Abstract.

We examine the impact of horizontal resolution and model time step on climate of the OpenIFS version 43R3 atmosphere general circulation model. A series of simulations for the period 1979-2019 are conducted with various horizontal resolutions (i.e., ~100, ~50, and ~25 km) while maintaining the same time step (i.e., 15 minutes) and using different time steps (i.e., 60, 30 and 15 minutes) at 100 km horizontal resolution. We find that the surface zonal wind bias reduces significantly over certain regions such as the Southern Ocean, the Northern Hemisphere mid-latitudes, and in tropical and subtropical regions at high horizontal resolution (i.e., ~25 km). Similar improvement is evident too when using a coarse resolution model (~100 km) with a smaller time step (i.e., 30 and 15 minutes). We also find improvements in Rossby wave amplitude and phase speed as well as weather regime patterns when a smaller time step or higher horizontal resolution is used. The improvement in the wind bias when using the shorter time step is mostly due to an increase in shallow and mid-level convection that enhances vertical mixing in the lower troposphere. The enhanced mixing allows frictional effects to influence a deeper layer and reduces wind and wind speed throughout the troposphere. However, precipitation biases generally increase with higher horizontal resolution or smaller time step, whereas the surface-air temperature bias exhibits a small improvement over North America and the Eastern Eurasian continent. We argue that the bias improvement in the highest horizontal resolution (i.e., ~25 km) configuration benefits from a combination of both the enhanced horizontal resolution and the shorter time step. In summary, we demonstrate that by reducing the time step in the OpenIFS model, one can alleviate some climate biases at a lower cost than by increasing the horizontal resolution.

35

36 1. Introduction

37 In the last few decades, Atmospheric-Ocean General Circulation Model (AOGCM) simulations from the Coupled Model
38 Intercomparison Project (CMIP) are widely used to study the internal climate variability and the climate response to external
39 forcing such as increasing atmospheric greenhouse gas concentrations causing global warming. These simulations, however,
40 suffer from long-standing biases (Bayr et al., 2018; Flato et al., 2014; Gates et al., 1999; Kim et al., 2014; Zhou et al.,
41 2020), which leads to significant uncertainties in short-term and long-term climate projections and potential ecosystem impacts
42 (Athanasiadis et al., 2022; Couldrey et al., 2021; Meehl and Teng, 2014; Meng et al., 2022). These biases can arise from
43 a variety of sources, including inaccurate representation of physical processes, poor initialization of model conditions, or
44 inadequate representation of the Earth's topography and land cover.

45

46 Simulations using Atmospheric General Circulation Models (AGCMs) from the Atmosphere Model Intercomparison Project
47 (AMIP), a part of CMIP, are used to study the internal variability of the atmosphere. The AGCMs are less complex than the
48 AOGCMs as the former are constrained by observed Sea Surface Temperature (SST) and Sea Ice Concentration (SIC). Despite
49 being constrained by the observations, the AGCMs also exhibit biases (e.g., Gates et al., 1999), and some of these biases have
50 persisted for over several phases of AMIP (He and Zhou, 2014). The biases in AGCMs are largely due to the fact that many
51 unresolved processes, such as atmospheric convection, precipitation, clouds, cloud-microphysical and aerosol processes,
52 boundary layer processes, and interactions between the land surface and hydrologic processes, have to be included in a
53 parameterized form in the coarse resolution model (Ma et al., 2022). The treatment of unresolved gravity waves and the
54 relatively large model time step also contribute to the biases in AGCMs (Flato et al., 2014; Gates et al., 1999).

55

56 Recently, Liu et al. (2022) analyzed AOGCM simulations and reported that increasing the horizontal resolution of the ocean
57 component one can reduce SST and precipitation biases in the equatorial Pacific, whereas increasing the horizontal resolution
58 of the atmospheric component did not have the same effect. However, other studies found that a high-horizontal resolution
59 atmosphere model better simulates the main features of tropical precipitation, tropical atmospheric circulation, and extra-
60 tropical cyclones while moving from 125 km to 40 km horizontal resolution with relatively small improvements for further
61 enhanced horizontal resolution (Branković and Gregory, 2001; Jung et al., 2012; Williamson et al., 1995). Similarly,
62 Roberts et al. (2018) found that there was not much improvement in the Integrated Forecasting System (IFS) from the
63 European Centre for Medium-Range Weather Forecasting (ECMWF) when moving horizontal resolution from 50 to 25 km.

64

65 Jung et al. (2012) and Roberts et al. (2018) demonstrated a time step sensitivity in the coarse and high horizontal resolution
66 model simulations using the OpenIFS and IFS model. Jung et al. (2012) found that the precipitation and wind biases were

67 reduced at the coarse horizontal resolution when shortening the model time step from 60 to 15 minutes. **Roberts et al. (2018)**
68 did not find such a significant improvement when reducing the model time step from 20 to 15 minutes in their high-resolution
69 (~25 km) configuration. However, both studies did not investigate the model's sensitivity to changes in the model time step in
70 detail.

71

72 In the research community, there is no standard definition for coarse horizontal resolution, as one study considered 200 km as
73 a coarse resolution (~2°) configuration (**Branković and Gregory, 2001**), whereas another study considered 50 km (0.5°) as a
74 coarse resolution (**Roberts et al., 2018**). Likewise, there is no unique rule for setting the model time step dependent on model
75 resolution. Groups using either the IFS or OpenIFS model at horizontal resolutions of ~100 km have used a relatively long
76 time step of 1 hour (**Hazeleger et al., 2012; Kjellsson et al., 2020; Streffing et al., 2022**) or 45 minutes (**Van Noije et al.,**
77 **2021**), while other groups using the ARPEGE-Climat with a similar dynamical core use 15 minutes (**Voltaire et al., 2019**).
78 The model's horizontal resolution and time steps are rather chosen on what can be afforded computationally, and their relative
79 contributions to biases in the model's climate are not well documented.

80

81 In this study, we systematically investigate the sensitivity of the OpenIFS model version 43r3v2 to the model time step and
82 horizontal resolution. We mostly focus on the surface zonal winds since they play a crucial role for the ocean circulation in
83 the AOGCMs. We also study the representation of the synoptic-scale variability such as Rossby waves and weather regimes.
84 The paper is structured as follows: section 2 describes the model, experimental design, data and methodology; section 3
85 describes the results and section 4 summarizes the conclusions of this work.

86 **2. Model, Experimental design, Data and Methodology**

87 We conducted a series of experiments with the OpenIFS model. The OpenIFS model is derived from the Integrated Forecasting
88 System at the European Centre for Medium-range Weather Forecasting (ECMWF-IFS) cycle 43 release 3 (43r3). The
89 dynamical core is the same as ECMWF-IFS that uses a two-time-level semi-implicit time stepping with semi-Lagrangian
90 advection (**Temperton et al., 2001**) on a reduced Gaussian grid with a hybrid-sigma vertical coordinate (**Simmons and**
91 **Burridge, 1981**). Likewise, the OpenIFS uses the same model physics as the ECMWF-IFS (**cf. Forbes and Tompkins, 2011;**
92 **Hogan and Bozzo, 2018; Tiedtke, 1993**) but does not include the tangent-linear code or 4D-VAR capabilities. Our version,
93 OpenIFS, is similar to cy43r1 used in **Roberts et al., (2018)**, with the main difference being the new radiation scheme, ecRad
94 (**Hogan and Bozzo, 2018**), introduced in cy43r3. Our experiments are run at three different horizontal resolutions: a low-
95 resolution (T_{co95} , ~100 km), a medium-resolution (T_{co199} , ~50 km), and a high resolution (T_{co399} , ~25 km). All the
96 configurations share the same vertical L91 grid. We did not modify any other model parameters when changing the model
97 horizontal resolutions or model time steps, but we note that some parameters such as launch momentum flux for non-orographic

98 gravity waves scales with resolution in the model. We performed 5 experiments in total (**Table 1**). For simplicity, we now
99 refer now OpenIFS as OIFS in the rest of the sections.

