## 16 **Abstract**

17 The cosmogenic radionuclides  $^7\text{Be}$  and  $^{10}\text{Be}$  are useful tracers for atmospheric transport studies. Combining  $^7\text{Be}$   
18 and  $^{10}\text{Be}$  measurements with an atmospheric transport model can not only improve our understanding of the  
19 radionuclide transport and deposition processes but also provide an evaluation of the transport process in the  
20 model. To simulate these aerosol tracers, it is critical to evaluate the influence of radionuclide production  
21 uncertainties on simulations. Here we use the GEOS-Chem chemical transport model driven by the MERRA-2  
22 reanalysis to simulate  $^7\text{Be}$  and  $^{10}\text{Be}$  with the state-of-the-art production rate from the CRAC:Be (Cosmic Ray  
23 Atmospheric Cascade: Beryllium) model considering realistic spatial geomagnetic cut-off rigidities (denoted as  
24 P16spa). We also perform two sensitivity simulations: one with the default production rate in GEOS-Chem based  
25 on an empirical approach (denoted as LP67), and the other with the production rate from the CRAC:Be but  
26 considering only geomagnetic cut-off rigidities for a geocentric axial dipole (denoted as P16). The model results  
27 are comprehensively evaluated with a large number of measurements including surface air concentrations and  
28 deposition fluxes. The simulation with the P16spa production can reproduce the absolute values and temporal  
29 variability of  $^7\text{Be}$  and  $^{10}\text{Be}$  surface concentrations and deposition fluxes on annual and sub-annual scales, as well  
30 as the vertical profiles of air concentrations. The simulation with the LP67 production tends to overestimate the  
31 absolute values of  $^7\text{Be}$  and  $^{10}\text{Be}$  concentrations. The P16 simulation suggests less than 10% differences compared  
32 to P16spa but a significant positive bias (~18%) in the  $^7\text{Be}$  deposition fluxes over East Asia. We find that the  
33 deposition fluxes are more sensitive to the production in the troposphere and downward transport from the  
34 stratosphere. Independent of the production models, surface air concentrations and deposition fluxes from all  
35 simulations show similar seasonal variations, suggesting a dominant meteorological influence. The model can  
36 also reasonably simulate the stratosphere-troposphere exchange process of  $^7\text{Be}$  and  $^{10}\text{Be}$  by producing  
37 stratospheric contribution and  $^{10}\text{Be}/^7\text{Be}$  ratio values that agree with measurements. Finally, we illustrate the  
38 importance of including the time-varying solar modulations in the production calculation, which significantly  
39 improve the agreement between model results and measurements, especially at mid- and high- latitudes. Reduced

40 uncertainties in the production rates, as demonstrated in this study, improve the utility of  $^7\text{Be}$  and  $^{10}\text{Be}$  as aerosol  
41 tracers for evaluating and testing transport and scavenging processes in global models. For future GEOS-Chem  
42 simulations of  $^7\text{Be}$  and  $^{10}\text{Be}$ , we recommend using the P16spa (versus default LP67) production rate.

## 43 **1 Introduction**

44 The naturally occurring cosmogenic radionuclide  $^7\text{Be}$  (half-life of 53.2 days) is monitored worldwide and has  
45 been recognized as a useful tracer in atmospheric dynamic studies (Aldahan et al., 2001; Hernández-Ceballos et  
46 al., 2016; Terzi et al., 2019; Liu et al., 2016). Especially, ratios of radionuclides concentrations with very different  
47 half-lives, such as the  $^{10}\text{Be}/^7\text{Be}$  ratio, have become powerful tools (e.g., Liu et al., 2022b; Raisbeck et al., 1981)  
48 to disentangle the influence of transport and deposition since both  $^7\text{Be}$  and  $^{10}\text{Be}$  in the troposphere are mainly  
49 removed by wet deposition. In this paper, we aim to improve the utility of  $^7\text{Be}$  and  $^{10}\text{Be}$  as tracers for atmospheric  
50 transport by using state-of-the-art production rates in a global 3-D chemical transport model.

51  $^7\text{Be}$  and  $^{10}\text{Be}$  are produced through interactions between atmospheric atoms (mostly oxygen and nitrogen)  
52 and incoming cosmic rays in the atmosphere (Lal and Peters, 1967, referred to as LP67 hereafter; Poluianov et  
53 al., 2016, referred to as P16 hereafter). Due to the atmospheric depth-profile of fluxes of primary cosmic rays, the  
54 formed secondary particles, and their energy,  $^7\text{Be}$  and  $^{10}\text{Be}$  production rates reach their maxima in the lower  
55 stratosphere (Poluianov et al., 2016). About two-thirds of  $^7\text{Be}$  and  $^{10}\text{Be}$  are produced in the stratosphere while the  
56 rest is produced in the troposphere (Poluianov et al., 2016; Heikkilä and Smith, 2013; Golubenko et al., 2022).  
57 Once produced,  $^7\text{Be}$  and  $^{10}\text{Be}$  rapidly attach to aerosol particles and get transported and deposited with their carrier  
58 aerosols by wet and dry depositions (Delaygue et al., 2015; Heikkilä et al., 2013).  $^{10}\text{Be}$  has a half-life of 1.39  
59 million years (Chmeleff et al., 2010) and its decay is thus negligible compared to its average atmospheric residence  
60 time (about 1-2 years) (Heikkilä et al., 2008b). During transport away from the regions of their production, the  
61  $^{10}\text{Be}/^7\text{Be}$  ratio increases because  $^7\text{Be}$  decays. The ratio  $^{10}\text{Be}/^7\text{Be}$  therefore could indicate the path-integrated age  
62 of the air mass. Due to different aerosol residence times in the stratosphere (more than 1 year) and troposphere  
63 (~weeks), the  $^{10}\text{Be}/^7\text{Be}$  ratio is higher in the stratosphere than in the troposphere. Hence the  $^{10}\text{Be}/^7\text{Be}$  ratio can be  
64 used to detect the stratosphere-troposphere exchange.

65 Many studies have focused on understanding the signals in surface  $^7\text{Be}$  measurements from worldwide  
66 monitoring stations (e.g., Hernandez-Ceballos et al., 2015; Rodriguez-Perulero et al., 2019; Uhlar et al., 2020;  
67 Ajtić et al., 2021; Burakowska et al., 2021). Due to the cosmogenic origin of  $^7\text{Be}$ , surface air  $^7\text{Be}$  concentrations  
68 are found to be connected to the 11-year cycle of solar modulation (Leppänen et al., 2010; Zheng et al., 2021a).  
69 In addition,  $^7\text{Be}$  concentrations in the surface air are affected by different meteorological processes depending on  
70 locations, such as stratospheric intrusions (Jordan et al., 2003; Pacini et al., 2015; Yamagata et al., 2019),  
71 scavenging by precipitation (Chae and Kim, 2019; Kusmierczyk-Michulec et al., 2015), vertical transport in the  
72 troposphere (Aldahan et al., 2001; Ajtić et al., 2018; Zheng et al., 2021a) and large-scale atmospheric circulations  
73 (Hernández-Ceballos et al., 2022; Terzi and Kalinowski, 2017).

74 The ability of general circulation models (GCMs, e.g., GISS ModelE, ECHAM5-HAM and EMAC) and  
75 chemical transport models (CTMs, e.g., GEOS-Chem and GMI) to capture the main characteristics in  $^7\text{Be}$  and  
76  $^{10}\text{Be}$  transport and deposition has been demonstrated in previous studies (e.g., Heikkilä et al., 2008b; Koch and  
77 Rind, 1998; Field et al., 2006; Usoskin et al., 2009; Brattich et al., 2021; Spiegl et al., 2022; Liu et al., 2016;  
78 Sukhodolov et al., 2017). For example, Usoskin et al. (2009) found that the influence of the solar proton-induced

79  $^7\text{Be}$  production peak at the surface in early 2005 is small through the comparison of GISS ModelE simulations  
80 and surface air measurements. Heikkilä et al. (2009) showed that stratospheric  $^{10}\text{Be}$  contribution is dominant in  
81 the global  $^{10}\text{Be}$  deposition by tracing tropospheric and stratospheric  $^{10}\text{Be}$  separately in the aerosol-climate model  
82 ECHAM5-HAM. Spiegl et al. (2022) used the EMAC climate model to investigate the transport and deposition  
83 process of  $^{10}\text{Be}$  produced by the extreme solar proton event in 774/5 A.D. They suggested that the downward  
84 transport of  $^{10}\text{Be}$  from the stratosphere is mainly controlled by the Brewer-Dobson circulation in the stratosphere  
85 and cross-tropopause transport. By comparing the measurements with GEOS-Chem simulations over January-  
86 March 2003, Brattich et al. (2021) found that increased  $^7\text{Be}$  values in surface air samples in Northern Europe in  
87 early 2003 were associated with the instability of the Arctic polar vortex. They also showed that, while the model  
88 generally simulates well the month-to-month variation in surface  $^7\text{Be}$  concentrations, it tends to underestimate the  
89 observations (see their Table 2) partly due to the use of the default LP67 production rate for a solar maximum  
90 year (1958) in the GEOS-Chem model (Liu et al., 2001). By using the GMI CTM driven with four different  
91 meteorological datasets, Liu et al. (2016) showed that the observational constraints for  $^7\text{Be}$  and observed  $^7\text{Be}$  total  
92 deposition fluxes can be used to provide a first-order assessment of cross-tropopause transport in global models.  
93 In comparison to GCMs with or without nudged winds (e.g., Golubenko et al., 2021; Heikkilä et al., 2008b; Spiegl  
94 et al., 2022) which involve simulating the entire global circulation and climate, the “offline” CTMs are driven by  
95 archived meteorological data sets, either from output of GCMs or from atmospheric data assimilation systems.  
96 For example, GEOS-Chem can be driven by the GEOS assimilated meteorology (e.g., MERRA-2 reanalysis data;  
97 Gelaro et al., 2017a) or output from the GISS GCM (e.g., Murray et al., 2021).

98 In comparison with the LP67 production rate using an empirical approach (Lal and Peters, 1967; Liu et al.,  
99 2001; Brattich et al., 2021), the recent production models apply full Monte-Carlo simulations of the cosmic-ray-  
100 induced atmospheric nucleonic cascade (e.g., Poluianov et al., 2016; Masarik and Beer, 1999). LP67 shows the  
101 highest  $^7\text{Be}$  and  $^{10}\text{Be}$  production rates compared to other production models (Elsässer, 2013). P16 suggests that  
102 LP67 overestimates the  $^7\text{Be}$  production rate by 30-50% compared to their production model (Poluianov et al.,  
103 2016). Furthermore, the LP67 production rate implemented in GEOS-Chem is only validated for the year 1958, a  
104 year with a high solar modulation function (i.e., high solar activity) of 1200 MeV (Herbst et al., 2017). This  
105 highlights the problem of quantitatively comparing these uncorrected model outputs with measurements from  
106 other time periods. Some studies (e.g., Koch et al., 1996; Liu et al., 2016) have applied a scale factor to account  
107 for this solar modulation influence on LP67 production rate. However, this correction is not ideal as the influence  
108 of varying solar modulation is latitudinally and vertically dependent. In earlier studies, the  $^{10}\text{Be}$  production rate in  
109 GEOS-Chem was simply scaled to the  $^7\text{Be}$  production rate based on the ratio estimated from the surface  
110 measurements (Koch and Rind, 1998). In addition,  $^{10}\text{Be}$  as simulated by GEOS-Chem has not been evaluated so  
111 far. It is hence necessary to update the  $^7\text{Be}$  and  $^{10}\text{Be}$  production rates in GEOS-Chem and assess the corresponding  
112 impacts on model simulation results.

