validate the OIFS-simulated weather regimes. We also compare our results with the MERRA2 reanalysis (Gelaro et al., 2017) and find similar results. Therefore, the comparison with MERRA2 is not shown. The bootstrapping (in total 2000 iterations) method is used to compute the 95% confidence interval for the RMSE and the WRPs correlation.

167 3. Results

168 3.1.1 Global and regional surface bias and deriving processes

The annual mean 10m zonal wind (surface wind hereafter) bias during the period 1979–2019 for the different OIFS configurations is shown in **Fig. 1**. We find that the OIFS-LRA-1h configuration has a large surface wind bias over most of the world ocean, with positive biases in the mid-latitudes (the Southern Ocean, North Atlantic and North Pacific) and negative surface wind biases over the tropical oceans (Tropical Pacific, Tropical Indian and Atlantic Ocean) (**Fig. 1b**). Thus, the OIFS-LRA-1h configuration simulates too strong surface westerly winds (and wind speed) over the mid-latitude oceans, which, if coupled to an ocean model, may cause biases in upper-ocean mixing and oceanic uptake of heat and carbon.

175

The surface wind bias in the OIFS-HRA-15m configuration is reduced significantly (Fig. 1f) over most of the world ocean 176 177 compared to the OIFS-LRA-1h configuration (Fig. 1b), indicating that increasing the horizontal resolution from 100 km to 25 178 km and shortening the time step from 1h to 15-min improves the representation of the surface winds. The surface wind bias 179 also significantly reduces everywhere in the OIFS-MRA-15m configuration (Fig. 1e) compared to the OIFS-LRA-1h 180 configuration (Fig. 1b). The surface wind bias in OIFS-MRA-15m is larger than that in the OIFS-HRA-15m configuration but 181 smaller than that in the OIFS-LRA-1h configuration. Similar conclusions are obtained by performing Root Mean Square Error (RMSE) analysis, which shows that the OIFS-HRA-15m configuration has the lowest annual and global mean RMSE of 182 183 surface wind while the OIFS-LRA-1h configuration has the highest RMSE (Fig. 2a, black line). Though we have found a 184 significant improvement in the wind bias in the OIFA-HRA-15m configuration, it is not clear yet whether the improvement is 185 due to the increased horizontal resolution or the shorter time step.

186

Surface wind bias is also reduced in both the OIFS-LRA-30m (Fig. 1c) and OIFS-LRA-15m (Fig. 1d) configurations compared to the OIFS-LRA-1h configuration (Fig. 1b), and the bias improvement is mostly observed at the same places as in the OIFS-HRA-15m configuration (Fig. 1f). The surface-wind bias improvement is similar in the OIFS-LRA-30m and OIFS-LRA-15 configurations, except over the North Pacific and Southern Ocean where the OIFS-LRA-15m configuration has a smaller wind bias than the OIFS-LRA-30m configuration. However, we have not seen a Jarge difference between the OIFS-LRA-30m and

192 OIFS-LRA-15 configurations in the global average RMSE analysis (Fig. 2a).

193

The surface-wind bias improvement in the OIFS-HRA-15m and OIFS-LRA-15m configurations not only exists in the annual average but also in boreal winter (DJF) and summer (JJA) (**Fig. 2a blue and red lines**, respectively). Our results are consistent with **Jung et al. (2012)**, as they found a reduction in wind bias in the tropical Pacific region when they shortened the time step in their coarse resolution configuration. However, this study and the **Jung et al. (2012)** study are not consistent with that of **Robert et al. (2020)** who did not find much time-step sensitivity. We speculate that in **Robert et al. (2020)**, the reduction from 20 to 15 minutes in their high horizontal resolution (25 km) may be too small. Alternatively, the 20-minute time step could be the optimal time step for the 25 km configuration.

201

The surface wind bias in the OIFS-HRA-15m and OIFS-LRA-15m configurations looks similar in pattern, but they differ in magnitude. The OIFS-HRA-15m configuration has a smaller bias in the North Pacific, Peru upwelling and Agulhas Bank regions compared to the OIFS-LRA-15m configuration. We hypothesize that the reduction in surface-wind bias in the OIFS-HRA-15m configuration (**Fig. 1f**) compared to the OIFS-LRA-1h configuration (**Fig. 1b**) is a combination of the enhanced horizontal resolution and shorter time step. The improvement in the OIFS-HRA-15m configuration (**Fig. 1f**) compared to the OIFS-LRA-15m configuration (**Fig. 1d**) is due to only the enhanced horizontal resolution as both configurations use the same time step.