100

101 The lower boundary conditions, i.e., SST and SIC, are taken the from Atmospheric Model Intercomparison Project (AMIP)
102 version 1.1.6 (**Eyring et al., 2016; Taylor et al., 2012**), which are available as monthly means on a $1^\circ \times 1^\circ$ horizontal grid. The
103 external forcing is identical to that used in the CMIP6 simulations except for the aerosol and ozone concentrations, which are
104 taken from monthly mean climatology. SST and SIC are interpolated from monthly to daily frequency and from $1^\circ \times 1^\circ$
105 horizontal resolution to the OIFS horizontal grid using bilinear interpolation. All the simulations are run for the period 1979–
106 2019. We extend the simulations beyond the AMIP protocol for 1979-2014 up to 2019 by using SST and SIC from the ERA5
107 reanalysis and the Shared Socioeconomic Pathways 5 (SSP5) emission scenario. Ozone concentrations are taken from monthly
108 photochemical equilibrium state and aerosol concentrations from monthly CAMS climatology of 11 species.

109

110 Amplitude and phase speed of Rossby wave were computed by performing a Fourier decomposition analysis on 300 hPa daily
111 meridional winds. First, we interpolated both ERA5 and OIFS datasets onto a $2.5^\circ \times 2.5^\circ$ grid using bilinear interpolation. We
112 then applied the Fourier decomposition analysis to determine amplitude and position for each Rossby wave number at each
113 latitude as a function of time. The Rossby-wave amplitude and phase speed were computed for the boreal and austral winter
114 seasons respectively using daily values of amplitude and phase speed over the time period 1979–2019. The phase speed is
115 weighed by daily amplitude squared when computing the seasonal averages. The results are presented in wavenumber-latitude
116 diagrams similar to previous studies (e.g., **Pilch Kedzierski et al., 2020; Wolf and Wirth, 2017**). Our wavenumber-latitude
117 analysis is not directly comparable to both studies mentioned above, because we did not apply any high-pass filtering in time
118 before the Fourier decomposition. While the previous literature had similar diagrams with varying measures of wave
119 amplitude, our detailed analysis of phase speed in such a manner is novel in literature to our knowledge.

120

121 The Weather Regime Patterns (WRPs) were calculated using daily 500-hPa geopotential height (z500) anomalies over the
122 Euro-Atlantic region (30° – 90° N, 80° W– 40° E) for the boreal winter season during the period 1979-2019. The daily z500
123 daily anomalies were computed by subtracting the daily climatology smoothed by a 20-day running mean from the raw z500
124 data. We calculated the first four Empirical Orthogonal Functions (EOFs) from the ERA5 dataset. In the next step, the OIFS-
125 simulated z500 anomalies were projected on the ERA5 EOFs to obtain Pseudo-Principal Components (Pseudo-PCs). We then
126 applied a K-means clustering algorithm to the individual model pseudo-PCs and observation PCs using four clusters. We chose
127 four clusters because these give the most of the significant clustering. Spatial WRPs are obtained by compositing over all daily
128 z500 anomalies for each regime. More information about the methodology can be found in **Fabiano et al. (2020)**, section 3.1.
129 In order to evaluate the WRPs simulated by the OIFS across configurations more quantitatively, we have additionally estimated
130 the Pattern Correlation Coefficient (PCC) between the WRPs identified in the model and ERA5.

131

132 We compare the climate of OIFS to observational and reanalysis datasets. Precipitation is validated against the Global
133 Precipitation Climatology Project (GPCP; Huffman et al., 1997), and the surface air temperature (SAT) against the
134 CRUTEM4 (Harris et al., 2014; Osborn and Jones, 2014). We have used the ERA5 reanalysis (Hersbach et al., 2020) to
135 evaluate 10-meter surface wind as well as the zonal wind at 300 hPa for the Rossby wave analysis. We use z500 from ERA5
136 to validate the OIFS-simulated weather regimes. We also compare our results with the MERRA2 reanalysis (Gelaro et al.,
137 2017) and find similar results. Therefore, the comparison with MERRA2 is not shown.

138 3. Results

139 3.1 Global and regional surface bias and deriving processes

140 The annual mean 10m zonal wind (surface wind hereafter) bias during the period 1979–2019 for the different OIFS
141 configurations is shown in Fig. 1. We find that the OIFS-LRA-1h configuration has a large surface wind bias over most of the
142 world ocean, with positive biases in the mid-latitudes (the Southern Ocean, North Atlantic and North Pacific) and negative
143 surface wind biases over the tropical oceans (Tropical Pacific, Tropical Indian and Atlantic Ocean) (Fig. 1b). Thus, the OIFS-
144 LRA-1h configuration simulates too strong surface westerly winds (and wind speed) over the mid-latitude oceans, which, if
145 coupled to an ocean model, may cause biases in upper-ocean mixing and oceanic uptake of heat and carbon.

146
147 The surface wind bias in the OIFS-HRA-15m configuration is reduced significantly (Fig. 1f) over most of the world ocean
148 compared to the OIFS-LRA-1h configuration (Fig. 1b), indicating that increasing the horizontal resolution from 100 km to 25
149 km and shortening the time step from 1h to 15-min improves the representation of the surface winds. The surface wind bias
150 also significantly reduces everywhere in the OIFS-MRA-15m configuration (Fig. 1e) compared to the OIFS-LRA-1h
151 configuration (Fig. 1b). The surface wind bias in OIFS-MRA-15m is larger than that in the OIFS-HRA-15m configuration but
152 smaller than that in the OIFS-LRA-1h configuration. Similar conclusions are obtained by performing Root Mean Square Error
153 (RMSE) analysis, which shows that the OIFS-HRA-15m configuration has the lowest annual and global mean RMSE of
154 surface wind while the OIFS-LRA-1h configuration has the highest RMSE (Fig. 2a, black line). Though we have found a
155 significant improvement in the wind bias in the OIFA-HRA-15m configuration, it is not clear yet whether the improvement is
156 due to the increased horizontal resolution or the shorter time step.

157
158 Surface wind bias is also reduced in both the OIFS-LRA-30m (Fig. 1c) and OIFS-LRA-15m (Fig. 1d) configurations compared
159 to the OIFS-LRA-1h configuration (Fig. 1b), and the bias improvement is mostly observed at the same places as in the OIFS-
160 HRA-15m configuration (Fig. 1f). The surface-wind bias improvement is similar in the OIFS-LRA-30m and OIFS-LRA-15
161 configurations, except over the North Pacific and Southern Ocean where the OIFS-LRA-15m configuration has a smaller wind
162 bias than the OIFS-LRA-30m configuration. However, we have not seen a big difference between the OIFS-LRA-30m and
163 OIFS-LRA-15 configurations in the global average RMSE analysis (Fig. 2a).

164

165 The surface-wind bias improvement in the OIFS-HRA-15m and OIFS-LRA-15m configurations not only exists in the annual
166 average but also in boreal winter (DJF) and summer (JJA) (**Fig. 2a blue and red lines**, respectively). Our results are consistent
167 with **Jung et al. (2012)**, as they found a reduction in wind bias in the tropical Pacific region when they shortened the time step
168 in their coarse resolution configuration. However, this study and the **Jung et al. (2012)** study are not consistent with that of
169 **Robert et al. (2020)** who did not find much time-step sensitivity. We speculate that in **Robert et al. (2020)**, the reduction
170 from 20 to 15 minutes in their high horizontal resolution (25 km) may be too small. Alternatively, the 20-minute time step
171 could be the optimal time step for the 25 km configuration.

172

173 The surface wind bias in the OIFS-HRA-15m and OIFS-LRA-15m configurations looks similar in pattern, but they differ in
174 magnitude. The OIFS-HRA-15m configuration has a smaller bias in the North Pacific, Peru upwelling and Agulhas Bank
175 regions compared to the OIFS-LRA-15m configuration. We hypothesize that the reduction in surface-wind bias in the OIFS-
176 HRA-15m configuration (**Fig. 1f**) compared to the OIFS-LRA-1h configuration (**Fig. 1b**) is a combination of the enhanced
177 horizontal resolution and shorter time step. The improvement in the OIFS-HRA-15m configuration (**Fig. 1f**) compared to the
178 OIFS-LRA-15m configuration (**Fig. 1d**) is due to only the enhanced horizontal resolution as both configurations use the same
179 time step.