113 In this study, we incorporate global  $^7\text{Be}$  and  $^{10}\text{Be}$  production rates from the recently published “CRAC:Be”  
114 (Cosmic Ray Atmospheric Cascade: Beryllium) model (Poluianov et al., 2016) into the GEOS-Chem model. We  
115 simulate  $^7\text{Be}$  and  $^{10}\text{Be}$  using GEOS-Chem with the following three production scenarios.

- 116 • Scenario I: production rate derived from the “CRAC:Be” model considering realistic geomagnetic  
117 cut-off rigidity (P16spa production rate)

- 118 • Scenario II: production rate derived from the “CRAC:Be” model considering an approximation of  
119 geomagnetic cut-off rigidities using a geocentric axial dipole (P16 production rate)
- 120 • Scenario III: default production rate in GEOS-Chem using an empirical approximation (LP67  
121 production rate)

122 Scenario I is treated as the standard simulation while the other two are sensitivity tests that also enable  
123 comparison to earlier studies. This paper is organized as follows. Section 2 introduces the GEOS-Chem model  
124 and three different  $^7\text{Be}$  and  $^{10}\text{Be}$  production rates, discusses the methodology and experiment design, and describes  
125 the observational data for model evaluations. In section 3, we first investigate the differences between three  
126 different production scenarios (section 3.1). Then, we evaluate model simulations of  $^7\text{Be}$  and  $^{10}\text{Be}$  with several  
127 published datasets of  $^7\text{Be}$  and  $^{10}\text{Be}$  measurements, in terms of absolute values (section 3.2-3.3), vertical profiles  
128 (section 3.4), and seasonal variations (section 3.6). The budgets and residence times of  $^7\text{Be}$  and  $^{10}\text{Be}$  are given in  
129 section 3.5. We also examine the  $^{10}\text{Be}/^7\text{Be}$  ratio in the model to assess its ability in capturing the stratosphere-  
130 troposphere exchange (section 3.7). Finally, we investigate the influence of including solar-induced production  
131 rate variability on  $^7\text{Be}$  simulations (section 3.8). Summary and conclusions are given in section 4.

## 132 **2 Models and Data**

### 133 **2.1 GEOS-Chem model**

134 GEOS-Chem is a global 3-D chemical transport model (<http://www.geos-chem.org>) that simulates gases and  
135 aerosols in both the troposphere and stratosphere (Eastham et al., 2014; Bey et al., 2001). It is driven by archived  
136 meteorological data. We use version 14.0.2 ([https://wiki.seas.harvard.edu/geos-chem/index.php/GEOS-](https://wiki.seas.harvard.edu/geos-chem/index.php/GEOS-Chem_14.0.2)  
137 [Chem\\_14.0.2](https://wiki.seas.harvard.edu/geos-chem/index.php/GEOS-Chem_14.0.2)) to simulate the transport and deposition of atmospheric  $^7\text{Be}$  and  $^{10}\text{Be}$ . We drive the model with the  
138 Modern-Era Retrospective analysis for Research and Applications, Version 2 (MERRA-2) meteorological  
139 reanalysis (<http://gmao.gsfc.nasa.gov/reanalysis/MERRA-2/>; Gelaro et al., 2017b). MERRA-2 has a native  
140 resolution of  $0.5^\circ$  latitude by  $0.667^\circ$  longitude, with 72 vertical levels up to 0.01 hPa (80 km). Here the MERRA-  
141 2 data are re-gridded to  $4^\circ$  latitude by  $5^\circ$  longitude for input to GEOS-Chem for computational efficiency.

142 GEOS-Chem includes a radionuclide simulation option ( $^{222}\text{Rn}$ - $^{210}\text{Pb}$ - $^7\text{Be}$ - $^{10}\text{Be}$ ), which simulates transport  
143 (advection, convection, boundary layer mixing), deposition, and decay of the radionuclide tracers (e.g., Liu et al.,  
144 2001; Liu et al., 2004; Zhang et al., 2021a; Yu et al., 2018). The model uses the TPCORE algorithm of Lin and  
145 Rood (1996) for advection, archived convective mass fluxes to calculate convective transport (Wu et al., 2007),  
146 and the non-local scheme implemented by Lin and McElroy (2010) for boundary-layer mixing. As mentioned in  
147 the introduction section, the standard GEOS-Chem model uses the LP67  $^7\text{Be}$  and  $^{10}\text{Be}$  production rates. After  
148 production,  $^7\text{Be}$  and  $^{10}\text{Be}$  attach to ambient submicron aerosols ubiquitously and their behavior becomes that of  
149 aerosols until they are removed by wet deposition (precipitation scavenging) and dry deposition processes. Note  
150 that neither is the process of attachment explicitly represented nor is the aerosol size distribution considered in the  
151 model. In addition, the decay process is included for the short-lived  $^7\text{Be}$  with a half-life time of 53.2-day. The  
152 decay is minor for the long-living  $^{10}\text{Be}$ , which has a half-life time of 1.39 million years (e.g., Chmeleff et al.,  
153 2010).

154 Wet deposition includes rainout (in-cloud scavenging) due to stratiform and anvil precipitation (Liu et al.,  
155 2001), scavenging in convective updrafts (Mari et al., 2000), and washout (below-cloud scavenging) by

156 precipitation (Wang et al., 2011). Scavenged aerosols from vertical layers above are allowed to be released to the  
 157 atmosphere during re-evaporation of precipitation below cloud. In case of partial re-evaporation, we assume that  
 158 half of the corresponding fraction of the scavenged aerosol mass is released at that level because some of the re-  
 159 evaporation of precipitation are due to partial shrinking of the raindrops, which does not release aerosol (Liu et  
 160 al., 2001). MERRA-2 fields of precipitation formation and evaporation are used directly by the model wet  
 161 deposition scheme. Dry deposition is based on the resistance-in-series scheme of Wesely (1989). The process of  
 162 sedimentation is not included in the model.

163 To quantify the stratospheric contribution to  $^7\text{Be}$  and  $^{10}\text{Be}$  in the troposphere, we separately transport  $^7\text{Be}$   
 164 and  $^{10}\text{Be}$  produced in the model layers above the MERRA-2 thermal tropopause (i.e., stratospheric  $^7\text{Be}$  and  $^{10}\text{Be}$   
 165 tracers). This approach was previously used to study cross-tropopause transport of  $^7\text{Be}$  in GEOS-Chem (Liu et al.,  
 166 2001; Brattich et al., 2021) and Global Modeling Initiative chemical transport models (Liu et al., 2016; Brattich  
 167 et al., 2017). The stratospheric fractions of  $^7\text{Be}$  and  $^{10}\text{Be}$  are defined as the ratio of the stratospheric  $^7\text{Be}$  and  $^{10}\text{Be}$   
 168 concentrations to the  $^7\text{Be}$  and  $^{10}\text{Be}$  concentrations.

## 169 2.2 $^7\text{Be}$ and $^{10}\text{Be}$ production models

170 The GEOS-Chem currently uses the LP67 production rates of  $^7\text{Be}$  and  $^{10}\text{Be}$  (Lal and Peters, 1967). These  
 171 production rates are calculated using an analytically estimated rate of nuclear disintegration (stars) in the  
 172 atmosphere (stars/g air/s), multiplied by the mean production yield of 0.045 atoms/star for  $^7\text{Be}$  and 0.025  
 173 atoms/star for  $^{10}\text{Be}$  (Lal and Peters, 1967). These rates are represented as a function of latitude and altitude for the  
 174 year 1958 and are not time varying.

175 Here we update the atmospheric  $^7\text{Be}$  and  $^{10}\text{Be}$  production rates in GEOS-Chem with the latest production  
 176 model: CRAC:Be model by P16 (Poluianov et al., 2016) using the solar modulation function record by Herbst et  
 177 al. (2017). The solar modulation function record is based on the local interstellar spectrum by Herbst et al. (2017),  
 178 which was also used in the production model. Given spatially and temporally resolved geomagnetic cut-off  
 179 rigidities, the P16 model allows the calculation of 3-dimensional, temporally variable  $^7\text{Be}$  and  $^{10}\text{Be}$  production  
 180 rates, which are necessary for input to atmospheric transport models. The P16 production model is regarded as  
 181 the latest and one of the most accurate production models for  $^7\text{Be}$  and  $^{10}\text{Be}$  and was used in recent general  
 182 circulation model simulations (e.g., Golubenko et al., 2021; Sukhodolov et al., 2017).

183 The production rates of  $^7\text{Be}$  and  $^{10}\text{Be}$  are calculated by an integral of the yield functions of  $^7\text{Be}$  and  $^{10}\text{Be}$  ( $Y_i$ ,  
 184 atoms  $\text{g}^{-1} \text{cm}^2 \text{sr}$ ), and the energy spectrum of cosmic rays ( $J_i$ , ( $\text{sr sec cm}^2$ ) $^{-1}$ ) above the cutoff energy  $E_c$ :

$$185 \quad Q(\Phi, h, P_c) = \sum_i \int_{E_c}^{\infty} Y_i(E, h) J_i(E, \Phi) dE$$

186 The  $i$  refers to different types of primary cosmic ray particles (e.g., proton, alpha and heavier particles). For  
 187 modelling the contribution of alpha and heavier particles to the total production, their nucleonic ratio in the local  
 188 interstellar spectrum was set to 0.353 (Koldobskiy et al., 2019). The yield function  $Y_i$  is a function of height ( $h$ )  
 189 and kinetic energy per incoming primary nucleon ( $E$ ) and is directly taken from P16. The energy spectrum of  
 190 cosmic rays  $J_i$  is a function of the kinetic energy ( $E$ ) and depends on the solar modulation function ( $\Phi$ ) (Herbst et  
 191 al., 2017).  $E_c$  is calculated as a function of the local geomagnetic rigidity cutoff ( $P_c$ ):

192

$$E_c = E_r \left( \sqrt{1 + \left( \frac{Z_i P_c}{A_i E_r} \right)^2} - 1 \right)$$

193

194

where  $Z_i$  and  $A_i$  are the charge and mass numbers of particles, respectively.  $E_r$  is the rest mass of a proton (0.938 GeV).

205

The geomagnetic rigidity cutoff  $P_c$  is a quantitative estimation of the Earth's geomagnetic field shielding effect (Smart and Shea, 2005). Cosmic ray particles with rigidity (momentum per unit charge of the particle) higher than the geomagnetic cutoff rigidity value can enter the Earth's atmosphere. In several model simulations of  $^7\text{Be}$  and  $^{10}\text{Be}$  (e.g., Field et al., 2006; Koch et al., 1996; Liu et al., 2001), the production is calculated with a  $P_c$  simplified as a function of the geomagnetic latitude and geomagnetic dipole moment, called the vertical Stoermer cut-off rigidity equation (see equation 5.8.2-2 in Beer et al., 2012). However, this is different from the real geomagnetic cut-off rigidity inferred from the trajectories of particles with different energies using real geomagnetic field measurements (e.g., Copeland, 2018) which also includes non-dipole moments of the field (Beer et al., 2012) (Fig. S1). Earlier studies suggested that using the simple centered dipole models (e.g., Stoermer cut-off rigidity) for cut-off rigidity approximation is limited as they can significantly distort the cut-off rigidity for some regions (e.g., low-latitude regions) (Pilchowski et al., 2010; Nevalainen et al., 2013)

213

Here we take the geomagnetic cutoff rigidity from Copeland (2018) that provides the cut-off rigidity at a fine interval (one degree) in both latitude and longitude. This production rate is denoted as P16spa. To investigate the effect of this more realistic representation of cut-off rigidity on  $^7\text{Be}$  and  $^{10}\text{Be}$  simulations, we also perform simulations where the cut-off rigidities are approximated by the Stoermer equation (denoted as P16). The influence of the geomagnetic field intensity variations can be considered negligible on annual and decadal timescales and are ignored here (e.g. Muscheler et al., 2007; Zheng et al., 2020). It should be mentioned that the LP67 production is based on an ideal axial dipole cut-off rigidity similar to the P16 production model.