209

Deleted: big

211 The zonal-wind bias improvement in the OIFS-LRA-15m is further explored using the online zonal wind tendencies from 212 OIFS which are split into dynamics and physics that includes turbulent diffusion, gravity-wave drag and convection:

- 213
- 214

 $du/dt = du/dt_{Dyn} + du/dt_{Turb} + du/dt_{Gwd} + du/dt_{Conv}$ (1)

215

where du/dt_{Dyn} is the sum of the tendencies from advection, pressure gradient and Coriolis force, du/dt_{Turb} includes tendencies from surface processes, vertical diffusion and orography drag, du/dt_{Gwd} includes gravity-wave drag and non-orographic drag, and du/dt_{conv} is the tendency from convection. The individual tendencies on the right-hand side of equation (1) are referred to as Dyn, Turb, Gwd and Conv, respectively. They were stored for each model level in the OIFS-LRA-1h and OIFS-LRA-15m configurations. The lowest model level is at 10m height (assuming surface pressure of 1013hPa), so the 10m wind will behave very similarly to the wind at level k=91.

222

223 The averaged zonal wind and zonal wind tendencies over the Southern Ocean ($40^{\circ} \text{ S} - 60^{\circ} \text{ S}$ and all longitude) in the OIFS-LRA-1h and OIFS-LRA-15m configurations are shown in Fig. 3a & b, respectively. The zonal wind tendency (i.e., dw/dt) in 224 225 both OIFS-LRA-15m and OIFS-LRA-1h configurations is very small (~-2 to 0.04 m/s⁻¹) compared to the other processes (Fig. 226 3b, black lines). Conv provides westward acceleration between the 700 and 900 hPa pressure levels and eastward acceleration 227 below, indicating a downward transport of westward momentum. Dyn acts to accelerate the flow eastward from 700 hPa and below, likely via momentum advection, pressure-gradient and Coriolis forces, while Turb has the opposite effect, likely via 228 229 surface friction and vertical mixing processes. In the OIFS-LRA-15m configuration, we find a similar balance as in the OIFS-230 LRA-1h, but the westward acceleration above and eastward acceleration below is enhanced by Conv, likely by increased 231 downward momentum transport, in agreement with the increased shallow and mid-level convection (Fig. 3d). The vertical 232 momentum mixing by shallow and mid-level convection reduces the vertical wind shear, making the westerly winds more 233 barotropic. As a result, the westerly winds weaken throughout the troposphere and even in the stratosphere (Fig. 3a). We note 234 similar changes in the Northern Hemisphere mid-latitudes, suggesting similar mechanisms are acting. Gwd has a negligible 235 role for the winds in the lower stratosphere and troposphere, and the Gwd term does not appear sensitive to model time step 236 (Fig. 3b, orange lines).

237

Fig. 3c shows the zonal average of the zonal wind tendencies at the lowest level of the model, as a function of the latitude. In the OIFS-LRA-1h configuration, Conv and Dyn accelerate the surface westerly wind in the mid-latitudes (~40° N to ~60° N) in both hemispheres, and these westerly winds are partly balanced by Turb (Fig. 3c, solid lines). Dyn has a larger contribution to accelerating the surface westerly winds than Conv (Fig. 3c, solid lines). However, the Conv contribution is enhanced in the OIFS-LRA-15m configuration, while the Dyn contribution reduces (Fig. 3c, dashed lines). We also find that the contribution to slowing the westerly wind is reduced by Turb in the OIFS-LRA-15m configuration (Fig. 3c, dashed lines).

244

It is also noteworthy that the individual wind tendencies contribute significantly more in the Southern Hemisphere than in the 245 246 Northern Hemisphere (Fig. 3c). In the low latitudes, both Dyn and Conv contribute to accelerating the easterly winds, which 247 is partly balanced by Turb in the OIFS-LRA-1h configuration (Fig. 3c, solid lines). There are no discernible changes in Conv, 248 Dyn or Turb from OIFS-LRA-1h to OIFS-LRA-15m, indicating that the tropical surface winds are relatively insensitive to 249 model time step (Fig. 3c, dashed lines). 250

251 In addition to surface wind, we also investigated the sensitivity of model time step and horizontal resolution for SAT and 252 precipitation. The RMSEs for SAT and precipitation are shown in Figure 2b and 2c, respectively. We find that the OIFS-HRA-253 15m has the lowest SAT RMSE of all model experiments in both annual and seasonal means, although the RMSE difference 254 across the configurations is not significant (Fig. 2b). The reduced SAT RMSE in OIFS-HRA-15m configuration is primarily