180

181 The zonal-wind bias improvement in the OIFS-LRA-15m is further explored using the online zonal wind tendencies from
182 OIFS which are split into dynamics and physics that includes turbulent diffusion, gravity-wave drag and convection:

183

$$184 \quad du/dt = du/dt_{Dyn} + du/dt_{Turb} + du/dt_{Gwd} + du/dt_{Conv} \quad (1)$$

185

186 where du/dt_{Dyn} is the sum of the tendencies from advection, pressure gradient and Coriolis force, du/dt_{Turb} includes tendencies
187 from surface processes, vertical diffusion and orography drag, du/dt_{Gwd} includes gravity-wave drag and non-orographic drag,
188 and du/dt_{conv} is the tendency from convection. The individual tendencies on the right-hand side of equation (1) are referred to
189 as Dyn, Turb, Gwd and Conv, respectively. They were stored for each model level in the OIFS-LRA-1h and OIFS-LRA-15m
190 configurations. The lowest model level is at 10m height (assuming surface pressure of 1013hPa), so the 10m wind will behave
191 very similarly to the wind at level $k=91$.

192

193 The averaged zonal wind and zonal wind tendencies over the Southern Ocean (40° S – 60° S and all longitude) in the OIFS-
194 LRA-1h and OIFS-LRA-15m configurations are shown in **Fig. 3a & b**, respectively. The zonal wind tendency (i.e., du/dt) in
195 both OIFS-LRA-15m and OIFS-LRA-1h configurations is very small compared to the other processes (**Fig. 3b, black lines**).
196 Conv provides westward acceleration between the 700 and 900 hPa pressure levels and eastward acceleration below, indicating
197 a downward transport of westward momentum. Dyn acts to accelerate the flow eastward from 700 hPa and below, likely via

198 momentum advection, pressure-gradient and Coriolis forces, while Turb has the opposite effect, likely via surface friction and
199 vertical mixing processes. In the OIFS-LRA-15m configuration, we find a similar balance as in the OIFS-LRA-1h, but the
200 westward acceleration above and eastward acceleration below is enhanced by Conv, likely by increased downward momentum
201 transport, in agreement with the increased shallow and mid-level convection (**Fig. 3d**). The vertical momentum mixing by
202 shallow and mid-level convection reduces the vertical wind shear, making the westerly winds more barotropic. As a result, the
203 westerly winds weaken throughout the troposphere and even in the stratosphere (**Fig. 3a**). We note similar changes in the
204 Northern Hemisphere mid-latitudes, suggesting similar mechanisms are acting. Gwd has a negligible role for the winds in the
205 lower stratosphere and the Gwd term does not appear sensitive to model time step (**Fig. 3b, orange lines**).

206

207 **Fig. 3c** shows the zonal average of the zonal wind tendencies at the lowest level of the model, as a function of the latitude. In
208 the OIFS-LRA-1h configuration, Conv and Dyn accelerate the surface westerly wind in the mid-latitudes ($\sim 40^\circ$ N to $\sim 60^\circ$ N)
209 in both hemispheres, and these westerly winds are partly balanced by Turb (**Fig. 3c, solid lines**). Dyn has a larger contribution
210 to accelerating the surface westerly winds than Conv (**Fig. 3c, solid lines**). However, the Conv contribution is enhanced in the
211 OIFS-LRA-15m configuration, while the Dyn contribution reduces (**Fig. 3c, dashed lines**). We also find that the contribution
212 to slowing the westerly wind is reduced by Turb in the OIFS-LRA-15m configuration (**Fig. 3c, dashed lines**).

213

214 It is also noteworthy that the individual wind tendencies contribute significantly more in the Southern Hemisphere than in the
215 Northern Hemisphere (**Fig. 3c**). In the low latitudes, both Dyn and Conv contribute to accelerating the easterly winds, which
216 is partly balanced by Turb in the OIFS-LRA-1h configuration (**Fig. 3c, solid lines**). There are no discernible changes in Conv,
217 Dyn or Turb from OIFS-LRA-1h to OIFS-LRA-15m, indicating that the tropical surface winds are relatively insensitive to
218 model time step (**Fig. 3c, dashed lines**).

219

220 The OIFS-HRA-15m also has the lowest SAT RMSE of all model experiments in both annual and seasonal means, although
221 the RMSE difference across the configurations is not significant (**Fig. 2b**). The reduced SAT RMSE in OIFS-HRA-15m
222 configuration is primarily due to the lowered SAT bias over North America and the eastern part of Russia. Compared to the
223 OIFS-LRA-1h, the SAT RMSE decreases with increased horizontal resolution (OIFS-HRA-15m and OIFS-MRA-15m) and
224 shortened time step (OIFS-LRA-30m and OIFS-LRA-15m) (figure not shown).

225

226 The OIFS-LRA-1h experiment exhibits the lowest precipitation RMSE of all experiments, with RMSE increasing with shorter
227 time step (OIFS-LRA-15m) and increased horizontal resolution (OIFS-HRA-15m) for both the annual and boreal winter means
228 (**Fig. 2c, black and blue lines**). The patterns of regional precipitation biases are similar across the configurations in the mid-
229 and high-latitudes, whereas the precipitation biases increase in the tropics at the high horizontal resolution or in the smaller
230 time step configuration (not shown). The results suggest that some of the cloud and/or convection parameters may be dependent
231 on resolution or time step and need retuning for each configuration.

232 3.2 Rossby wave analysis

233 **Fig. 4** shows the Rossby wave amplitude (gray and black contours) for ERA5 and the individual OIFS simulations for the
234 boreal winter (**Fig. 4A, DJF, Northern Hemisphere; NH**) and austral winter (**Fig. 4B, JJA, Southern Hemisphere; SH**).
235 The color in **Fig. 4** denotes the wave amplitude bias relative to ERA5 (model – ERA5), normalized by the ERA5 detrended
236 variability expressed by the standard deviation (std). We focus only on those wave numbers and latitudes that have the highest
237 wave amplitude, because these waves explain most of the variability. The region where the wave amplitude is larger than 5
238 ms^{-1} is termed “core region”, which mostly covers the area that is occupied by the thick black contours in **Fig. 4**. In DJF (NH),
239 at north of 70°N , the Rossby wave numbers $k=1$ and $k=2$ have the largest amplitude in ERA5 whereas at the mid-latitudes
240 (30°N to 60°N), the wave numbers between about $k=3$ and $k=9$ have large amplitude with the largest amplitude amounting
241 to 8ms^{-1} at about 40°N for the wave number $k=6$ (**Fig. 4Aa**). During JJA (SH), the wave amplitude is located in a similar core
242 region (**Fig. 4Ba**) as that in DJF (NH). The amplitude is largest south of 70°S for the wave numbers $k=1$ and $k=2$ whereas at
243 the mid-latitudes (45°S to 65°S), the wave numbers between about $k=3$ to 5 have large amplitude with the largest amplitude
244 amounting to 9ms^{-1} is found at 57.5°S for the wave number $k=4$ (**Fig. 4Ba**).

245
246 In DJF (NH) the OIFS-LRA-1h configuration exhibits a positive bias of ~ 1.5 std in Rossby wave amplitude (i.e., the waves
247 amplitude bias in OIFS-LRA-1h is 50% larger than the variance from ERA-5) in the core region, in particular for wave numbers
248 $k=3-8$ at latitudes between 25°N to 45°N (**Fig. 4Af**). The large wave amplitude biases (~ -4 to -2 std) outside of the core region
249 (mostly near the poles for higher wave numbers) in OIFS-LRA-1h are unimportant as these waves have a small amplitude and
250 little effect on variability. Therefore, these biases are not discussed further for other configurations for both hemispheres.