227

An overview of the performed simulations is shown in Table S1. The simulation with the P16spa production rate is considered as the standard simulation while the simulations with the P16 and LP67 production rates are sensitivity tests. The simulation with the P16 production rate is conducted to evaluate the influence of a simplified approximation of cutoff rigidities resulting from a geocentric dipole. In earlier studies, the LP67 production rate was used for global model simulations of  $^7\text{Be}$  (e.g., Liu et al., 2016; Brattich et al., 2017; Liu et al., 2001; Koch et al., 1996). The purpose of performing the simulation with the LP67 production rate is to evaluate to what extent model simulations are biased when applying the default LP67 production. Since the LP67 production rate applies only for the year 1958 (with a solar modulation function of about 1200 MeV) and does not consider the influences of the solar variations (e.g., 11-year solar cycle), it underestimates the production rate for the period of 2008-2018 that has an average solar modulation function of 500 MeV. To correct for this solar modulation influence, we follow the previous studies (e.g., Liu et al., 2016; Koch et al., 1996) by multiplying the model results by a scale factor of 1.39. It should be noted that this correction is not ideal as the effects of a varying solar modulation on cosmogenic radionuclide production rates depend on altitude and latitude. All simulations are performed from

228 2002 to 2018 with the first six-year for spin-up to make sure the  $^{10}\text{Be}$  nearly reaches equilibrium in the atmosphere  
229 and the 2008-2018 period (11 years) for analysis. The simulations are conducted using a  $4^\circ$  latitude  $\times$   $5^\circ$  longitude  
230 resolution for computational efficiency (e.g., Liu et al., 2016; Liu et al., 2004).

231 To evaluate the model's ability to reproduce the variabilities in the observations, we use the statistical  
232 parameters: Spearman correlation coefficients and Root Mean Square Error (RMSE) (Chang and Hanna, 2004).  
233 Spearman rank correlation (R) (Myers et al., 2013) is used as it does not make any assumptions about the variables  
234 being normally distributed. It is less sensitive to outliers in the data compared to the commonly used Pearson  
235 correlation. The fraction of modeled concentrations within a factor of 2 of observations (FA2) is calculated, i.e.,  
236 for which  $0.5 < X_{\text{model}}/X_{\text{observation}} < 2$ . Usually, if the scatter plot of the model and measurements is within a  
237 factor of 2 of observations, the model is considered to have a reasonably good performance (e.g., Heikkilä et al.,  
238 2008b; Brattich et al., 2021). For model comparison with surface air concentrations, the model value from the  
239 bottom grid box closest to the corresponding measurement site is selected.

240

#### 241 **2.4 $^7\text{Be}$ and $^{10}\text{Be}$ observational data for model validation**

242 The annual mean  $^7\text{Be}$  surface air concentration and deposition measurements are taken from a compilation by  
243 Zhang et al. (2021b). The compilation includes a total of 494 annual mean values for surface air  $^7\text{Be}$  concentrations  
244 and 304 for  $^7\text{Be}$  deposition fluxes. For the deposition measurements, most of them include both wet and dry  
245 deposition, while a few are collected only during rainfall events and thus include only wet deposition. It includes  
246 the data from:

- 247 • The Environmental Measurements Laboratory (EML,  
248 <https://www.wipp.energy.gov/namp/emlegacy/index.htm>) Surface Air Sampling Program (SASP),  
249 which began in the 1980s,
- 250 • The ongoing international monitor program Radioactivity Environmental Monitoring (REM) network  
251 (e.g., Hernandez-Ceballos et al., 2015; Sangiorgi et al., 2019),
- 252 • International Monitoring System (IMS) organized by the Comprehensive Nuclear-Test-Ban Treaty  
253 Organization (CTBTO) (e.g., Terzi and Kalinowski, 2017),
- 254 • Some additional datasets in publications not included in the above programs.

255 We only include the data covering more than 1 year to reduce the influence of inherent seasonal variations. We  
256 further include several recently published data for  $^7\text{Be}$  surface air concentrations and deposition fluxes records  
257 that cover more than 1 year (Burakowska et al., 2021; Liu et al., 2022b; Kong et al., 2022).

258 The dataset used for investigating the seasonality of  $^7\text{Be}$  surface air concentrations are mainly taken from a  
259 multiyear compilation dataset of IMS from Terzi and Kalinowski (2017). The seasonal  $^7\text{Be}$  deposition data are  
260 taken from Courtier et al. (2017), Du et al. (2015), Dueñas et al. (2017), Hu et al. (2020), Lee et al. (2015), and  
261 Sangiorgi et al. (2019). The vertical profile of  $^7\text{Be}$  concentrations is taken from the Environmental Measurements  
262 Laboratory (EML) High Altitude Sampling Program (HASP) spanning the years of 1962-1983. It should be noted,  
263 different from surface air measurements, the vertical air samples were usually collected during single-day flight  
264 campaigns.

265 There are fewer  $^{10}\text{Be}$  measurements compared to  $^7\text{Be}$ . Here we compiled two datasets of published  $^{10}\text{Be}$   
266 surface air measurements (Table S2) (Aldahan et al., 2008; Liu et al., 2022a; Yamagata et al., 2019; Padilla et al.,

267 2019; Rodriguez-Perulero et al., 2019; Huang et al., 2010; Méndez-García et al., 2022; Elsässer et al., 2011; Dibb  
268 et al., 1994) and deposition fluxes (Table S3) covering more than 1 year, to validate the model performance. The  
269 air samples are continuously collected by filters using a high-flow aerosol sampler. The sampling volume is  
270 approximately 700 m<sup>3</sup> of air for daily samples (e.g., Liu et al., 2022a) and between 3000 m<sup>3</sup> and 5000 m<sup>3</sup> for  
271 weekly samples (e.g., Yamagata et al., 2019). The deposition data include the precipitation samples (wet  
272 deposition) (Graham et al., 2003; Monaghan et al., 1986; Somayajulu et al., 1984; Heikkilä et al., 2008a; Raisbeck  
273 et al., 1979; Maejima et al., 2005) and ice core samples (wet and dry deposition) that cover the recent period  
274 (Heikkilä et al., 2008a; Zheng et al., 2021b; Pedro et al., 2012; Baroni et al., 2011; Aldahan et al., 1998; Berggren  
275 et al., 2009; Auer et al., 2009; Zheng et al., 2023b). The <sup>10</sup>Be vertical profile measurements are mainly taken from  
276 Dibb et al. (1994, 1992) and Jordan et al. (2003).

277

## 278 **3 Results and Discussions**

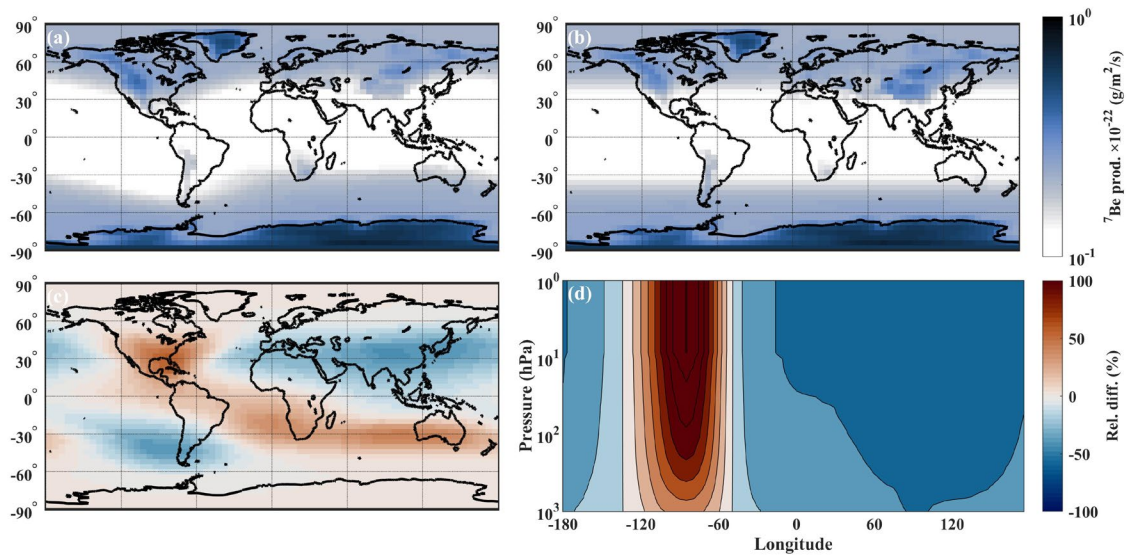

### 279 **3.1 <sup>7</sup>Be and <sup>10</sup>Be production rates**

280 Figure S2 shows the comparison between <sup>7</sup>Be<sub>P16</sub> and <sup>7</sup>Be<sub>LP67</sub> production rates for the year 1958. Generally, the  
281 <sup>7</sup>Be<sub>P16</sub> production rate shows a similar production distribution as the <sup>7</sup>Be<sub>LP67</sub> production rate, with a maximum <sup>7</sup>Be  
282 production over the polar stratosphere (~100 hPa). The <sup>7</sup>Be<sub>LP67</sub> production rate shows, on average, about 72%  
283 higher production rate compared to <sup>7</sup>Be<sub>P16</sub> in the stratosphere and about 38% in the troposphere (Fig. S2c; Table  
284 S4). On a global average, the <sup>7</sup>Be<sub>LP67</sub> production rate is about 60% higher than that of <sup>7</sup>Be<sub>P16</sub> as shown in previous  
285 studies (Poluianov et al., 2016). The stratospheric production contributes about 67% to the total production for  
286 the <sup>7</sup>Be<sub>LP67</sub> production rate while it is about 62% for the <sup>7</sup>Be<sub>P16</sub> production rate for the year 1958.

287 The <sup>10</sup>Be<sub>LP67</sub> production rate in the GEOS-Chem model uses the identical source distribution as <sup>7</sup>Be with a  
288 scaling factor based on the estimates from surface air measurements (Koch and Rind, 1998). This leads to a  
289 constant <sup>10</sup>Be<sub>LP67</sub>/<sup>7</sup>Be<sub>LP67</sub> production ratio (0.55) throughout the entire atmosphere. However, as shown in many  
290 <sup>7</sup>Be and <sup>10</sup>Be production models (e.g., Poluianov et al., 2016; Masarik and Beer, 2009), <sup>7</sup>Be and <sup>10</sup>Be have different  
291 altitudinal production distributions. The P16 production shows an increasing <sup>10</sup>Be/<sup>7</sup>Be production ratio from  
292 higher altitude (0.35) to lower altitude (0.6) (Fig. S3). Using a constant <sup>10</sup>Be/<sup>7</sup>Be production ratio may thus result  
293 in large errors in the modeled <sup>10</sup>Be concentrations as well as <sup>10</sup>Be/<sup>7</sup>Be ratios. The stratospheric production  
294 contributes about 67% of the total production with <sup>10</sup>Be<sub>LP67</sub> while it is about 58% with the <sup>10</sup>Be<sub>P16</sub> production for  
295 the year 1958 (Table S4).

296 Figure 1 shows the comparison between <sup>7</sup>Be<sub>P16</sub> and <sup>7</sup>Be<sub>P16spa</sub> production rates for the period 2008-2018. The  
297 global production is similar for P16spa and P16 (Table S4). However, considering non-dipole moment influence  
298 on geomagnetic cut-off rigidity, <sup>7</sup>Be<sub>P16spa</sub> and <sup>10</sup>Be<sub>P16spa</sub> production rates in the Southern Hemisphere show ~11%  
299 higher production rates compared to the Northern Hemisphere (Table S4). This difference is not present when an  
300 axial dipole is assumed. Compared to P16 production rate, the <sup>7</sup>Be<sub>P16spa</sub> production rate shows 30-40% lower  
301 production over eastern Asia and southeastern Pacific, but 40-50% higher over North America and from  
302 subtropical South Atlantic to Australia (Fig. 1). <sup>10</sup>Be<sub>P16spa</sub> shows similar results as the <sup>7</sup>Be<sub>P16spa</sub>. These differences  
303 are not constant throughout the atmospheric column but generally increase with altitude (Fig. 1d).