255 due to the lowered SAT bias over North America and the eastern part of Russia. Compared to the OIFS-LRA-1h, the SAT

256 RMSE decreases with increased horizontal resolution (OIFS-HRA-15m and OIFS-MRA-15m), and there is no notable

- 257 improvement when shortened the time step (OIFS-LRA-30m and OIFS-LRA-15m) (Fig 2b). 258
- 259 We have computed the SAT and precipitation biases with a 3-point smoothing, i.e., approximately 3x3 degree spatial
- 260 smoothing, which eliminates the wiggles near steep topography arising from the Gibbs' phenomenon in the model spectral
- 261 fields. We find that smoothing the fields does not change the main result that precipitation biases increase with shorter time
- 262 step in Tco95 and then decreases somewhat with higher horizontal resolution. Hence, the wiggles are not the main source of
- 263 precipitation biases and their presence does not impact the findings in this study.
- 264

265 The OIFS-LRA-1h experiment exhibits the lowest precipitation RMSE of all experiments, with RMSE increasing with shorter 266 time step (OIFS-LRA-15m) and increased horizontal resolution (OIFS-HRA-15m) for both the annual and boreal winter means (Fig. 2c, black and blue lines). The patterns of regional precipitation biases are similar across the configurations in the mid-267 and high-latitudes, whereas the precipitation biases increase in the tropics at the high horizontal resolution or in the smaller 268 269 time step configuration (not shown). The results suggest that some of the cloud and/or convection parameters may be dependent

270 on resolution or time step and need retuning for each configuration.

3.1.2 Wind and temperature bias in upper-atmosphere 271

272 We examined the zonal mean u wind bias at different model levels, and it is shown in Figures 4. We find that zonal mean u

273 wind bias over the tropical region (40°S and 40°N) is positive and independent of model horizontal resolution and model time

274 step (Fig. 4b-f). The OIFS-HRA-15m configuration has a relatively large negative bias in the Northern Hemisphere compared

275 to the other configurations. The OIFS-LRA-15m and OIFS-HRA-15m zonal mean u wind bias is similar to that in Robert et

276 al. (2018). However, the zonal mean u wind bias in the Southern Hemisphere is not consistent across horizontal resolution or

model time step. The zonal mean u wind bias in midlatitudes (i.e., 70°S to 50°S) is positive and large in the OIFS-LRA-1h 277

Deleted: figure not shown

281 configuration and reduces throughout the pressure levels by shortening the model time step in the coarse resolution OpenIFS 282 configuration (i.e., OIFS-LRA-30m and OIFS-LRA-15m). Whereas, the negative zonal wind bias south 70°S in the coarse 283 resolution configuration is consistent across the different time steps (Fig. 3b-d). It is also interesting to note that both OIFS-284 MRA-15m and OIFS-HRA-15m configurations exhibit a negative bias over the Southern Ocean (SO) at most of the pressure 285 levels, which is not seen in the standard OIFS-LRA-1h, nor in the OIFS-LRA-30m or OIFS-LRA-15m configurations. Overall, 286 we conclude that by reducing the model time step in the coarse resolution configuration, we improve winds not only at the 287 surface but also at higher model levels mostly over the SO. A similar conclusion does not hold for the OIFS-MRA-15m and 288 OIFS-HRA-15m configurations, as both suffer from large negative bias over the SO. 289 290 We also examined the zonal mean temperature bias at different pressure levels. We find a cold bias (1.5 to 6 °C) in the 291 troposphere and lower stratosphere, and a warm bias (1.5 to 6 °C) above the stratosphere across the configurations (Figure not

shown). This indicates that OpenIFS simulations (independent of model time step and horizontal resolution) are colder than
 observations in the lower stratosphere and warmer above. The cold bias in the lower stratosphere is larger in the high resolution

294 (i.e., OIFS-HRA-15m), and the warm bias above the stratosphere is smaller compared to the other configurations. Robert et

al. (2018) noticed a similar zonal mean temperature bias and speculated that the zonal mean temperature bias is linked with

296 the sensitivity of spurious mixing due to convection and diffusion.