251
252 The Rossby wave amplitude biases in the OIFS-HRA-15m configuration are strongly reduced compared to the OIFS-LRA-1h
253 configuration over the core region (**Fig. 4Ab and 4Af**). The Rossby wave amplitude bias reduction in the OIFS-MRA-15m
254 configuration is similar to that in the OIFS-HRA-15m configuration except for the wave number $k=7$ at 45°N , where the wave
255 amplitude bias is larger in the OIFS-HRA-15m configuration (**Fig. 4Ab and 4Ac**). The Rossby wave amplitude biases are
256 progressively reduced from the OIFS-LRA-1h configuration to the OIFS-LRA-30m and OIFS-LRA-15m configurations (**Fig.**
257 **4Ad-Af**), indicating a sensitivity of model bias to the time step. The wave amplitude bias for wave number $k=7$ at 45°N exists
258 in all the configurations, and it is smaller in the OIFS-LRA-15m configuration than in the other configurations. Overall, both
259 OIFS-LRA-15m and OIFS-HRA-15m configurations are able to reproduce the observed Rossby-wave amplitudes in DJF (NH)
260 better than OIFS-LRA-1h.

261
262 In JJA (SH), the Rossby wave amplitude bias in the core region is smaller than in DJF (NH) for all the configurations (**Fig.**
263 **4A and 4B**). OIFS-LRA-1h exhibits a positive bias of ~ 1 std in JJA (SH) for the wave number $k=2$ at latitude between $\sim 50^\circ \text{S}$
264 and $\sim 62.5^\circ \text{S}$ and for wave numbers $k=4$ to 5 between 30°S and 40°S (**Fig. 4Bf**). The OIFS-HRA-15m and OIFS-MRA-15m

265 configurations exhibits biases above ~ 2 std at wave numbers $k > 6$ and latitude 50° S to 70° S, which does not exist in the other
266 coarse resolution configurations (**Fig. 4Bb-Bf**), although we note that the absolute amplitudes are very small for these waves
267 and the impact of the biases is negligible.

268

269 We also analyze the phase speed of Rossby waves for ERA5 and across the OIFS' configurations for DJF (NH) and JJA (SH)
270 seasons (**Fig. 5**). In the ERA5 dataset (**Fig. 5Aa**), the Rossby wave phase speed is positive (i.e., eastward moving, solid contour)
271 for wave numbers greater than 2 (i.e., $k > 2$) at most latitudes. The wave numbers $k=1$ to 2 have a positive wave phase speed
272 from the equator to 55° N and a negative wave phase speed (i.e., westward moving, dashed contours) between 60° N and 80°
273 N in DJF (NH) (**Fig. 5Aa**). The maximum phase speed is found at wave number $k=8$ at 40° N, while the minimum is found at
274 wave number $k=1$ at 60° N (**Fig. 5Aa**). In JJA (SH) (**Fig. 5Ba**), the wave phase speeds are mostly positive and large for all the
275 wave numbers and at each latitude, with the maximum phase speed is observed for the wave numbers between $k=6$ and $k=8$
276 and latitudes between 40° S and 60° S, and these waves are moving faster than that in DJF (NH).

277

278 The OIFS-LRA-1h configuration suffers from positive phase speed bias for wave numbers $k=4$ to 8 at latitudes between 42.5°
279 N and 60° N, i.e., waves move faster eastward than in ERA5, and the bias is larger than 1 std. The bias of ~ 1 std for wave
280 number $k = 6$ to 8 at 40° N and 60° N is of particular concern as it is near the maximum wave amplitudes in DJF (**Fig. 4Af**).
281 In general, phase speed biases in the OIFS-LRA-1h configuration are strongly reduced as either horizontal resolution is
282 increased or time step is shortened (**Fig. 5Ab-5Af**). In JJA (SH), the OIFS-LRA-1h configuration exhibits a very large (~ 1.5
283 std) Rossby wave phase speed bias for most of the wave numbers, which is largest for the wave numbers $k=3$ to 8 between 25°
284 S to 55° S (**Fig. 5Bf**). Large biases can be found between 15° S and 25° S (~ 2 std) for most of the wave numbers, but the wave
285 activity is low there (**Fig. 4Bf**). The large phase speed biases are strongly reduced in the OIFS-LRA-30m and OIFS-LRA-15m
286 configurations (**Fig. 5Bd-Bf**), indicating a strong sensitivity to the reduced biases in mean winds and wind speeds (Fig. 1).
287 Overall, the Rossby wave speed bias in the OIFS-HRA-15m configuration is smaller than in the OIFS-LRA-1h configuration
288 (**Fig. 5Bb and 5Bf**). However, we note that both the OIFS-MRA-15m and OIFS-HRA-15m configurations exhibit negative
289 biases south of 55° S for wave numbers $k=1$ to 5, that is, the eastward moving waves are slower than in the ERA5 (**Fig. 5Bb**).

290

291 The wave phase speed analysis reveals a clear improvement in the representation of the Rossby waves in the boreal winter
292 (i.e., NH) when increasing the horizontal resolution and shortening the model time step compared to OIFS-LRA-1h
293 configuration. In austral winter, however, the representation of Rossby wave amplitudes and phase speeds are the most realistic
294 in OIFS-LRA-15m configuration, with longer time steps introducing too fast phase speeds and higher horizontal resolution
295 introducing too slow phase speeds at wave number less than 6 (i.e., $k < 6$).

296

297 3.3 Weather regimes pattern

298 We derive the four weather regimes patterns (WRPs) over NH in the Euro-Atlantic region from ERA5. The patterns resemble
299 the positive and negative phases of the North Atlantic Oscillation (NAO+ and NAO-, respectively), Scandinavian blocking
300 (Sc. Blocking), and the North Atlantic ridge (Atl. Ridge) pattern (**Fig. 6, bottom row**). These WRPs are consistent with the
301 previous findings (**Dawson et al., 2012; Fabiano et al., 2020; Fabiano et al., 2021**).

302
303 The OIFS-HRA-15m configuration produces WRPs that are more visually similar to those in ERA-5 than does OIFS-LRA-1h
304 (Fig. 6), a result confirmed by the higher pattern correlation coefficient (PCC) between OIFS-HRA-15m and ERA5 compared
305 to the OIFS-LRA-1h and ERA-5 (**Fig. 6 and 7**). The PCCs for NAO+, NAO- and Sc. Blocking all exceed 0.8 in OIFS-HRA-
306 1h while OIFS-LRA-1h does not achieve PCC above 0.8 for any WRP (**Fig. 6**).

307
308 The OIFS-MRA-15m configuration shows smaller PCCs than both the OIFS-HRA-15m and OIFS-LRA-1h configurations
309 (**Fig. 7**), i.e., the improvement from OIFS-LRA-1h to OIFS-HRA-15m does not have a linear relationship with model
310 horizontal resolution or time step. Compared to other configurations and ERA5, OIFS-MRA-15m the z500 anomaly in the
311 NAO+ pattern is too elongated in the southwest-northeast direction, and an unrealistic negative z500 anomaly over the North
312 Atlantic appears in the Sc. Blocking regime (Fig 6). Furthermore, OIFS-MRA-15m shows an Atl. Ridge pattern with neither
313 the right structure nor amplitude.

314
315 There is an improvement in the representation of the NAO- regime in the OIFS-LRA-30m configuration over the OIFS-LRA-
316 1h configuration (**Fig. 6**) while the Sc. Blocking regime becomes worse due to the ridge shifting westward. These changes are
317 also reflected in the PCCs (**Fig 7**). Similarly, the OIFS-LRA-15m better represents NAO- and Atl. Ridge than OIFS-LRA-1h
318 while NAO+ and Sc. Blocking worsened. The westward shift of the Sc. Blocking is similar in OIFS-LRA-15m and OIFS-
319 LRA-30m, and the worse NAO+ is related to a northward shift of both the positive and negative z500 anomalies. We note that
320 all experiments use the same SST and sea-ice conditions and that OIFS-LRA-1h, 30m and 15m share the same horizontal
321 resolution, i.e., the changes from OIFS-LRA-1h to OIFS-LRA-15m are not due to SST biases or representation of orography.
322 There does not seem to be a clear improvement as time step is shortened, despite the reduction in mean state biases and Rossby-
323 wave amplitudes and phase speeds.

324
325 The PCC is greater than 0.8 for three out of four WRPs in the OIFS-HRA-15m configuration, hence we argue that the OIFS-
326 HRA-15m has the most realistic representation of the weather regimes pattern out of all experiments here. Large improvement
327 in OIFS-HRA-15m over the other configurations could be due to better resolved topography and land-sea contrasts.