304

306

307 **Figure 1.** Upper panels: Spatial distribution of (a)  ${}^7\text{Be}_{\text{P16spa}}$  and (b)  ${}^7\text{Be}_{\text{P16}}$  production rates at 825 hPa over the period 2008-  
 308 2018. Lower panels: (c) Relative differences (%), i.e.,  $({}^7\text{Be}_{\text{P16spa}} - {}^7\text{Be}_{\text{P16}}) / {}^7\text{Be}_{\text{P16}} \times 100\%$ , between production rates with and  
 309 without considering the detailed spatial cut-off rigidity. (d) Relative differences (%) of the zonal mean production rates  
 310 between P16spa and P16 at 30°N.

311

### 312 3.2 ${}^7\text{Be}$ surface air concentrations and deposition fluxes

313 Figure 2 compares the simulated  ${}^7\text{Be}_{\text{P16spa}}$  averaged over 2008-2018 with the measurements. Due to the data  
 314 availability, the measurements do not necessarily cover the same period as model simulations. The model  
 315 deposition fluxes here include both dry and wet deposition. About 93.7% of modeled air  ${}^7\text{Be}_{\text{P16spa}}$  concentrations  
 316 agree within a factor of 2 with the observed values. The model also shows reasonable agreement with the measured  
 317 deposition fluxes (60.9% within a factor of 2) although the discrepancy between the modeled and observed  
 318 deposition fluxes is larger than that for surface air concentrations. The deposition fluxes are usually less well  
 319 monitored compared to the air  ${}^7\text{Be}$  samples and cover usually only shorter periods (e.g., one or two years). Further,  
 320 the limited model resolution applied here may not be able to capture meteorological conditions on local scales  
 321 (e.g., precipitation, convection, and tropopause folding) in some sites (e.g., Yu et al., 2018; Spiegl et al., 2022),  
 322 especially for coastal regions when the sub-grid scale orographic precipitation is important.

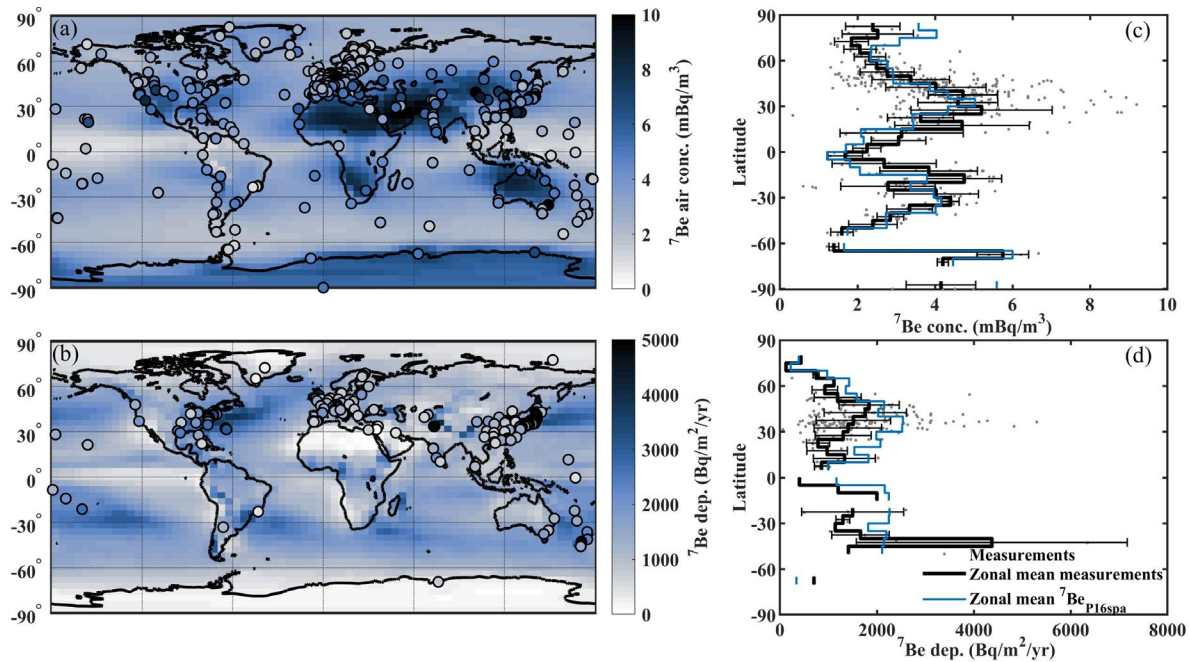

324

325 **Figure 2.** Scatter plot of modeled <sup>7</sup>Be<sub>P16spa</sub> versus observed <sup>7</sup>Be surface air concentrations (left panel) and deposition fluxes  
 326 (right panel). The model values are averaged over the years of 2008-2018. The dashed lines are the factor of 2 of 1:1 line  
 327 (straight lines). The “FA2” indicates the fraction of modeled concentrations within a factor of 2 of observations while “RMSE”  
 328 indicates the root mean square error.

329

Figure 3 shows the spatial distribution and zonal mean of measurements in comparison with the model  
 330 simulated <sup>7</sup>Be<sub>P16spa</sub> surface air concentrations and deposition fluxes. Generally, the model captures the spatial  
 331 distribution of <sup>7</sup>Be air concentrations and deposition fluxes. The “latitudinal pattern” of surface air <sup>7</sup>Be  
 332 concentrations differs from that of <sup>7</sup>Be production rate, reflecting the effects of atmospheric transport and  
 333 deposition processes. The model suggests high <sup>7</sup>Be air concentrations mainly over the dry regions (Fig. 3a) due  
 334 to low wet deposition rates (e.g., desert regions over Northern Africa, Arabian Peninsula, central Australia, and  
 335 central Antarctica) and over high-altitude regions (e.g., Tibetan Plateau). The model captures the observed  
 336 latitudinal peaks in surface air concentrations over the subtropics and mid-latitudes (Fig. 3c around 30°N-40°N  
 337 and 30°S -40°S). These peaks are consistent with the high stratospheric contribution (25%-30%) at mid-latitudes  
 338 (Fig. S4). The model overestimates <sup>7</sup>Be air concentrations over the Arctic (70°N-90°N, Fig. 3c) by about 30%-  
 339 40%. By contrast, high <sup>7</sup>Be deposition fluxes are observed at mid-latitudes due to the influence of the high  
 340 precipitation (wet deposition) and strong stratosphere-troposphere exchange (Fig. 3d). In the Northern  
 341 Hemisphere, the model simulated deposition fluxes peak at a lower latitude (~30°N) relative to the observations  
 342 (~45°N). These modeled spatial distributions of the air concentrations and deposition rates of <sup>7</sup>Be also agree  
 343 generally well with previous model simulations (e.g., Heikkilä and Smith, 2012).

344

345

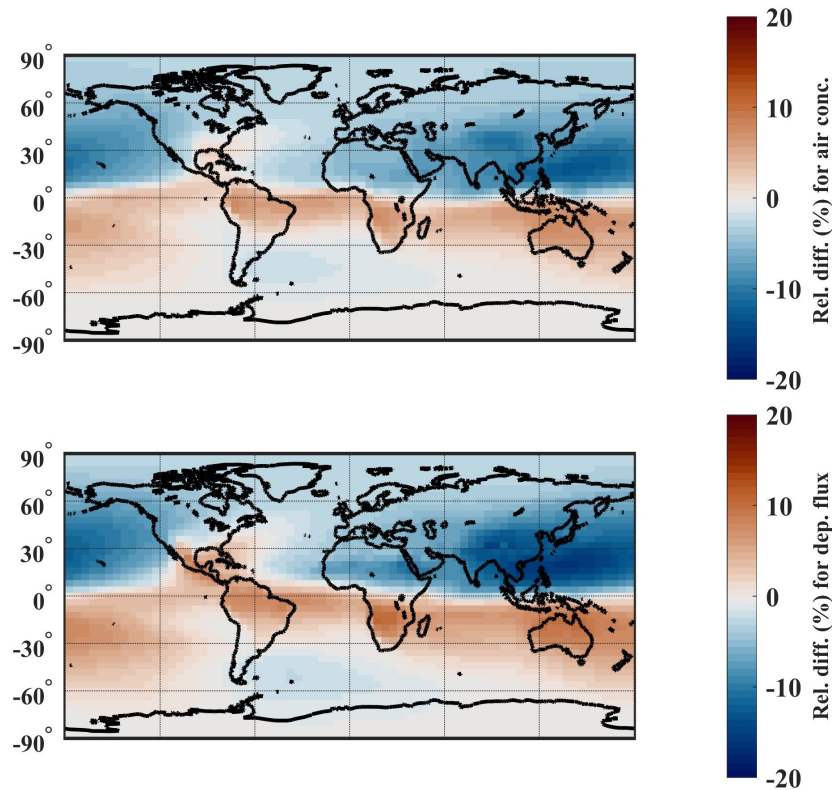

346 **Figure 3.** Left column: (a) modeled  ${}^7\text{Be}_{\text{P16spa}}$  surface air concentrations ( $\text{mBq}/\text{m}^3$ ) and (b) deposition fluxes ( $\text{Bq}/\text{m}^2/\text{yr}$ )  
 347 averaged over the period 2008-2018. Color-coded dots denote  ${}^7\text{Be}$  measurements. Right column: zonal mean of (c) observed  
 348  ${}^7\text{Be}$  surface air concentrations and (d) deposition fluxes (black lines, for each  $5^\circ$  latitude bin) compared with the model  
 349 simulation using the P16spa production rate (blue lines). Dots are individual measurements. The error bars indicate one  
 350 standard deviation. The outliers, defined as more than three scaled median absolute deviations (MAD) away from the median,  
 351 are excluded from the calculation. The observations are averaged over the years available.

352 The modeled  ${}^7\text{Be}_{\text{P16spa}}$  air concentrations show better agreements (smaller RMSE and higher FA2 values)  
 353 with the measurements in comparison to  ${}^7\text{Be}_{\text{LP67}}$  (Fig. S5).  ${}^7\text{Be}_{\text{LP67}}$  tends to overestimate the absolute values of  
 354  ${}^7\text{Be}$  concentrations. This is caused by i) the overestimation of  ${}^7\text{Be}$  production rate by LP67 for a given solar  
 355 modulation function and ii) using a simple scale factor to account for the solar modulation influence on the LP67  
 356  ${}^7\text{Be}$  production rate.