297 3.2 Rossby wave analysis

298 Fig. 5, shows the Rossby wave amplitude (gray and black contours) for ERA5 and the individual OIFS simulations for the boreal winter (Fig. 5A, DJF, Northern Hemisphere; NH)) and austral winter (Fig. 5B, JJA, Southern Hemisphere; SH). 299 300 The color in Fig. 5 denotes the wave amplitude bias relative to ERA5 (model - ERA5). We focus only on those wave numbers 301 and latitudes that have the highest wave amplitude, because these waves explain most of the variability. The region where the 302 wave amplitude is larger than 5 ms⁻¹ is termed "core region", which mostly covers the area that is occupied by the thick black 303 contours in Fig. 5. In DJF (NH), at north of 70° N, the Rossby wave numbers k=1 and k=2 have the largest amplitude in ERA5 whereas at the mid-latitudes (30° N to 60° N), the wave numbers between about k=3 and k=9 have large amplitude with the 304 305 largest amplitude amounting to 8 ms⁻¹ at about 40° N for the wave number k=6 (Fig. 5Aa). During JJA (SH), the wave 306 amplitude is located in a similar core region (Fig. 5Ba) as that in DJF (NH). The amplitude is largest south of 70° S for the 307 wave numbers k=1 and k=2 whereas at the mid-latitudes (45° S to 65° S), the wave numbers between about k=3 to 5 have large 308 amplitude with the largest amplitude amounting to 9 ms⁻¹ is found at 57.5° S for the wave number k=4 (Fig. 5Ba). 309

310 In DJF (NH) the OIFS-LRA-1h configuration exhibits a positive bias of $\sim 1 \frac{\text{ms}^{-1}}{\text{v}}$ in Rossby wave amplitude (i.e., the waves

amplitude bias in OIFS-LRA-1h is larger than the ERA-5) in the core region, in particular for wave numbers k=3-8 at latitudes

312 between 25° N to 55° N and a negative bias at latitudes between 60° N to 80° N for waver number 2 (Fig. 5Af). The wave

Deleted: The large wave amplitude biases (~-4 to -2 std) outside of the core region (mostly near the poles for higher wave numbers) in OIFS-LRA-1h are unimportant as these waves have a small amplitude and little effect on variability. Therefore, these biases are not discussed further for other configurations for both hemispheres.¶

333	amplitude biases around the core region in OIFS-LRA-1h in the midlatitudes (20° N to 40° N) are small (~0.2) for the higher	
334	wave numbers and get better with a shorter time step configuration (OIFS-LRA-15m).	
335		
336	The Rossby wave amplitude biases in the OIFS-HRA-15m configuration are strongly reduced compared to the OIFS-LRA-1h	
337	configuration over the core region (Fig. 5Ab and 5Af). The Rossby wave amplitude bias reduction in the OIFS-MRA-15m	
338	configuration is mostly similar to that in the OIFS-HRA-15m configuration except for the wave number k=7 at 45° N, where	
339	the wave amplitude bias is larger in the OIFS-HRA-15m configuration (Fig. 5Ab and 5Ac). The OIFS-HRA-15 m and OIFS-	
340	MRA-15m configurations also exhibit a positive bias for wave number 2 at high-latitudes 60° N to 80° N. The OIFS-MRA-	
341	15m configuration also show a negative bias for the wave number 3 at latitudes between 60° N to 65° N in the core region,	
342	which is not present in the other configurations. The OIFS-HRA-15m and OIFS-MRA-15m configurations show similar bias	
343	around the core region as in the OIFS-LRA-1h configuration, i.e., high resolution and OIFS-LRA-1h configurations	
344	overestimate wave amplitudes for the higher wave numbers. The Rossby wave amplitude biases are progressively reduced	
345	from the OIFS-LRA-1h configuration to the OIFS-LRA-30m and OIFS-LRA-15m configurations (Fig. 5Ad-Af), indicating a	
346	sensitivity of model bias to the time step. The wave amplitude bias for wave number $k\!=\!7$ at $45^{\rm o}$ N exists in all the	
347	configurations, and it is smaller in the OIFS-LRA-15m and OIFS-MRA-15m configuration than in the other configurations.	
348	Overall, both OIFS-LRA-15m and OIFS-HRA-15m configurations are able to reproduce the observed Rossby-wave	
349	amplitudes in DJF (NH) better than OIFS-LRA-1h.	
350		
351	In JJA (SH), the Rossby wave amplitude bias in the core region is smaller than in DJF (NH) for all the configurations (Fig.	
352	5A and 5B). OIFS-LRA-1h exhibits a positive bias of $\sim 0.5 \text{ ms}^{-1}$ in JJA (SH) for the wave number k=2 at latitude between $\sim 50^{\circ}$	1

wave numbers and at each latitude, with the maximum phase speed is observed for the wave numbers between k=6 and k=8
and latitudes between 40° S and 60° S, and these waves are moving faster than that in DJF (NH).