328

329 3.4 Discussion and Conclusions

330 We have investigated the sensitivity of the climate biases in the OpenIFS atmosphere model to changes in horizontal resolution
331 and time step by analyzing AMIP simulations for the period 1979-2019 (**Table 1**). The strong positive surface zonal wind bias
332 over the Southern Ocean and Northern Hemisphere mid-latitudes and the negative bias in the tropical and subtropical regions
333 have significantly improved in the high horizontal resolution configuration with a short time step (~25km, OIFS-HRA-15m).
334 A similar improvement is observed at the coarse horizontal resolution version with a shorter time step (~100 km with 30 or
335 15-minutes). The zonal wind bias over the mid-latitudes in both hemispheres is reduced throughout the air column when a
336 smaller time step is used in the coarse resolution version, and we find that the changes in the surface winds are largely due to
337 enhanced shallow and mid-level convection which increases vertical momentum transport. Biases in the surface westerlies in
338 midlatitudes are common in CMIP-class climate models (**Bracegirdle et al., 2020**) and a sensitivity to friction has been noted
339 in idealized model studies (**Chen and Plumb, 2009**). We hypothesize that the enhanced shallow and mid-level convection
340 with a shorter model time step and/or increased horizontal resolution deepened the layer over which friction acts in the lower
341 troposphere so that the frictional effects on the barotropic jet increased, leading to a poleward shift in the jet and reduced biases
342 in zonal wind.

343

344 We also find a notable improvement in the representation of the Rossby wave amplitude and phase speed with increased
345 horizontal resolution and shorter time step at least for the waves accounting most variability in both austral and boreal winter
346 seasons. The reduced zonal wind throughout the troposphere with a shorter time step (**Fig. 3**) would decrease the eastward
347 phase speed of Rossby waves, which may explain part of the reduced phase speeds (**Fig. 5**) and reduced biases. However,
348 changes in air-sea interactions or eddy-mean flow interactions may also play a role. In particular, we note that a very large
349 reduction in phase speed biases in austral winter in OIFS-LRA-15m compared to OIFS-LRA-1h were concurrent with very
350 large reduction in zonal surface wind biases.

351

352 The weather regime patterns are also more realistic in the high horizontal resolution and short time step configuration OIFS-
353 HRA-15m than OIFS-LRA-1h, but we note that there is no consistent improvement from OIFS-LRA-1h to OIFS-HRA-15m
354 as either horizontal resolution is increased or time step is shortened. For example, both OIFS-MRA-15m and OIFS-LRA-15m
355 are worse than OIFS-LRA-1h. The improvements in the weather regime patterns and Rossby wave amplitude and speed could
356 very well be related to each other as e.g. variations in Rossby wave breaking have been linked to the onset of NAO phases
357 (**Strong and Magnusdottir, 2008**) but this would require further and more targeted analysis. The overall good representation
358 of weather regimes in OIFS-LRA-1h compared to simulations with shorter time steps (OIFS-LRA-30m, OIFS-LRA-15m) may
359 be due to compensation of errors. For example, it is possible that improving the wave amplitudes and phase speeds in OIFS-
360 LRA-30m compared to OIFS-LRA-1h exposes the effect of a biases caused by both the coarse resolution in both
361 configurations, e.g., weak interactions with topography, leading to an overall worse representation of weather regimes.

362 We found a gradual reduction in SAT biases in OpenIFS with increased resolution or shorter time steps. The improvements
363 were largely driven by improvements over North America and eastern Russia. **Roberts et al. (2018)** noted similar SAT biases
364 and linked them to surface albedo, which is thus likely the cause here as well. The improvement with increased resolution
365 and/or shorter time step may be a result of improved snow cover. Systematic improvements in the precipitation biases were
366 not observed. Instead, precipitation biases generally increased with finer horizontal resolution or shorter time step, suggesting
367 that some tuning may be required in the physics parameters when changing horizontal resolution and time step.

368

369 We stress that the results presented in this study are specific to the OpenIFS atmosphere model and are crucial for the modeling
370 community that uses the OpenIFS in their climate models such as EC-Earth (**Haarsma et al., 2020**), CNRM (**Voldoire et al.,**
371 **2019**), AWI (**Streffing et al., 2022**), and GEOMAR (**Kjellsson et al., 2020**). However, the results may also have implications
372 for other climate modeling communities, at least for those that use a semi-Lagrangian scheme similar to the IFS (e.g., **Walters**
373 **et al., 2019**) in the atmospheric component where long time steps are both possible and often desirable to reduce the
374 computational cost of the model.

375

376 The zonal wind bias improvement in the OpenIFS is important for research questions linked with the Southern Ocean climate
377 dynamics that plays a crucial role in both the global atmosphere and ocean circulation. We propose that the model time step
378 not be longer than 30 minutes at any horizontal resolution to minimize surface wind biases over the ocean. The computational
379 cost increases linearly with dt (time step), whereas the cost scales with horizontal resolution as dx^3 as the number of grid
380 points increases in both dimensions and the time step is likely shortened as well. Hence, reducing the model time step from 45
381 or 60 minutes to 20 or 30 minutes may double the computational cost, but lead to significant improvements in the simulated
382 climate. The optimal model time step for the OpenIFS coarse resolution model (1°) is suggested to be 30-minute, but should
383 likely be somewhat shorter, e.g., 15 min, for higher resolutions.

384

385

388

389

390

391

392

393 **Code and data availability**

394 The OpenIFS model requires a software license agreement with ECMWF, and OpenIFS' license is easily given free of charge
395 to any academic or research institute. The details of the different versions of the OpenIFS model, including the OpenIFS
396 version used in this study, i.e., 43R3, can be found at <https://confluence.ecmwf.int/display/OIFS/About+OpenIFS>. The
397 OpenIFS model source code has been made available for the editor and reviewers.

398 The input datasets (both initial and boundary conditions) needed to run the OpenIFS model, run scripts, the model output, and
399 the Jupiter notebook that support the finding of this study are available at (Savita, 2023). The source code for XIOS 2.5,
400 revision 1910, is available from the official repository at <https://forge.ipsl.jussieu.fr/ioserver/> under CeCILL_V2 license.
401 OpenIFS experiments were made using ESM-Tools (https://github.com/esm-tools/esm_tools/). The OASIS coupler is
402 available at <https://oasis.cerfacs.fr/en/>. The XIOS, ESM-Tools and OASIS coupler used in this study can be downloaded from
403 <https://doi.org/10.5281/zenodo.8189718>.

404 The observational datasets used to validate OpenIFS model results in this study are downloaded from the ERA5
405 (<https://cds.climate.copernicus.eu/>), GPCP (<https://psl.noaa.gov/data/gridded/data.gpcp.html>) and CRUTEM4
406 (<http://badc.nerc.ac.uk/data/cru/>) websites. Total model output exceeds 10 Tb and it not publicly available, but is available
407 from the authors upon reasonable requests.

408 **Author contributions**

409 All the model simulations were conducted by AS and JK. Analysis of the output and the writing of text for this paper
410 coordinated by Savita with substantial contributions from JK, RPK, ML, TR, SW and WP.

411 **Competing interest**

412 The authors declare that they have no conflict of interest.

413 **Acknowledgement**

414 AS, JK and MK are supported by JPI Climate/Ocean (ROADMAP project grant 01LP2002C). We wish to thank the OpenIFS
415 team at ECMWF for the technical support. All simulations were performed on the HLRN machine under shk00018 project
416 resources. All analyses were performed on computer clusters at GEOMAR and Kiel University Computing Center (NESH).
417 We thanks to Anton Beljaars for discussion on ECMWF model physics.

Table

Experiment Name	Horizontal resolution	Vertical grid	Time step
OIFS-LRA-15m	Tco95/100km	L91	15m
OIFS-MRA-15m	Tco199/50km	L91	15m
OIFS-HRA-15m	Tco399/25km	L91	15m
OIFS-LRA-30m	Tco95/100km	L91	30m
OIFS-LRA-1h	Tco95/100km	L91	1h

Table 1. List of the experiments performed across different horizontal resolutions and model time steps using OIFS model.