357 We also examine whether using the dipole-approximation of the cut-off rigidity or real cut-off rigidity (P16  
 358 and P16spa, respectively) in the production model leads to significantly different results (Fig. 4). Although large  
 359 regional differences (up to 40-50%, Fig. 1) in the production model are observed between P16spa and P16  
 360 production rates, such differences are reduced in surface air concentrations and deposition fluxes due to transport  
 361 and deposition processes, as expected. The  ${}^7\text{Be}_{\text{P16sap}}$  air concentrations show higher values ( $\sim 7\%$ ) over  $10^\circ\text{S}$ - $40^\circ\text{S}$   
 362 and lower values ( $\sim 12\%$ ) over the east Asian region (Fig. 4) compared to  ${}^7\text{Be}_{\text{P16}}$ . These differences are higher for  
 363 the deposition fluxes with up to 10% higher over the  $10^\circ\text{S}$ - $40^\circ\text{S}$  and up to 18% lower over the east Asian region  
 364 (Fig. 4). Since the total deposition flux reflects precipitation scavenging through the tropospheric column, it tends  
 365 to be more sensitive to  ${}^7\text{Be}$  air concentrations at higher altitudes and downward transport of  ${}^7\text{Be}$  from the  
 366 stratosphere. Indeed, model results suggest that deposition fluxes have a higher stratospheric fraction compared  
 367 to surface air concentrations (Fig. S4), as previously shown by Liu et al. (2016). The  ${}^7\text{Be}_{\text{P16spa}}$  deposition fluxes  
 368 show better agreement with measurements than those of  ${}^7\text{Be}_{\text{P16}}$  (Fig. S5). The comparison for  ${}^{10}\text{Be}$  shows similar  
 369 results as  ${}^7\text{Be}$  except with less than 10% differences. For  ${}^{10}\text{Be}$  deposition fluxes in Antarctica and Greenland, this  
 370 influence is less than 3%. This is because the dominant contribution of  ${}^{10}\text{Be}$  is from the stratosphere where the  
 371 hemispheric production differences are diminished by the long stratospheric residence time of  ${}^{10}\text{Be}$ . However, it  
 372 does not suggest that the cut-off rigidity including the non-dipole influence could be ignored for  ${}^{10}\text{Be}$  depositions  
 373 in polar regions, as the spatial pattern of cut-off rigidities was very different in the past time, e.g., during the

374 Laschamps geomagnetic field minimum around 41,000 years before the present (Gao et al., 2022). Further studies  
375 are warranted to investigate this spatial cut-off rigidity influence on  $^{10}\text{Be}$  in more detail.  
376

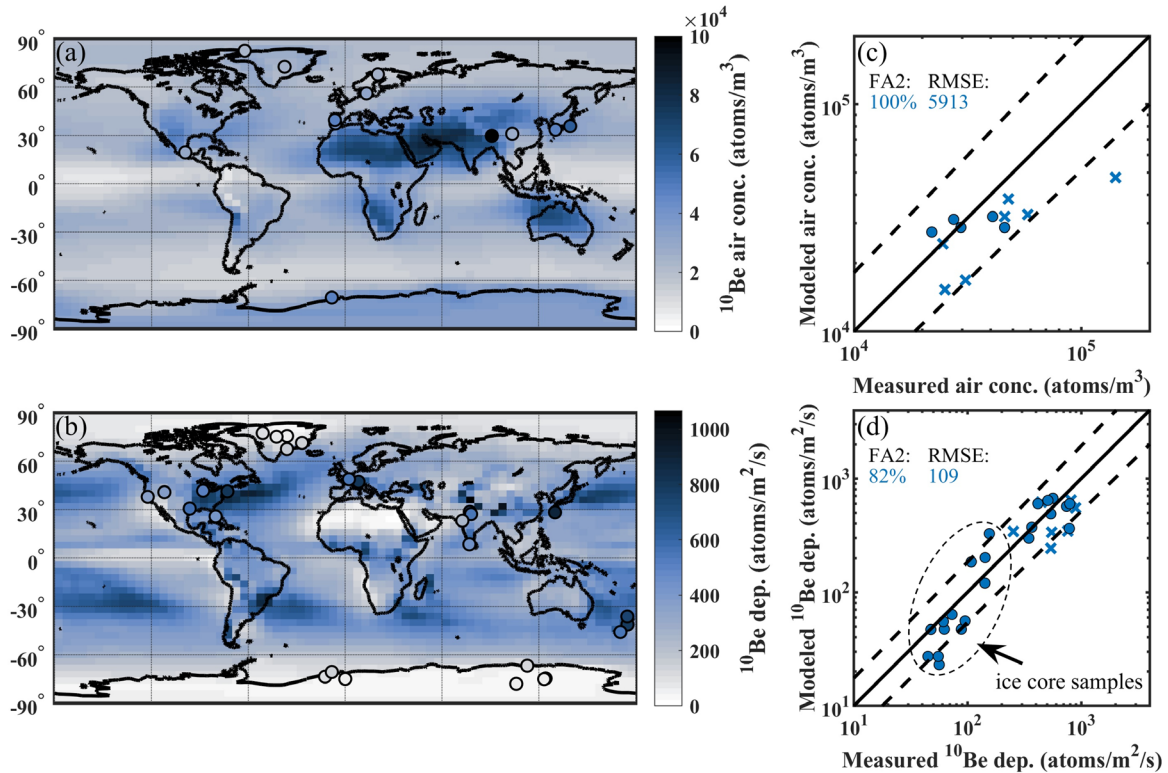

377 **Figure 4.** Relative differences (percentage) of surface air concentrations (upper panel) and deposition fluxes  
378 (lower panel) between  $^7\text{Be}_{\text{P16spa}}$  and  $^7\text{Be}_{\text{P16}}$  for the period 2008-2018, i.e.,  $(^7\text{Be}_{\text{P16spa}} - ^7\text{Be}_{\text{P16}}) / ^7\text{Be}_{\text{P16}} \times 100\%$ .  
379

### 380 3.3 $^{10}\text{Be}$ surface air concentrations and deposition fluxes

381 Figure 5 shows the comparison between modeled annual mean  $^{10}\text{Be}_{\text{P16spa}}$  surface air concentrations (or deposition  
382 fluxes) averaged over 2008-2018 and measurements. The  $^{10}\text{Be}_{\text{P16spa}}$  shows similar spatial distributions as  $^7\text{Be}_{\text{P16spa}}$   
383 because both radionuclides share the same transport and deposition processes. The model underestimates the  
384 measured  $^{10}\text{Be}$  surface air concentrations and deposition fluxes at some sites (Fig. 5b, 5d). This may be attributed  
385 to the influence of resuspended dust with  $^{10}\text{Be}$  attached, which could typically contribute 10%-35% to the air  $^{10}\text{Be}$   
386 concentrations (Monaghan et al., 1986). It should be mentioned that  $^7\text{Be}$  decays in the dust because of its short  
387 half-life, and therefore does not contribute to the surface air  $^7\text{Be}$  concentrations. Indeed, data where a careful  
388 examination of the recycled dust  $^{10}\text{Be}$  in samples was conducted (e.g., Monaghan et al., 1986), or from locations  
389 that are less influenced by recycled dust  $^{10}\text{Be}$  (e.g., Polar regions; dots in Fig. 5b-5d), show better agreement with  
390 the model simulations. This suggests the importance of considering the dust contribution when measuring the air  
391  $^{10}\text{Be}$  samples. The model also shows relatively good agreement with most  $^{10}\text{Be}$  deposition data from polar ice  
392 cores (marked as dots in Fig. 5d) within a factor of 2.  
393

394  
 395 **Figure 5.** Left column: the modeled annual mean  $^{10}\text{Be}_{\text{P16spa}}$  (a) surface air concentrations and (b) deposition fluxes averaged  
 396 over 2008-2018 overplotted with measurements (color-coded dots). Right column: (c)-(d) the scatter plot between model  
 397 results and measurements for (c) surface air concentrations and (d) deposition fluxes. The dots in (c-d) indicate measurements  
 398 with careful examination of dust  $^{10}\text{Be}$  contributions or from the polar regions which are not influenced by dust  $^{10}\text{Be}$ . The  
 399 crosses indicate the samples without examining dust contributions. The FA2 and RMSE are calculated only using the dust-free  
 400 samples (dots). Blue and orange colors indicate the results using P16spa and LP67 production rates, respectively.

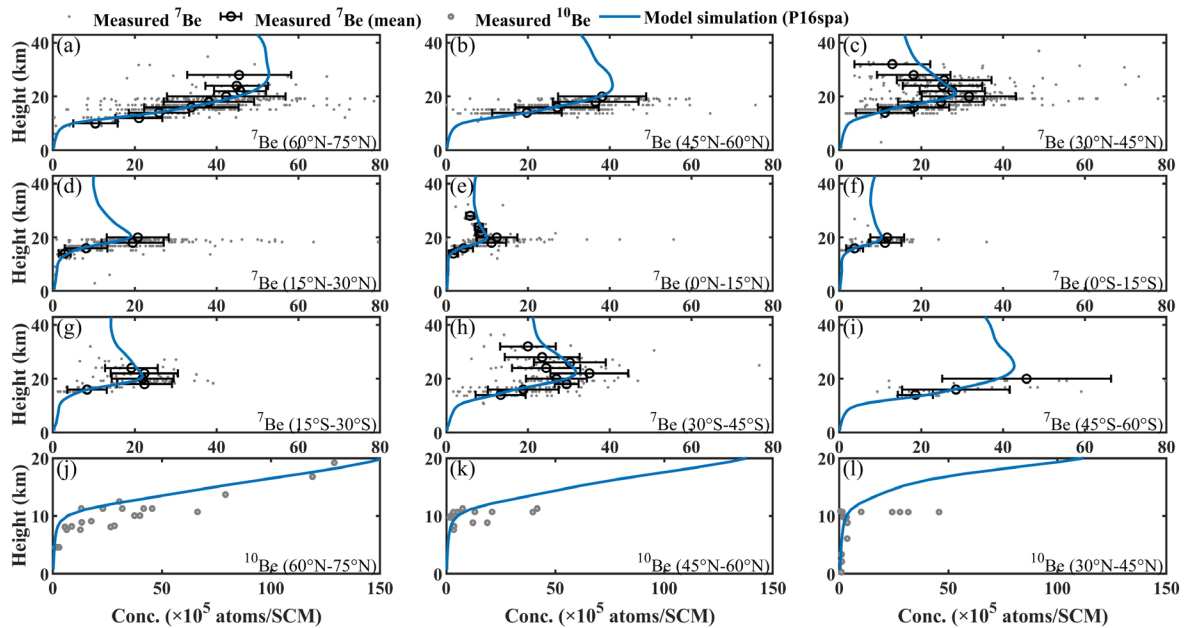

401

### 402 3.4 Vertical profiles of $^7\text{Be}$ and $^{10}\text{Be}$

403 Figure 6 shows the simulated annual zonal mean vertical profiles of  $^7\text{Be}_{\text{P16spa}}$  and  $^{10}\text{Be}_{\text{P16spa}}$  concentrations  
 404 compared with those from aircraft measurements in the troposphere and stratosphere from the EML/HASP. The  
 405 measurements cover different regions and specific meteorological conditions; hence they should only provide a  
 406 range in which the model results should lie. Following previous modelling studies (Heikkilä et al., 2008b; Koch  
 407 et al., 1996), we compare model zonal mean values in each  $15^\circ$  latitude band with the corresponding observations.

408 The simulated  $^7\text{Be}_{\text{P16spa}}$  profiles agree well with the measurements, especially capturing the peaks at  $\sim 20\text{-}22$   
 409 km at mid- and low- latitudes (e.g., Fig. 6c, 6e, 6h). The feature that  $^7\text{Be}$  increases with altitude without a peak at  
 410 22 km at northern high latitudes ( $60^\circ\text{N}\text{-}75^\circ\text{N}$ ) is also captured by the model (Fig. 6a). The  $^7\text{Be}_{\text{P16spa}}$  shows high  
 411 concentrations in the polar stratosphere and low values over the equatorial stratosphere (Fig. S6), mainly reflecting  
 412 the latitudinal distribution of the production. This “latitudinal structure” is modulated for  $^{10}\text{Be}_{\text{P16spa}}$  in the  
 413 stratosphere as  $^{10}\text{Be}$  is better mixed than  $^7\text{Be}$  due to its slow decay together with relatively long residence time in  
 414 the stratosphere (Waugh and Hall, 2002). Both  $^7\text{Be}$  and  $^{10}\text{Be}$  show very low concentrations in the tropical upper

415 troposphere, reflecting the frequent injection of air from the lower troposphere in wet convective updrafts, where  
 416 aerosols are efficiently scavenged (Fig. S6).