394

395 The OIFS-LRA-1h configuration suffers from positive phase speed bias for wave numbers k=4 to 8 at latitudes between 42.5° N and 60° N, i.e., waves move faster eastward than in ERA5, and the bias is larger than 1 ms^{-1} . The bias of ~1 ms⁻¹ for wave 396 397 number k = 6 to 8 at 40° N and 60° N is of particular concern as it is near the maximum wave amplitudes in DJF (Fig. 6Af). 398 In general, phase speed biases in the OIFS-LRA-1h configuration are strongly reduced as either horizontal resolution is 399 increased or time step is shortened (Fig. (Ab-5Af). In JJA (SH), the OIFS-LRA-1h configuration exhibits a very large (between 400 $\sim 1.5-2$ ms⁻¹) Rossby wave phase speed bias for most of the wave numbers, which is largest for the wave numbers k=2, to 8 401 between 15° S to 55° S (Fig. 6Bf). Large biases can be found between 15° S and 25° S (~1.5, ms⁻¹) for most of the wave 402 numbers, but the wave activity is low there (Fig. GBf). The large phase speed biases are strongly reduced in the OIFS-LRA-403 30m and OIFS-LRA-15m configurations (Fig. 6Bd-Bf), indicating a strong sensitivity to the reduced biases in mean winds 404 and wind speeds (Fig. 1). Overall, the Rossby wave speed bias in the OIFS-HRA-15m configuration is smaller than in the 405 OIFS-LRA-1h configuration (Fig. 6Bb and 6Bf). However, we note that both the OIFS-MRA-15m and OIFS-HRA-15m 406 configurations exhibit negative biases south of 55° S for wave numbers k= 1 to 5, that is, the eastward moving waves are 407 slower than in the ERA5 (Fig. 6Bb).

408

409 The wave phase speed analysis reveals a clear improvement in the representation of the Rossby waves in the boreal winter 410 (i.e., NH) when increasing the horizontal resolution and shortening the model time step compared to OIFS-LRA-1h 411 configuration. In austral winter, however, the representation of Rossby wave amplitudes and phase speeds are the most realistic 412 in OIFS-LRA-15m configuration, with longer time steps introducing too fast phase speeds and higher horizontal resolution

413 introducing too slow phase speeds at wave number less than 6 (i.e., k<6).

414 3.3 Weather regimes pattern

415 We derive the four weather regimes patterns (WRPs) over NH in the Euro-Atlantic region from ERA5. The patterns resemble

416 the positive and negative phases of the North Atlantic Oscillation (NAO+ and NAO-, respectively), Scandinavian blocking

417 (Sc. Blocking), and the North Atlantic ridge (Atl. Ridge) pattern (Fig. 7, bottom row). These WRPs are consistent with the

- 418 previous findings (Dawson et al., 2012; Fabiano et al., 2020; Fabiano et al., 2021).
- 419

420 The OIFS-HRA-15m configuration produces WRPs that are more visually similar to those in ERA-5 than does OIFS-LRA-1h

421 (Fig. 6), a result confirmed by the higher pattern correlation coefficient (PCC) between OIFS-HRA-15m and ERA5 compared

422 to the OIFS-LRA-1h and ERA-5 (Fig. 7, and 8). The PCCs for NAO+, NAO- and Sc. Blocking all exceed 0.8 in OIFS-HRA-

423 1h while OIFS-LRA-1h does not achieve PCC above 0.8 for any WRP (Fig. 7).

Deleted: 7	
Deleted: 6	

The OIFS-MRA-15m configuration shows smaller PCCs than both the OIFS-HRA-15m and OIFS-LRA-1h configurations
(Fig. §), i.e., the improvement from OIFS-LRA-1h to OIFS-HRA-15m does not have a linear relationship with model
horizontal resolution or time step. Compared to other configurations and ERA5, OIFS-MRA-15m the z500 anomaly in the
NAO+ pattern is too elongated in the southwest-northeast direction, and an unrealistic negative z500 anomaly over the North
Atlantic appears in the Sc. Blocking regime (Fig 7). Furthermore, OIFS-MRA-15m shows an Atl. Ridge pattern with neither
the right structure nor amplitude.
There is an improvement in the representation of the NAO- regime in the OIFS-LRA-30m configuration over the OIFS-LRA-