531

Figures

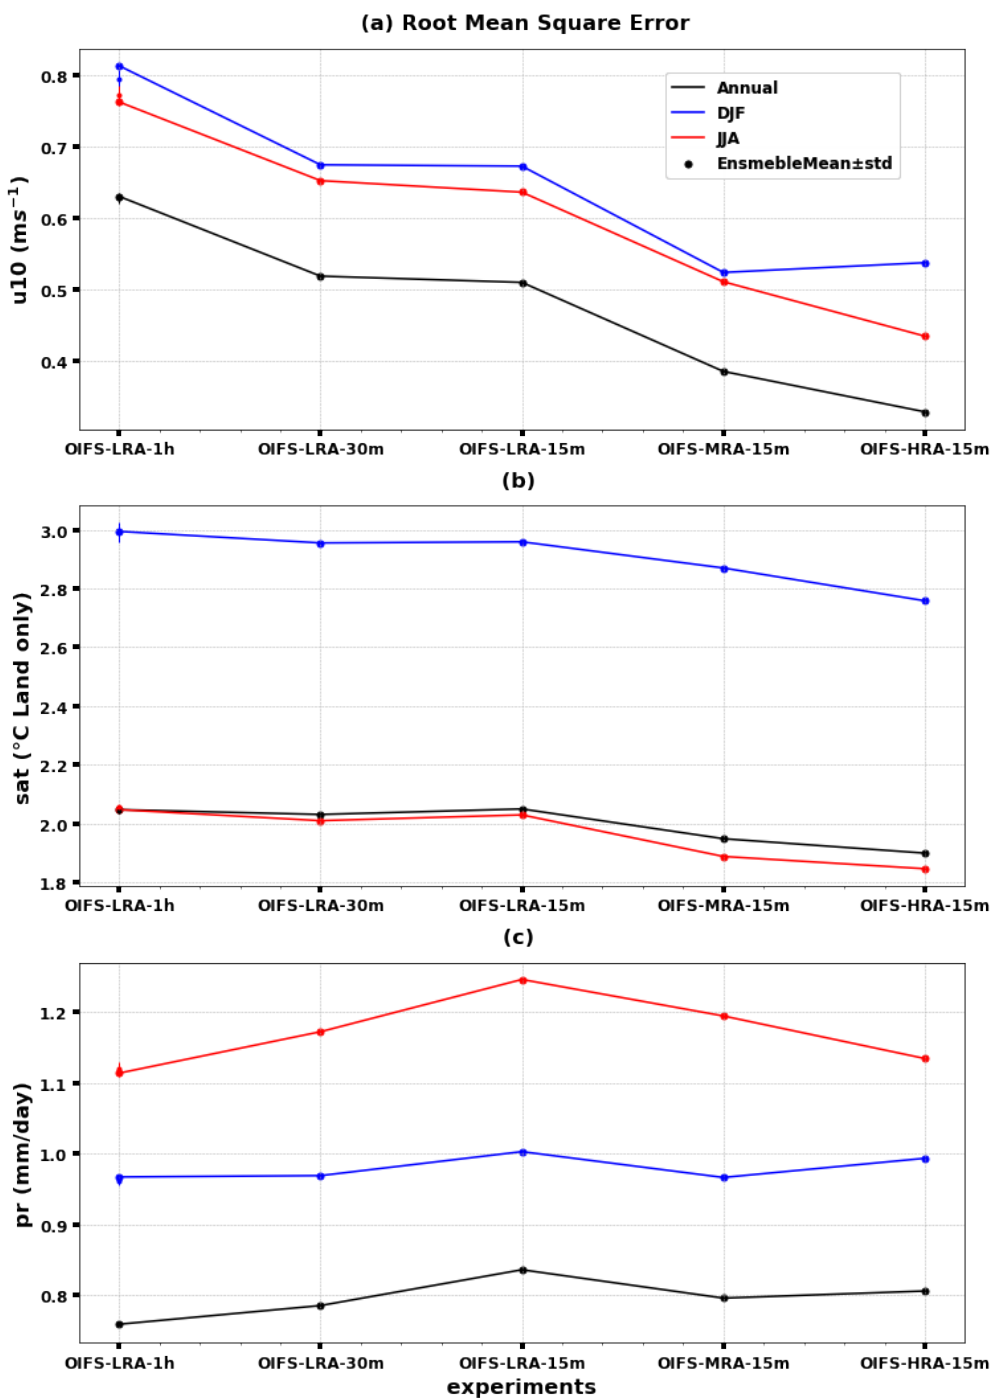

532

533

534 **Figure 1.** (a) Annual mean ERA5 surface zonal wind [ms^{-1}]. (b-d) Annual mean zonal wind [ms^{-1}] bias for different model
535 time steps (1h (b), 30m (c), and 15m (d)) using ~ 100 km resolution, and (e-f) with different horizontal resolutions, ~ 50 (e) and
536 ~ 25 km (f), respectively. Biases are computed with respect to ERA5 over the period 1979–2019.

537

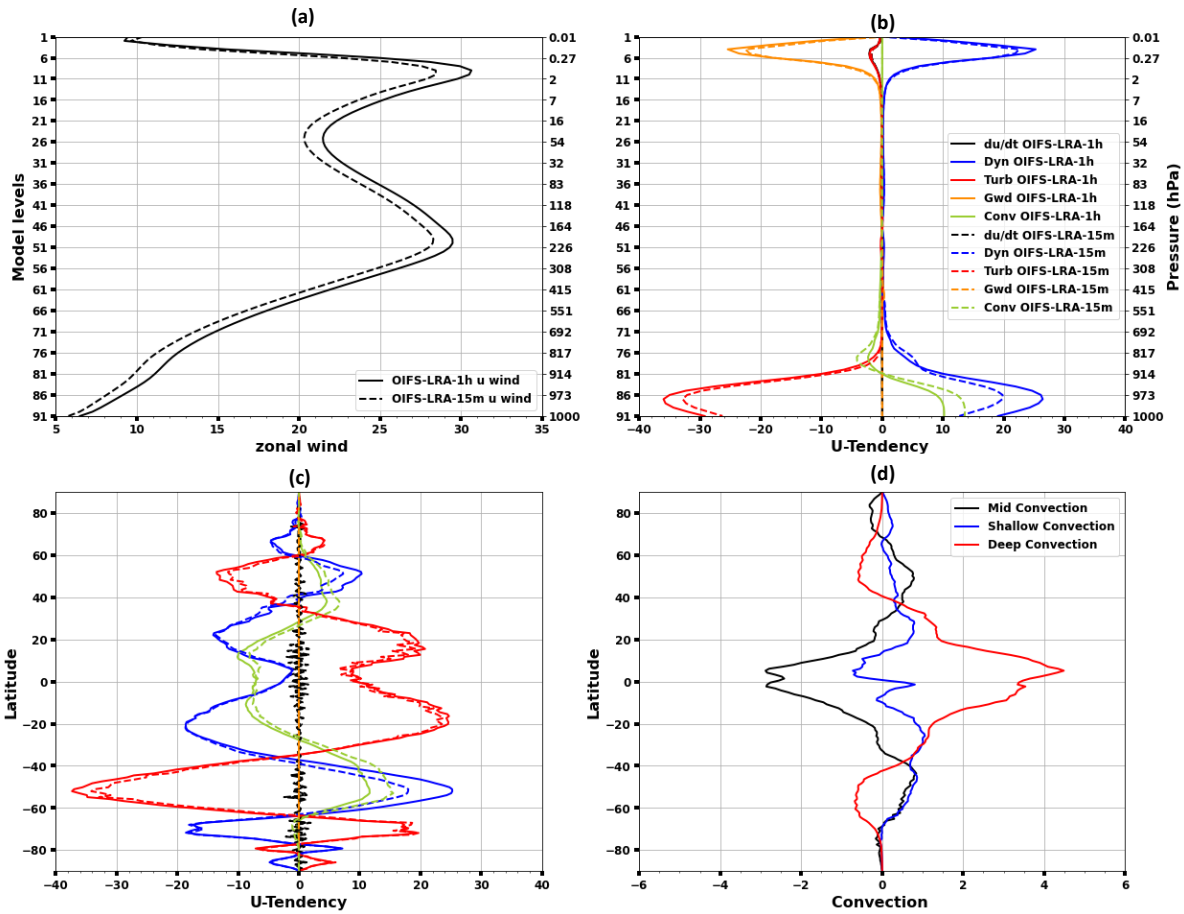

538

539 **Figure 2.** Root mean squared error of surface zonal wind (a), SAT (b), and precipitation (c) over the period 1979-2019 for all
 540 the configurations: annual (black) and seasonal mean (DJF: blue, JJA: red). We have also shown 5-member ensemble mean
 541 and standard deviation only for OIFS-LRA-1h configuration.