417  
 418 **Figure 6.** Comparison of the vertical profile between measurements (circles) and model zonal mean  ${}^7\text{Be}_{\text{P16spa}}$  and  
 419  ${}^{10}\text{Be}_{\text{P16spa}}$  concentrations for each latitudinal band ( $15^\circ$ ) over the period 2008-2018. The  ${}^7\text{Be}$  (circle with error bar)  
 420 observations (from the EML/HASP) are averaged for the altitude band of every 2 km where more than 5 samples  
 421 are available. We exclude the outlier from the calculation, which is defined as more than three scaled median  
 422 absolute deviations (MAD) away from the median. The  ${}^{10}\text{Be}$  profile measurements are mainly taken from Dibb et  
 423 al. (1994, 1992) and Jordan et al. (2003).  
 424

425 The model also reasonably simulated  ${}^{10}\text{Be}$  vertical profiles compared with observations, with a tendency to  
 426 underestimate observations in the stratosphere (Fig. 6j-6l). A previous general circulation model study by Heikkilä  
 427 et al. (2008b) also showed too low model stratospheric  ${}^{10}\text{Be}$  compared to measurements. They attributed this  
 428 underestimation to too short stratospheric air residence time in the model, which prevents  ${}^{10}\text{Be}$  concentrations  
 429 from sufficiently accumulating in the stratosphere. However, this may not be the case in our study, as the  
 430 stratospheric air residence time in the MERRA-2 reanalysis agrees reasonably with the observations (Chabrillat  
 431 et al., 2018). Another explanation is that the  ${}^{10}\text{Be}$  production rate may be underestimated in the stratosphere.  ${}^7\text{Be}$   
 432 is less affected by this process than  ${}^{10}\text{Be}$  because of its short half-life compared to its stratospheric residence time  
 433 (Delaygue et al., 2015).  
 434

### 435 3.5 Global budgets and residence time

436 Table 1 shows the global budgets for  ${}^7\text{Be}_{\text{P16spa}}$  and  ${}^{10}\text{Be}_{\text{P16spa}}$  over the period of 2008-2018. About 22.1% of  
 437 tropospheric  ${}^7\text{Be}_{\text{P16spa}}$  is lost by radioactive decay, 75.8% by convective and large-scale precipitation, and 2.1%  
 438 by dry deposition. The wet deposition contributes to about 97% of total deposition for  ${}^7\text{Be}_{\text{P16spa}}$  and  ${}^{10}\text{Be}_{\text{P16spa}}$   
 439 (Table 1; Fig. S7), which is slightly higher than the  $\sim 93\%$  contribution in previous model studies (Heikkilä et al.,  
 440 2008b; Koch et al., 1996; Spiegl et al., 2022). The global mean tropospheric residence time of  ${}^7\text{Be}_{\text{P16spa}}$  is about  
 441 21 days, which is comparable to those reported by previous model studies: 18 days by Heikkilä et al. (2008b) and

442 21 days by Koch et al. (1996) and Liu et al. (2001). This also agrees with the residence time of about 22-35 days  
 443 estimated from the observed deposition fluxes and air concentrations at 30°N - 75°N (Bleichrodt, 1978). The  
 444 averaged tropospheric residence time of  $^{10}\text{Be}_{\text{P16spa}}$  is about 24 days, which is consistent with the 20 days suggested  
 445 by Heikkilä et al. (2008b).

446

447 **Table 1.** Global budgets of  $^7\text{Be}$  and  $^{10}\text{Be}$  averaged over the period 2008-2018 in GEOS-Chem using P16spa.

### 449 3.6 Seasonality in $^7\text{Be}$ and $^{10}\text{Be}$

450 The seasonality of  $^7\text{Be}$  is influenced by a) the amount of precipitation; b) the stratosphere-troposphere exchange  
 451 processes; and c) the vertical transport of  $^7\text{Be}$  in the troposphere. The roles of these factors may vary depending  
 452 on location. We compare the seasonal variations of modeled  $^7\text{Be}_{\text{P16spa}}$  and  $^7\text{Be}_{\text{LP67}}$  concentrations with  
 453 measurements from a dataset compiled by Terzi and Kalinowski (2017) with the data covering more than 6 years  
 454 (Fig. 7). It should be noted that the model  $^7\text{Be}$  results and MERRA-2 precipitation rates are averaged over the  
 455 years of 2008-2018 while the measurements are based on the data availability over the period 2001-2015.

456

457 **Figure 7.** Seasonal cycle of simulated and measured surface air  $^7\text{Be}$  concentrations, MERRA-2 total precipitation ( $4^\circ \times 5^\circ$  bar  
 458 graph), and modeled stratospheric contributions to surface air. The plots are arranged based on the site latitudes. The model  
 459 results using the LP67 production rate are normalized to the ones using the P16spa production rate.

460

461 **Figure 7.** (continued)

462 In the Southern Hemisphere from  $25^\circ\text{S}$ - $40^\circ\text{S}$ , the  $^7\text{Be}$  concentration peak is observed in austral summer  
 463 (December-February), resulting from the combined influence of stratospheric intrusions and strong vertical  
 464 transport during this season (Villarreal et al., 2022; Zheng et al., 2021a; Koch et al., 1996). The summer peak is  
 465 also observed at northern mid-latitudes. This “summer peak” feature is well simulated by the model at some sites  
 466 (e.g., KWP40 ( $29.3^\circ\text{N}$ ,  $47.9^\circ\text{E}$ ), AUP04 ( $37.7^\circ\text{S}$ ,  $145.1^\circ\text{E}$ ) and AUP10 ( $31.9^\circ\text{S}$ ,  $116^\circ\text{E}$ ) shown in Fig. 7) but not

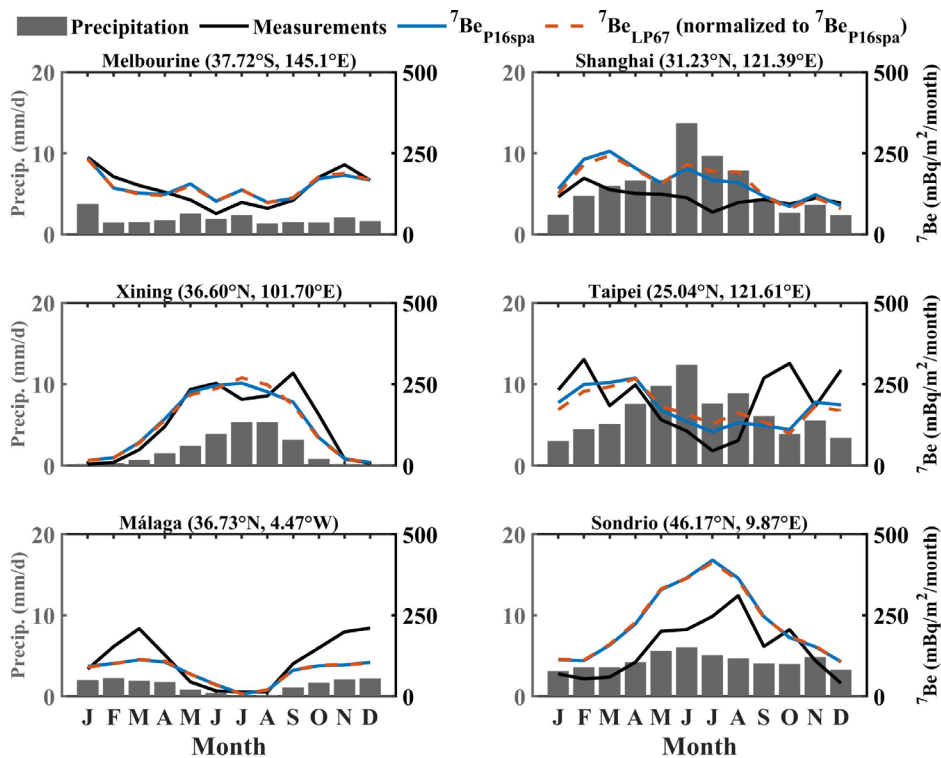

467 at others (e.g., GBP68 (37.1°S, 12.3°W) and PTP53 (37.7°N, 25.7°W) in Fig. 7). This may not be related to  
 468 stratospheric intrusion in the model as the simulated stratospheric contributions (Fig. S4) agree fairly well with  
 469 estimates inferred from measurements, i.e., ~25% on annual average at northern mid-latitude surface (Dutkiewicz  
 470 and Husain, 1985; Liu et al., 2016). Hence this could be due to the errors in vertical transport (e.g., convection)  
 471 during the summer season.

472 The sites at northern high-latitudes (>50°N) show spring peaks that are well simulated by the model (e.g.,  
 473 ISP3 (64.1°N, 21.9°W)). This spring peak coincides with high stratospheric contributions, reflecting the influence  
 474 of stratospheric intrusions. The influence of precipitation changes is also seen at several sites, especially in  
 475 locations with high precipitation rates (e.g., monsoon regions). For example, two sites from Japan (JPP38 (36.3°N,  
 476 139.1°E) and JPP37 (26.5°N, 127.9°E) in Fig. 7) show summer minima coinciding with the high precipitation,  
 477 even with relatively high stratospheric contributions in the same month.

478 The seasonal variation of stratospheric contribution is quite similar for the sites located in the Northern  
 479 Hemisphere, with a high contribution in spring and a low contribution in fall. This is consistent with the estimates  
 480 based on air samples that indicate stratospheric contributions varying from ~40% in spring to ~15% in fall at  
 481 latitudes 38°N-51°N (Dutkiewicz and Husain, 1985).

482 Generally, the model simulates well the annual cycle of surface air <sup>7</sup>Be concentrations for most sites in terms  
 483 of amplitude and seasonality (Fig.7). For a few sites (e.g., DEP33 (47.9°N, 7.9°E)), the model captures the  
 484 observed seasonality but not the correct absolute values. This could be partly due to the coarse resolution of the  
 485 model. The <sup>7</sup>Be<sub>LP67</sub> is normalized to <sup>7</sup>Be<sub>P16spa</sub> as we focus on the comparison of seasonal variability between these  
 486 simulations. The very similar features (differences within 1%) between all simulations using different production  
 487 rates indicate a dominant influence of the meteorological conditions on the seasonal variations of the air <sup>7</sup>Be  
 488 concentrations.

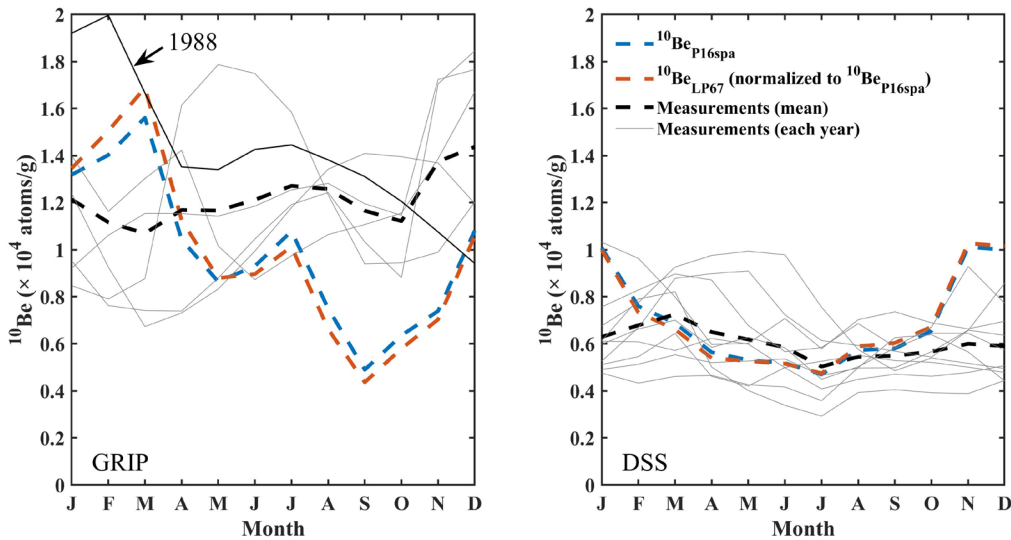

489

490 **Figure 8.** Seasonal cycle of simulated (color lines) and measured (black line)  $^7\text{Be}$  deposition fluxes together with MERRA-2  
 491 total precipitation ( $4^\circ \times 5^\circ$ , bar graph). The model results using the LP67 production rate are normalized to the ones using the  
 492 P16spa production rate.