452 Ih configuration (Fig. 7) while the Sc. Blocking regime becomes worse due to the ridge shifting westward. These changes are 453 also reflected in the PCCs (Fig 8). Similarly, the OIFS-LRA-15m better represents NAO- and Atl. Ridge than OIFS-LRA-1h while NAO+ and Sc. Blocking worsened. The westward shift of the Sc. Blocking is similar in OIFS-LRA-15m and OIFS-454 455 LRA-30m, and the worse NAO+ is related to a northward shift of both the positive and negative z500 anomalies. We note that all experiments use the same SST and sea-ice conditions and that OIFS-LRA-1h, 30m and 15m share the same horizontal 456 resolution, i.e., the changes from OIFS-LRA-1h to OIFS-LRA-15m are not due to SST biases or representation of orography. 457 458 There does not seem to be a clear improvement as time step is shortened, despite the reduction in mean state biases and Rossby-459 wave amplitudes and phase speeds.

460

461 The PCC is greater than 0.8 for three out of four WRPs in the OIFS-HRA-15m configuration, hence we argue that the OIFS462 HRA-15m has the most realistic representation of the weather regimes pattern out of all experiments here. Large improvement
463 in OIFS-HRA-15m over the other configurations could be due to better resolved topography and land-sea contrasts.
464

465 3.4 Discussion and Conclusions

We have investigated the sensitivity of the climate biases in the OpenIFS atmosphere model to changes in horizontal resolution 466 and time step by analyzing AMIP simulations for the period 1979-2019 (Table 1). The strong positive surface zonal wind bias 467 468 over the Southern Ocean and Northern Hemisphere mid-latitudes and the negative bias in the tropical and subtropical regions have significantly improved in the high horizontal resolution configuration with a short time step (~25km, OIFS-HRA-15m). 469 470 A similar improvement is observed at the coarse horizontal resolution version with a shorter time step (~100 km with 30 or 471 15-minutes). The zonal wind bias over the mid-latitudes in both hemispheres is reduced throughout the air column when a 472 smaller time step is used in the coarse resolution version, and we find that the changes in the surface winds are largely due to enhanced shallow and mid-level convection which increases vertical momentum transport. Biases in the surface westerlies in 473 474 midlatitudes are common in CMIP-class climate models (Bracegirdle et al., 2020) and a sensitivity to friction has been noted

12

Deleted: 7

Deleted: 6 Formatted: Font: Bold

Deleted: 6 Deleted: 7 in idealized model studies (Chen and Plumb, 2009). We hypothesize that the enhanced shallow and mid-level convection
with a shorter model time step and/or increased horizontal resolution deepened the layer over which friction acts in the lower
troposphere so that the frictional effects on the barotropic jet increased, leading to a poleward shift in the jet and reduced biases
in zonal wind.

483

We also find a notable improvement in the representation of the Rossby wave amplitude and phase speed with increased horizontal resolution and shorter time step at least for the waves accounting <u>for</u> most variability in both austral and boreal winter seasons. The reduced zonal wind throughout the troposphere with a shorter time step (**Fig. 3**) would decrease the eastward phase speed of Rossby waves, which may explain part of the reduced phase speeds (**Fig. 6**) and reduced biases. However, changes in air-sea interactions or eddy-mean flow interactions may also play a role. In particular, we note that a very large reduction in phase speed biases in austral winter in OIFS-LRA-15m compared to OIFS-LRA-1h were concurrent with very large reduction in zonal surface wind biases.

491

The weather regime patterns are also more realistic in the high horizontal resolution and short time step configuration OIFS-492 HRA-15m than OIFS-LRA-1h, but we note that there is no consistent improvement from OIFS-LRA-1h to OIFS-HRA-15m 493 494 as either horizontal resolution is increased or time step is shortened. For example, both OIFS-MRA-15m and OIFS-LRA-15m 495 are worse than OIFS-LRA-1h. The improvements in the weather regime patterns and Rossby wave amplitude and speed could very well be related to each other as e.g. variations in Rossby wave breaking have been linked to the onset of NAO phases 496 497 (Strong and Magnusdottir, 2008) but this would require further and more targeted analysis. The overall good representation of weather regimes in OIFS-LRA-1h compared to simulations with shorter time steps (OIFS-LRA-30m, OIFS-LRA-15m) may 498 499 be due to compensation of errors. For example, it is possible that improving the wave amplitudes and phase speeds in OIFS-500 LRA-30m compared to OIFS-LRA-1h exposes the effect of a biases caused by both the coarse resolution in both 501 configurations, e.g., weak interactions with topography, leading to an overall worse representation of weather regimes. 502 We found a gradual reduction in SAT biases in OpenIFS with increased resolution or shorter time steps. The improvements 503 were largely driven by improvements over North America and eastern Russia. Roberts et al. (2018) noted similar SAT biases 504 and linked them to surface albedo, which is thus likely the cause here as well. The improvement with increased resolution and/or shorter time step may be a result of improved snow cover. Systematic improvements in the precipitation biases were 505