542

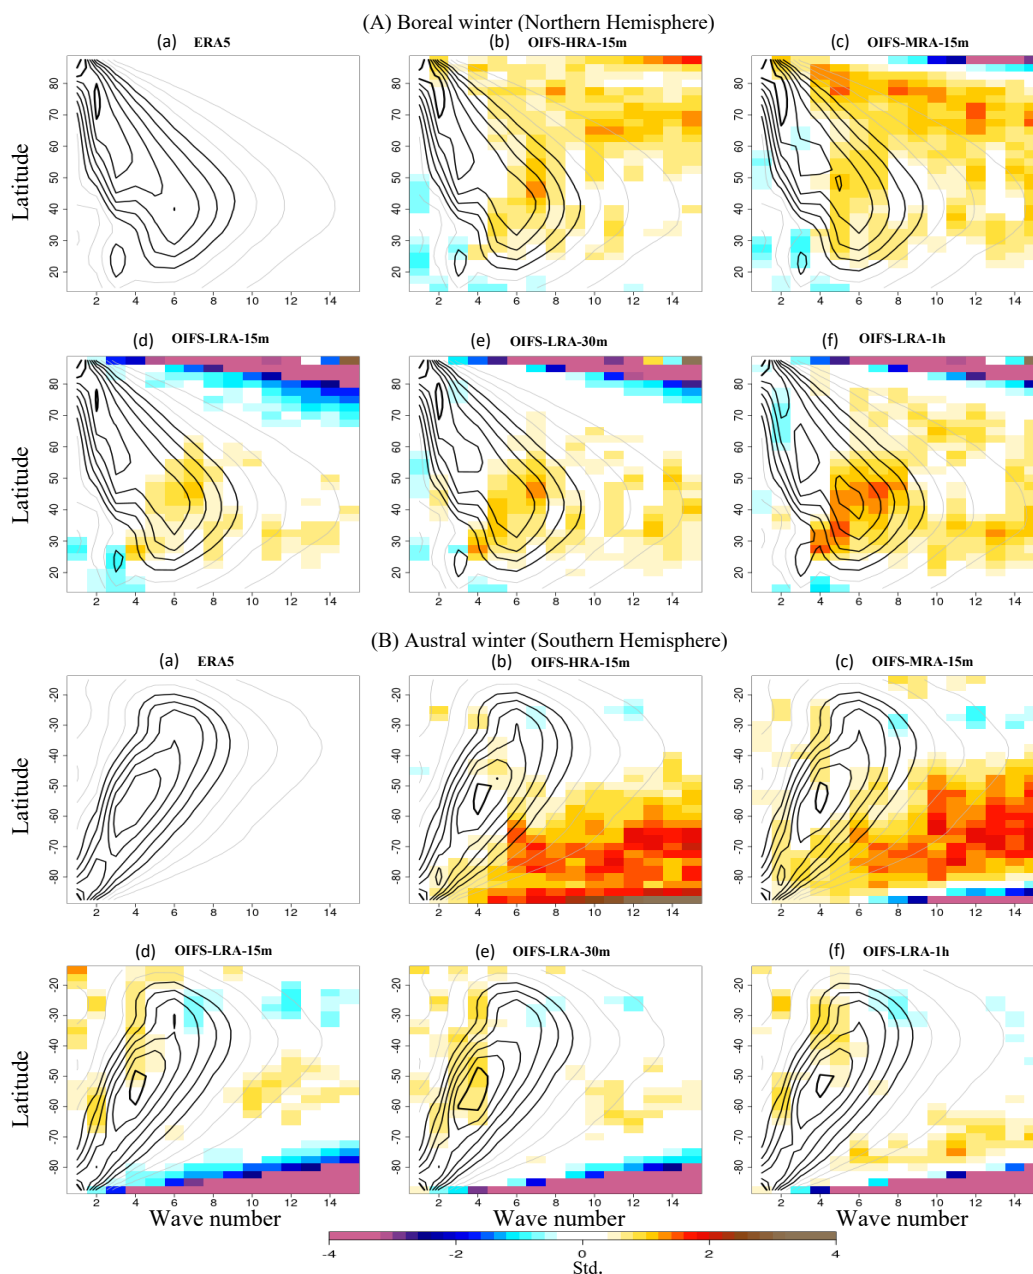

543

544

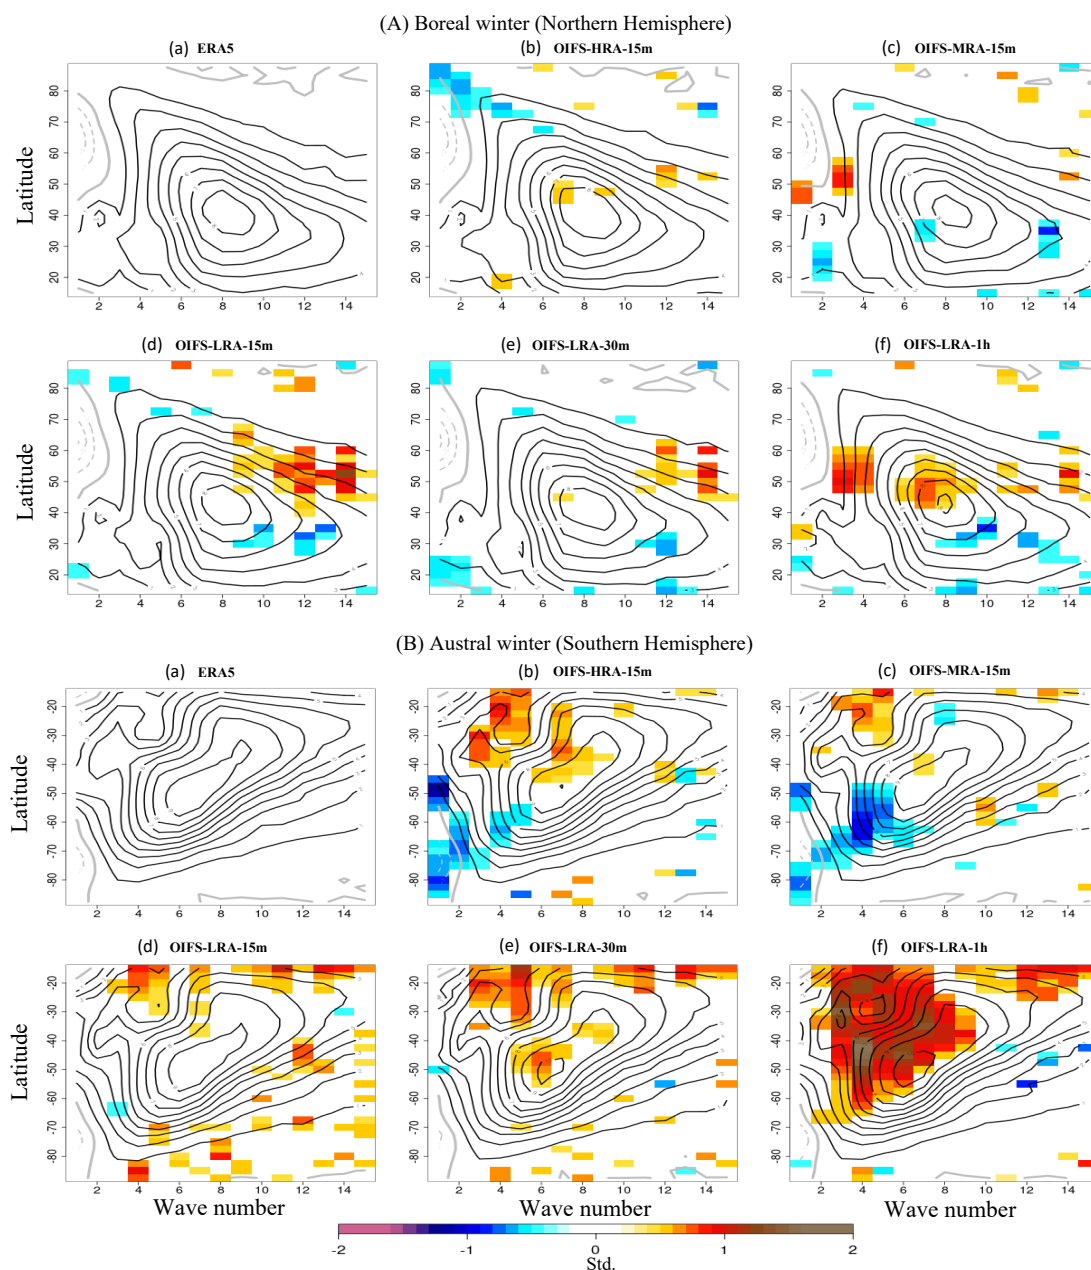

545 **Figure 3.** (a) Averaged zonal wind (u) [ms^{-1}] and zonal wind tendencies [$\text{ms}^{-2}/\text{hour}$] over the Southern Ocean ($40^{\circ}\text{S} - 60^{\circ}\text{S}$,
 546 all longitude) as a function of height for OIFS-LRA-1h and OIFS-LRA-15m. Model levels (y-axis left) and pressure levels (y-
 547 axis right). (c) Zonal and time average of zonal wind tendencies at the lowest level of the model as a function of latitude. (d)
 548 Zonal and time average convection difference [$\text{Kgm}^{-2}/\text{hour}$] between OIFS-LRA-15m and OIFS-LRA-1h configurations. The
 549 solid lines in panels (b) and (c) show the wind tendency for OIFS-LRA-1h configuration whereas the dashed lines are for
 550 OIFS-LRA-15m configuration. Shown are averages over 1979-2019.

551

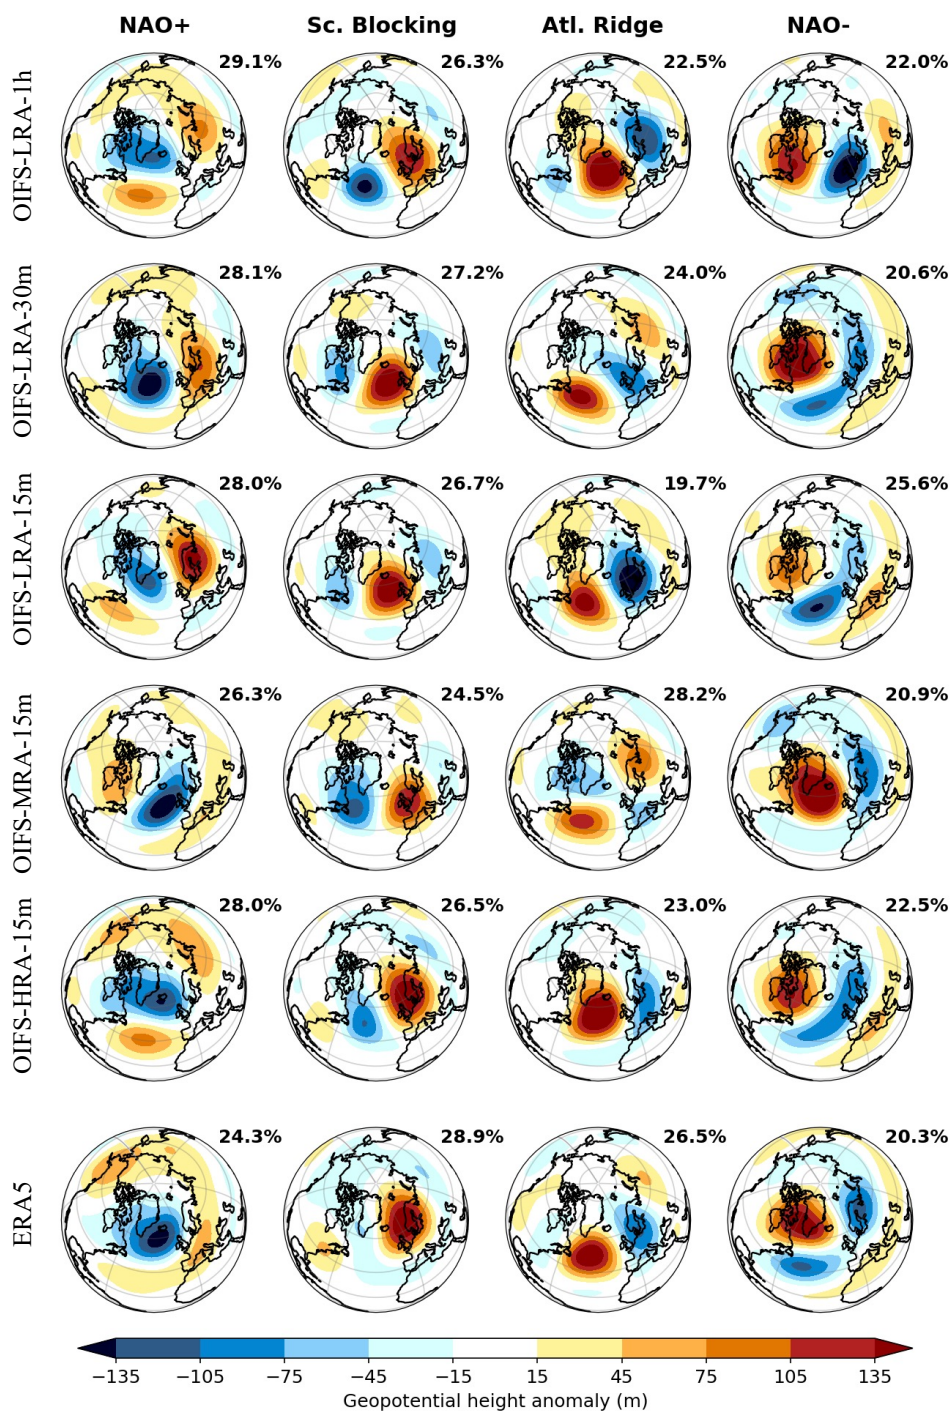

552

553 **Figure 4.** (A) The Rossby wave amplitude (contours) for different wave numbers in the Northern Hemisphere at 300 hPa (a)
554 in ERA5 observation and (b-f) in the OIFS model simulations during 1979-2019 in DJF (i.e., boreal winter). The color shows
555 the detrended and standardized difference of wave amplitude between the model and ERA5 where it is significant on the 95