493 Figure 8 compares model results with the seasonal  $^7\text{Be}$  deposition flux observations over the overlapping  
 494 periods. Usually, high precipitation leads to high  $^7\text{Be}$  deposition fluxes (e.g., Du et al., 2015). Interestingly, low  
 495 deposition fluxes are observed during the summer season in Taipei (Lee et al., 2015; Huh et al., 2006) coinciding  
 496 with high precipitation. This feature is well-captured in the model. Taipei has a typhoon season in summer when  
 497 strong precipitation can occur in a very short period. The atmospheric  $^7\text{Be}$  could be removed quickly at the early  
 498 stage of the precipitation event while at the later stage there is little  $^7\text{Be}$  left in the air that can be removed  
 499 (Ioannidou and Papastefanou, 2006).

500 To examine the ability of model to simulate  $^{10}\text{Be}$  in polar regions, we compare model results with two sub-  
 501 annual ice cores records (Fig. 9): the GRIP record from Greenland (1986-1990) (Heikkilä et al., 2008c) and the  
 502 DSS record from Antarctica (2000-2009) (Pedro et al., 2011a). It should be noted that the direct measurements  
 503 from ice cores are concentrations in the ice (atoms/g). To calculate deposition fluxes, the ice concentrations are  
 504 multiplied with ice accumulation rates. However, for sub-annual accumulations, this bears large uncertainties.  
 505 Therefore, we calculate the modeled  $^{10}\text{Be}$  concentrations for the selected sites using the model deposition fluxes  
 506 at the selected sites timed by ice density and then divided by the corresponding model precipitation rates.

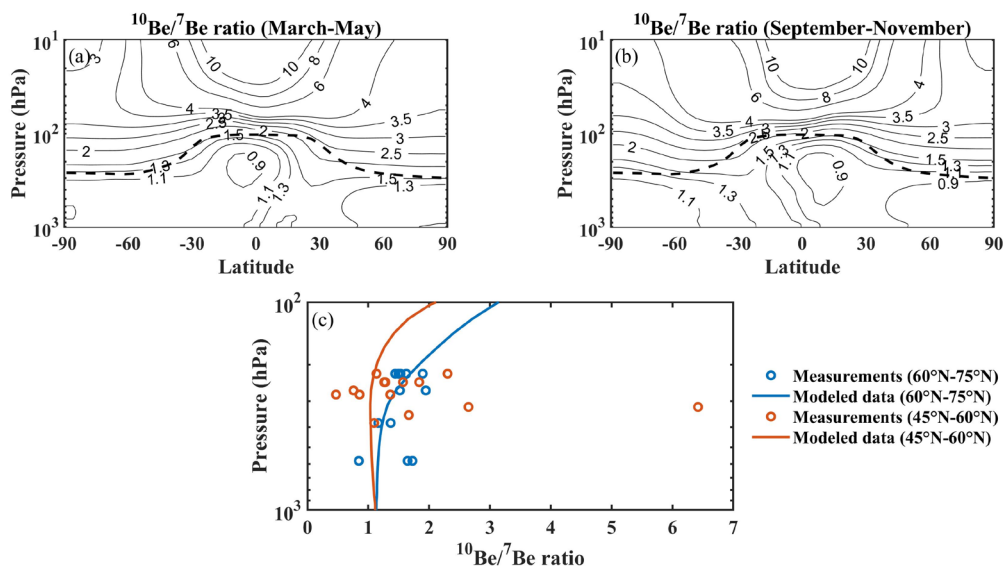

507 **Figure 9.** Seasonal cycle of simulated  $^{10}\text{Be}$  deposition fluxes (2008-2018) and measured  $^{10}\text{Be}$  deposition fluxes in GRIP (1986-  
 508 1990) and DSS (2000-2009) ice cores. The solid lines (grey) refer to seasonal variations of the measurements for each year.  
 509 The black solid line indicates seasonal data of measurements in the year 1988. The dashed lines indicate the averaged seasonal  
 510 variations of measured  $^{10}\text{Be}$  (black),  $^{10}\text{Be}_{\text{P16spa}}$  (blue), and  $^{10}\text{Be}_{\text{LP67}}$  (red) concentrations.  
 511

512 Firstly, there is no consistent seasonal cycle in the GRIP  $^{10}\text{Be}$  measurement, indicating a strong role of local  
 513 meteorology. The model does not reproduce the mean seasonal cycle partly because the model was not run for the  
 514 exact same period. However, we note that the measurements for the year 1988 show an annual cycle similar to  
 515 that in the model, suggesting that the model  $^{10}\text{Be}$  seasonality falls within the range of the observations. For the  
 516 DSS site, the model simulates the austral winter minima but not the austral fall maxima (February-April). These  
 517 model biases could be due to the limited model resolution and local effects (e.g., ice redistribution due to wind  
 518 blow) that are not resolved by the model. Such discrepancies were also reported by previous model studies using  
 519 the ECHAM5-HAM general circulation model ( $2.8^\circ \times 2.8^\circ$ ) over the overlap period (Heikkilä et al., 2008c; Pedro

520 et al., 2011b). Global model simulations at higher resolutions or using a regional model could help improve the  
 521 agreements between model results and measurements at Greenland and Antarctica. However, it should be kept in  
 522 mind that local surface processes can cause a high degree of spatial variability in the impurity concentrations in  
 523 ice cores even on short distances (Gfeller et al., 2014), which cannot be resolved in climate models.  
 524

### 525 3.7 $^{10}\text{Be}/^7\text{Be}$ ratio

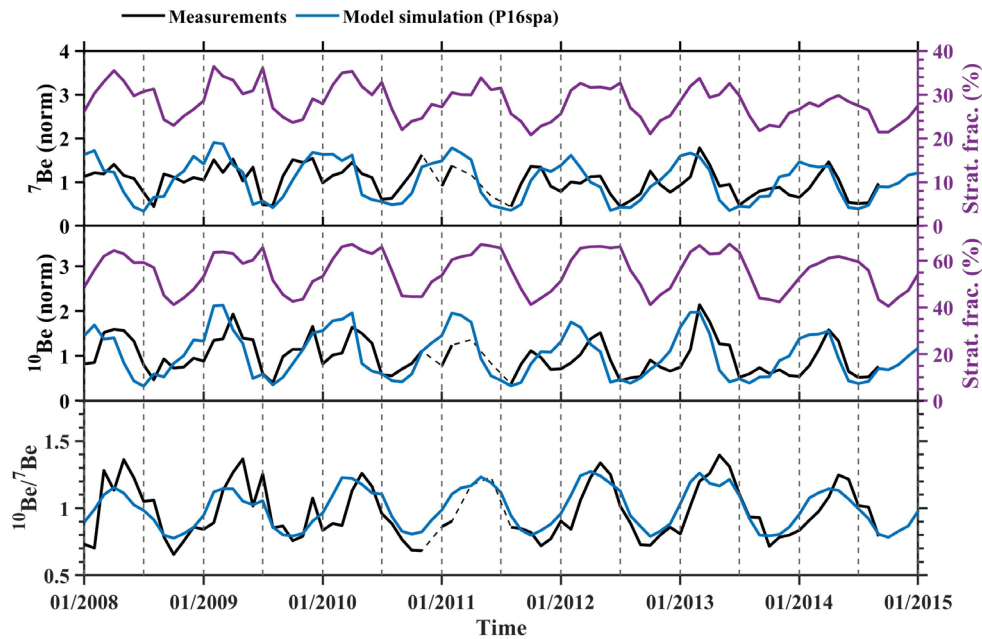

526 Figure 10 shows the modeled zonal mean  $^{10}\text{Be}_{\text{P16spa}}/^7\text{Be}_{\text{P16spa}}$  ratios during boreal spring (March-May) and  
 527 austral spring (September-November), respectively, when the stratosphere-troposphere exchange is strong in  
 528 either of the two hemispheres. Also shown are the comparison of the altitudinal profile of the  $^{10}\text{Be}_{\text{P16spa}}/^7\text{Be}_{\text{P16spa}}$   
 529 ratio with measurements from three aircraft missions (Jordan et al., 2003). The model  $^{10}\text{Be}_{\text{P16spa}}/^7\text{Be}_{\text{P16spa}}$  ratio  
 530 generally lies within the ranges of measurements (Fig. 10c). Due to the decay of  $^7\text{Be}$  and long residence time in  
 531 the stratosphere, the  $^{10}\text{Be}/^7\text{Be}$  ratio is higher ( $>1.5$ ) in the stratosphere and increase over the altitude, with a  
 532 maximum ( $>10$ ) in the tropical stratosphere. During the period without strong stratospheric intrusion (e.g., autumn  
 533 season in Northern Hemisphere, Fig.10b), the monthly  $^{10}\text{Be}/^7\text{Be}$  ratio near the surface is around 0.9~1. This  
 534 surface  $^{10}\text{Be}/^7\text{Be}$  ratio could be up to 1.4 when the strong stratosphere-troposphere exchange happens (e.g., spring  
 535 season in Northern Hemisphere, Fig. 10a).

536 **Figure 10.** Upper panels: simulated  $^{10}\text{Be}_{\text{P16spa}}/^7\text{Be}_{\text{P16spa}}$  ratio in spring (March-May) (a) and autumn (September-November)  
 537 (b) averaged over the years 2008-2018. Lower panel (c): comparison between the annual averaged model  $^{10}\text{Be}_{\text{P16spa}}/^7\text{Be}_{\text{P16spa}}$   
 538 ratios (lines) and those from measurements (circles; Jordan et al., 2003). The comparison is shown for the latitude bands of  
 539 60°N-75°N and 45°N-60°N, respectively.  
 540

541 Figure 11 compares model surface air  $^7\text{Be}_{\text{P16spa}}$  and  $^{10}\text{Be}_{\text{P16spa}}$  concentrations and  $^{10}\text{Be}_{\text{P16spa}}/^7\text{Be}_{\text{P16spa}}$  ratios  
 542 with monthly mean observations in Tokyo (Yamagata et al., 2019) during the period of 2008-2014. Here we  
 543 mainly focus on the relative variations, and  $^7\text{Be}$  and  $^{10}\text{Be}$  data are normalized. The model captures the observed  
 544 variability in Tokyo well. The  $^7\text{Be}$  and  $^{10}\text{Be}$  show a peak in early spring (March-May) while the  $^{10}\text{Be}/^7\text{Be}$  ratio  
 545 shows a wider peak over March-July. The summer minima of  $^7\text{Be}$  and  $^{10}\text{Be}$  are due to strong scavenging associated  
 546 with the monsoon/typhoon season precipitation. While the  $^{10}\text{Be}/^7\text{Be}$  ratio is independent of precipitation  
 547 scavenging, the peaks of  $^{10}\text{Be}/^7\text{Be}$  coincide well with the enhancements of stratospheric contribution in the model.

548 This indicates that the  $^{10}\text{Be}/^7\text{Be}$  ratio is a better indicator of the vertical transport and stratospheric intrusion  
 549 influences than either tracer alone.