506 not observed. Instead, precipitation biases generally increased with finer horizontal resolution or shorter time step, suggesting 507 that some tuning may be required in the physics parameters when changing horizontal resolution and time step.

508

We stress that the results presented in this study are specific to the OpenIFS atmosphere model and are crucial for the modeling community that uses the OpenIFS in their climate models such as EC-Earth (Haarsma et al., 2020; Döscher et al., 2022),

511 CNRM (Voldoire et al., 2019), AWI (Streffing et al., 2022), and GEOMAR (Kjellsson et al., 2020). However, the results

512 may also have implications for other climate modeling communities, at least for those that use a semi-Lagrangian scheme

13

Deleted: 5

514 similar to the IFS (e.g., Walters et al., 2019) in the atmospheric component where long time steps are both possible and often 515 desirable to reduce the computational cost of the model.

516

517 The zonal wind bias improvement in the OpenIFS is important for research questions linked with the Southern Ocean climate dynamics that plays a crucial role in both the global atmosphere and ocean circulation. We propose that the model time step 518 519 not be longer than 30 minutes at any horizontal resolution to minimize surface wind biases over the ocean. The computational cost increases linearly with dt (time step), whereas the cost scales with horizontal resolution as dx^3 as the number of grid 520 521 points increases in both dimensions and the time step is likely shortened as well. Hence, reducing the model time step from 45 522 or 60 minutes to 20 or 30 minutes may double the computational cost, but lead to significant improvements in the simulated 523 climate. The optimal model time step for the OpenIFS coarse resolution model (1º) is suggested to be 30-minute, but should likely be somewhat shorter, e.g., 15 min, for higher resolutions. 524

525

526 Code and data availability

527 The OpenIFS model requires a software license agreement with ECMWF, and OpenIFS' license is easily given free of charge 528 to any academic or research institute. The details of the different versions of the OpenIFS model, including the OpenIFS 529 version used in this study, i.e., 43R3, can be found at https://confluence.ecmwf.int/display/OIFS/About+OpenIFS. The 530 OpenIFS model source code has been made available for the editor and reviewers.

531 The input datasets (both initial and boundary conditions) needed to run the OpenIFS model, run scripts, the model output, and

532 the Jupiter notebook that support the finding of this study are available at (Savita, 2023). The source code for XIOS 2.5,

533 revision 1910, is available from the official repository at https://forge.ipsl.jussieu.fr/ioserver/ under CeCILL_V2 license.

534 OpenIFS experiments were made using ESM-Tools (https://github.com/esm-tools/esm_tools/). The OASIS coupler is

s35 available at https://oasis.cerfacs.fr/en/. The XIOS, ESM-Tools and OASIS coupler used in this study can be downloaded from 536 https://doi.org/10.5281/zenodo.8189718.

537 The observational datasets used to validate OpenIFS model results in this study are downloaded from the ERA5

538 (https://cds.climate.copernicus.eu/), GPCP (https://psl.noaa.gov/data/gridded/data.gpcp.html) and CRUTEM4

539 (http://badc.nerc.ac.uk/data/cru/) websites. Total model output exceeds 10 Tb and it not publicly available, but is available

540 from the authors upon reasonable requests.

541 Author contributions

542 All the model simulations were conducted by AS and JK. Analysis of the output and the writing of text for this paper

543 coordinated by Savita with substantial contributions from JK, RPK, ML, TR, SW and WP.

544 Competing interest

545 The authors declare that they have no conflict of interest.

546 Acknowledgement

- 547 AS, JK and MK are supported by JPI Climate/Ocean (ROADMAP project grant 01LP2002C). We wish to thank the OpenIFS
- 548 team at ECMWF for the technical support. All simulations were performed on the HLRN machine under shk00018 project
- 549 resources. All analyses were performed on computer clusters at GEOMAR and Kiel University Computing Center (NESH).
- 550 We thanks to Anton Beljaars for discussion on ECMWF model physics.