556 % confidence level. The wave amplitude and contour interval are shown in ms⁻¹. The grey contours start from 2 ms⁻¹ and the
557 black contours from 5 ms⁻¹ and the contour interval is 1 ms⁻¹. (B) is similar to (A), but for JJA (i.e., austral winter).

558

559 **Figure 5.** (A) The Rossby wave phase speed (contours) for different wave numbers at 300 hPa in the Northern Hemisphere in
 560 ERA5 (a) observation and (b-f) in the OIFS model simulations during 1979-2019 in DJF (i.e., boreal winter). The color shows
 561 the detrended and standardized difference of wave phase speed between model and ERA5 where it is significant on the 95 %
 562 confidence level. The wave phase speed and contour interval are shown in ms^{-1} . The contours start from 1 ms^{-1} and the contour
 563 interval is 1 ms^{-1} . Panel (B) is similar to panel (A), but for JJA (i.e., austral winter).

564

565

566 **Figure 6.** Weather regime patterns over the Euro–Atlantic regions from ERA5 observation (bottom row) and the individual
567 OIFS model simulations (1st to 5th row) over the time period 1979–2019 for DJF (boreal winter season).

568

569

570 **Figure. 7.** Pattern correlation coefficient of the individual weather regime between OIFS model configurations and ERA5
571 for the period 1979-2019 for the DJF season.