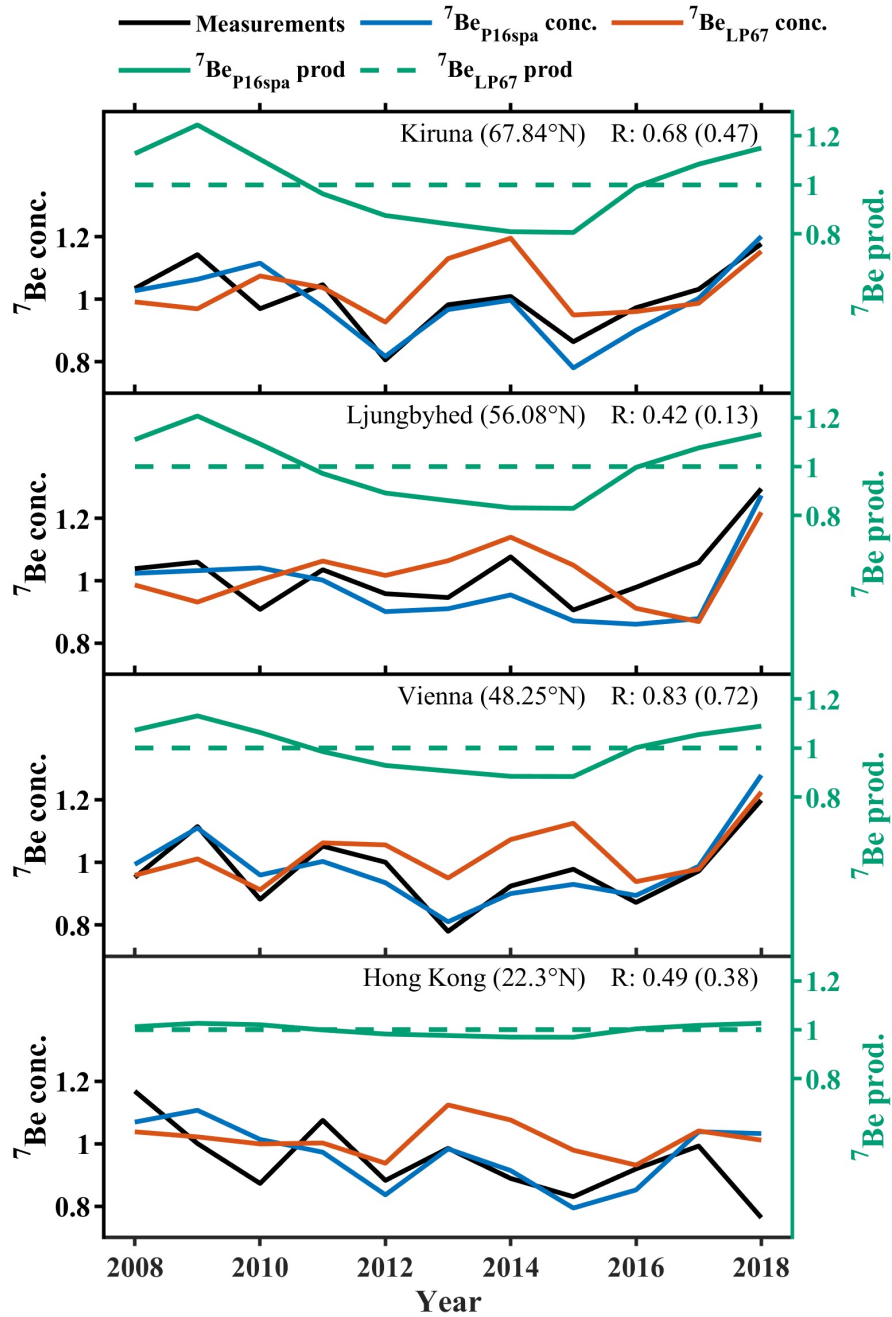

550  
 551 **Figure 11.** Comparison of monthly mean  $^7\text{Be}$  (top panel),  $^{10}\text{Be}$  (middle panel) concentrations, and  $^{10}\text{Be}/^7\text{Be}$  ratio (bottom  
 552 panel) between model results with P16spa production and measurements for the Tokyo station over the period 2008-2014.  
 553 Noted that all  $^7\text{Be}$  and  $^{10}\text{Be}$  values are normalized to focus on variability. The dashed black line bridges the gap in  
 554 measurements.

### 555 3.8 Solar modulation influences

556 Here we examine the ability of model to simulate the inter-annual variability of  $^7\text{Be}$  surface air concentrations,  
 557 especially whether the model can simulate the solar modulation influence using the updated production model.  
 558 Figure 12 shows the comparison of model simulated annual mean surface air  $^7\text{Be}$  concentrations with  
 559 measurements during 2008-2018 from four sites: Kiruna, Ljungbyhed, Vienna and Hong Kong (Kong et al., 2022;  
 560 Zheng et al., 2021a). The tropospheric  $^7\text{Be}$  production rate from each site is also plotted for comparison as  
 561 measured annual mean surface air  $^7\text{Be}$  concentrations are predominantly influenced by the local tropospheric  $^7\text{Be}$   
 562 production signal (Zheng et al., 2021a).

563 The model  $^7\text{Be}_{\text{P16spa}}$  surface air concentrations show a better agreement with annual  $^7\text{Be}$  measurements  
 564 (higher R-value) compared to  $^7\text{Be}_{\text{LP67}}$  concentrations at all surface sites (Fig. 12). The variability in the  
 565 measurements (Kiruna, Ljungbyhed, and Vienna) agrees well with the trend in production, suggesting a dominant  
 566 influence of solar modulations during this period. This is further supported by strong deviations between  $^7\text{Be}_{\text{P16spa}}$   
 567 and  $^7\text{Be}_{\text{LP67}}$  as no solar influence is considered in  $^7\text{Be}_{\text{LP67}}$ . This also emphasizes the importance of including solar  
 568 modulation of the  $^7\text{Be}$  and  $^{10}\text{Be}$  production in modeling studies, especially for high-latitude regions. The mismatch  
 569 of measurements and production at Kiruna from 2012 to 2015, together with the similar year-to-year variability  
 570 between  $^7\text{Be}_{\text{P16spa}}$  and  $^7\text{Be}_{\text{LP67}}$ , suggests the meteorological influence is dominant at Kiruna for this period. This  
 571 also suggests that meteorological influences can suppress the solar signal in the  $^7\text{Be}$  and  $^{10}\text{Be}$  observations.

572

573 **Figure 12.** Comparison of annual mean model surface air  $^7\text{Be}$  concentrations with measurements from 2008-2018. Also shown  
 574 are the model tropospheric  $^7\text{Be}$  production (green lines) at each station. All data are normalized by being divided by the mean  
 575 over the first five years. The linear spearman correlation coefficient R-value is between  $^7\text{Be}_{\text{P16spa}}$  and measurements while the  
 576 value in the bracket is between  $^7\text{Be}_{\text{LP67}}$  and measurements.

577 **4 Summary and conclusions**

578 We have incorporated the  $^7\text{Be}$  and  $^{10}\text{Be}$  production rates derived from the CRAC:Be model considering realistic  
 579 spatial geomagnetic cut-off rigidities (P16spa) into the GEOS-Chem global chemical transport model, enabling  
 580 the model output to be quantitatively comparable with the measurements. In addition to the standard simulation  
 581 using P16spa production rate, we further conducted two sensitivity simulations: one with the default production  
 582 rate in GEOS-Chem based on an empirical approach (LP67), and one with production rate from the CRAC:Be but

583 considering only geomagnetic cut-off rigidities for a geocentric axial dipole (P16). On global average, the LP67  
584 production rate is 60% higher compared to those of P16 and P16spa. The P16 production rate shows some regional  
585 differences (up to 50%) compared to the P16spa production rate.

586 In comparison with a large amount of air and deposition flux measurements, the model  ${}^7\text{Be}_{\text{P16spa}}$  shows good  
587 agreements with respect to surface air concentrations (93.7% of data within a factor of 2) and reasonably good  
588 agreements regarding deposition fluxes (60.9% of data within a factor of 2). The model simulates well the surface  
589 air concentration peaks in the subtropics associated strong downward transport from the stratosphere. This  
590 agreement is better than those using the default production  ${}^7\text{Be}_{\text{LP16}}$  and the  ${}^7\text{Be}_{\text{P16}}$  production with simplified axis  
591 symmetric dipole cut-off rigidity. The  ${}^7\text{Be}_{\text{LP67}}$  simulation overestimates the absolute value of  ${}^7\text{Be}$ . The  ${}^7\text{Be}_{\text{P16}}$   
592 simulation tends to produce a positive bias (~18%) for the  ${}^7\text{Be}$  deposition fluxes in East Asia region, nevertheless,  
593 no large bias is found for  ${}^7\text{Be}$  surface air concentrations. The surface deposition fluxes are more sensitive to the  
594 production in the mid- and upper-troposphere and downward transport of  ${}^7\text{Be}$  from the stratosphere, due to the  
595 effect of precipitation scavenging throughout the troposphere.

596 For the first time, the ability of GEOS-Chem to simulate  ${}^{10}\text{Be}$  is assessed with measurements. The model  
597  ${}^{10}\text{Be}_{\text{P16spa}}$  results agree well with  ${}^{10}\text{Be}$  observational data that were evaluated for dust influences or from the regions  
598 less influenced by dust (e.g., polar regions), while underestimating most samples that were not corrected for dust  
599 influences. This highlights the importance of examining the dust contribution to  ${}^{10}\text{Be}$  measurements when using  
600 these data to evaluate models.

601 Independent of the production models, surface  ${}^7\text{Be}$  and  ${}^{10}\text{Be}$  concentrations from all three simulations show  
602 similar seasonal variations, suggesting a dominant meteorological influence. The model generally simulates well  
603 the annual cycle of  ${}^7\text{Be}$  surface air concentrations and deposition fluxes at most sites in terms of amplitude and  
604 seasonality. The model fails to capture the “summer peak” in a few sites likely due to errors in convective transport  
605 during summer.

606 The model  ${}^{10}\text{Be}/{}^7\text{Be}$  ratios also lie within the measurements, suggesting the stratosphere-troposphere  
607 exchange process is reasonably represented in the model. The mismatch of the peaks between  ${}^7\text{Be}({}^{10}\text{Be})$  and  
608  ${}^{10}\text{Be}/{}^7\text{Be}$  ratios at the Tokyo site suggests that the  ${}^{10}\text{Be}/{}^7\text{Be}$  ratio is a better indicator of the vertical transport and  
609 stratospheric influences than either tracer alone as the ratio is independent of precipitation scavenging.

610 Finally, we demonstrate the value and importance of including time-varying solar modulation in  ${}^7\text{Be}$  and  
611  ${}^{10}\text{Be}$  production rates for model simulations of both tracers. It significantly improves the agreement of interannual  
612 variations between the model and measurements, especially at those surface sites from mid- and high- latitudes.  
613 The mismatch of trends in modeled  ${}^7\text{Be}$  production rate and observed air concentrations at Kiruna from 2012-  
614 2015 also suggests that the solar signal can be suppressed by meteorological influences.

615 In summary, we have shown that with the state-of-the-art P16spa production rate, the ability of GEOS-Chem  
616 to reproduce the  ${}^7\text{Be}$  and  ${}^{10}\text{Be}$  measurements (including interannual variability of  ${}^7\text{Be}$ ) is significantly improved.  
617 While uncertainties in transport and deposition processes play a major role in the model performance, reduced  
618 uncertainties in the production rates, as demonstrated in this study, allow us to use  ${}^7\text{Be}$  and  ${}^{10}\text{Be}$  tracers as better  
619 tools for evaluating and testing transport and scavenging in global models. We recommend using the P16spa  
620 (versus default LP67) production rate for GEOS-Chem simulations of  ${}^7\text{Be}$  and  ${}^{10}\text{Be}$  in the future.

621

622 *Author contributions.* MZ initiated the study. MZ performed the analysis and interpretation with contributions  
623 from HL and FA. MZ conducted the GEOS-Chem model simulations with the help from MW and ZL. All authors  
624 discussed the results and edited the manuscript.

625

626 *Competing interests.* The authors declare that there is no conflict of interest.

627

628 *Data and Code availability.* Observational data for model validation are available in the references described in  
629 section 2.3. The two compiled  $^{10}\text{Be}$  observation datasets are available in the Supplementary Information. The  
630 GEOS-Chem v14.0.2 model code, GEOS-Chem model output and  $^7\text{Be}$  and  $^{10}\text{Be}$  production rates are available at  
631 Zenodo repository (<https://doi.org/10.5281/zenodo.8372652>; Zheng et al., 2023a).