Table

Experiment Name	Horizontal resolution	Vertical grid	Time step	<u>CHPSY</u>	<u>SYPD</u>
OIFS-LRA-15m	Tco95/100km	L91	15m	<u>3.3 k</u>	<u>11</u>
OIFS-MRA-15m	Tco199/50km	L91	15m	<u>13.3 k</u>	<u>4</u>
OIFS-HRA-15m	Tco399/25km	L91	15m	<u>19.2 k</u>	<u>2</u>
OIFS-LRA-30m	Tco95/100km	L91	30m	<u>845</u>	<u>21</u>
OIFS-LRA-1h	Tco95/100km	L91	1h	<u>256</u>	<u>36</u>

671

672 Table 1. List of the experiments performed across different horizontal resolutions and model time steps using OIFS model. 673

In the above table CHPSY is core hours per simulation year, and SYPD is simulation year per day.

674 675

676

Figure 1. (a) Annual mean ERA5 surface zonal wind $[ms^{-1}]$. (b-d) Annual mean zonal wind $[ms^{-1}]$ bias for different model time steps (1h (b), 30m (c), and 15m (d)) using ~100 km resolution, and (e-f) with different horizontal resolutions, ~50 (e) and ~25 km (f), respectively. Biases are computed with respect to ERA5 over the period 1979–2019.

682

Deleted: We have also shown 5-member ensemble mean and standard deviation only for OIFS-LRA-1h configuration.

Figure 3. (a) Averaged zonal wind (u) [ms⁻¹] and zonal wind tendencies [ms⁻²/hour] over the Southern Ocean (40°S – 60°S, all longitude) as a function of height for OIFS-LRA-1h and OIFS-LRA-15m. Model levels (y-axis left) and pressure levels (y-axis right). (c) Zonal and time average of zonal wind tendencies at the lowest level of the model as a function of latitude. (d) Zonal and time average convection difference [Kgm⁻²/hour] between OIFS-LRA-15m and OIFS-LRA-1h configurations. The solid lines in panels (b) and (c) show the wind tendency for OIFS-LRA-1h configuration whereas the dashed lines are for OIFS-LRA-15m configuration. Shown are averages over 1979-2019.

699 Figure 4. (a) Annual zonal mean ERA5 zonal wind [ms⁻¹]. (b-d) Annual zonal mean zonal wind [ms⁻¹] bias for different model

700 time steps (1h (b), 30m (c), and 15m (d)) using ~100 km resolution, and (e-f) with different horizontal resolutions, ~50 (e) and

701 ~25 km (f), respectively. Biases are computed with respect to ERA5 over the period 1979-2019.

702

Figure 5, (A) The Rossby wave amplitude (contours) for different wave numbers in the Northern Hemisphere at 300 hPa (a) in ERA5 observation and (b-f) in the OIFS model simulations during 1979-2019 in DJF (i.e., boreal winter). The color shows

706 difference of wave amplitude between the model and ERA5 where it is significant on the 95 % confidence level. The wave

amplitude and contour interval are shown in ms⁻¹. The grey contours start from 2 ms⁻¹ and the black contours from 5 ms⁻¹ and

708 the contour interval is 1 ms⁻¹. (B) is similar to (A), but for JJA (i.e., austral winter).

25

Deleted: 4

Deleted: the detrended and standardized

712 Figure 6 (A) The Rossby wave phase speed (contours) for different wave numbers at 300 hPa in the Northern Hemisphere in

713 ERA5 (a) observation and (b-f) in the OIFS model simulations during 1979-2019 in DJF (i.e., boreal winter). The color shows

714 the difference of wave phase speed between model and ERA5 where it is significant on the 95 % confidence level. The wave

phase speed and contour interval are shown in ms⁻¹. The black contours start from 1 ms⁻¹ and the contour interval is 1 ms⁻¹.

716 Panel (B) is similar to panel (A), but for JJA (i.e., austral winter). The dahs contours show a negative phase speed and a gray

717 contour shows a zero-phase speed.

26

Deleted: 5

Deleted: the detrended and standardized

722 Figure. 7, Weather regime patterns over the Euro-Atlantic regions from ERA5 observation (bottom row) and the individual

723 OIFS model simulations (1st to 5th row) over the time period 1979–2019 for DJF (boreal winter season).
