## 16 **Abstract**

17 The cosmogenic radionuclides  $^7\text{Be}$  and  $^{10}\text{Be}$  are useful tracers for atmospheric transport studies. Combining  $^7\text{Be}$   
18 and  $^{10}\text{Be}$  measurements with an atmospheric transport model can not only improve our understanding of the  
19 radionuclide transport and deposition processes but also provide an evaluation of the transport process in the  
20 model. To simulate these aerosol tracers, it is critical to evaluate the influence of radionuclide production  
21 uncertainties on simulations. Here we use the GEOS-Chem chemical transport model driven by the MERRA-2  
22 reanalysis to simulate  $^7\text{Be}$  and  $^{10}\text{Be}$  with the state-of-the-art production rate from the CRAC:Be (Cosmic Ray  
23 Atmospheric Cascade: Beryllium) model considering realistic spatial geomagnetic cut-off rigidities (denoted as  
24 P16spa). We also perform two sensitivity simulations: one with the default production rate in GEOS-Chem based  
25 on an empirical approach (denoted as LP67), and the other with production rates from the CRAC:Be but  
26 considering only geomagnetic cut-off rigidities for a geocentric axial dipole (denoted as P16). The model results  
27 are comprehensively evaluated with a large number of measurements including surface air concentrations and  
28 deposition fluxes. The model with the P16spa production can reproduce the absolute values and temporal  
29 variability of  $^7\text{Be}$  and  $^{10}\text{Be}$  surface concentrations and deposition fluxes on annual and sub-annual scales, as well  
30 as the vertical profiles of air concentrations. Simulations with the LP67 production tend to overestimate the  
31 absolute values of  $^7\text{Be}$  and  $^{10}\text{Be}$  concentrations. The P16 simulations suggest less than 10% differences compared  
32 to P16spa but tend to produce a significant positive bias (~18%) in the  $^7\text{Be}$  deposition fluxes over East Asia. We  
33 find that the deposition fluxes are more sensitive to the production in the troposphere and downward transport  
34 from the stratosphere. Independent of the production models, surface air concentrations and deposition fluxes  
35 from all simulations show similar seasonal variations, suggesting a dominant meteorological influence. The model  
36 can also reasonably simulate the stratosphere-troposphere exchange process of  $^7\text{Be}$  and  $^{10}\text{Be}$  by producing  
37 stratospheric contribution and  $^{10}\text{Be}/^7\text{Be}$  ratio values that agree with measurements. Finally, we illustrate the  
38 importance of including the time-varying solar modulation in the production calculation, which can significantly  
39 improve the agreement between model results and measurements, especially at mid- and high- latitudes. Reduced

40 uncertainties in the production rates, as demonstrated in this study, improve the utility of  $^7\text{Be}$  and  $^{10}\text{Be}$  as aerosol  
41 tracers for evaluating and testing transport and scavenging processes in global models. For future GEOS-Chem  
42 simulations of  $^7\text{Be}$  and  $^{10}\text{Be}$ , we recommend using the P16spa (versus default LP67) production rate.

## 43 **1 Introduction**

44 The naturally occurring cosmogenic radionuclide  $^7\text{Be}$  (half-life of 53.2 days) is monitored worldwide and has  
45 been recognized as a useful tracer in atmospheric dynamic studies (Aldahan et al., 2001; Hernández-Ceballos et  
46 al., 2016; Terzi et al., 2019; Liu et al., 2016). Especially, ratios of radionuclides concentrations with very different  
47 half-lives, such as the  $^{10}\text{Be}/^7\text{Be}$  ratio, have become powerful tools (e.g., Liu et al., 2022b; Raisbeck et al., 1981)  
48 to disentangle the influence of transport and deposition since both  $^7\text{Be}$  and  $^{10}\text{Be}$  in the troposphere are mainly  
49 removed by wet deposition. In this paper, we aim to improve the utility of  $^7\text{Be}$  and  $^{10}\text{Be}$  as tracers for atmospheric  
50 transport by using state-of-the-art production rates in a global 3-D chemical transport model.

51  $^7\text{Be}$  and  $^{10}\text{Be}$  are produced through interactions between atmospheric atoms (mostly oxygen and nitrogen)  
52 and incoming cosmic rays in the atmosphere (Lal and Peters, 1967, referred to as LP67 hereafter; Poluianov et  
53 al., 2016, referred to as P16 hereafter). Due to the atmospheric depth-profile of fluxes of primary cosmic rays, the  
54 formed secondary particles, and their energy,  $^7\text{Be}$  and  $^{10}\text{Be}$  production rates reach their maxima in the lower  
55 stratosphere (Poluianov et al., 2016). About two-thirds of  $^7\text{Be}$  and  $^{10}\text{Be}$  are produced in the stratosphere while the  
56 rest is produced in the troposphere (Poluianov et al., 2016; Heikkilä and Smith, 2013; Golubenko et al., 2022).  
57 Once produced,  $^7\text{Be}$  and  $^{10}\text{Be}$  rapidly attach to aerosol particles and get transported and deposited with their carrier  
58 aerosol by wet and dry deposition (Delaygue et al., 2015; Heikkilä et al., 2013).  $^{10}\text{Be}$  has a half-life of 1.39 million  
59 years (Chmeleff et al., 2010) and its decay is thus negligible compared to its average atmospheric residence time  
60 (about 1-2 years) (Heikkilä et al., 2008b). During transport away from the regions of their production, the  $^{10}\text{Be}/^7\text{Be}$   
61 ratio increases because  $^7\text{Be}$  decays. The ratio  $^{10}\text{Be}/^7\text{Be}$  therefore could indicate the path-integrated age of the air  
62 mass. Due to different aerosol residence times in the stratosphere (more than 1 year) and troposphere (~weeks),  
63 the  $^{10}\text{Be}/^7\text{Be}$  ratio is higher in the stratosphere than in the troposphere. Hence the  $^{10}\text{Be}/^7\text{Be}$  ratio can be used to  
64 detect the stratosphere-troposphere exchange.

65 Many studies have focused on understanding the signals in surface  $^7\text{Be}$  measurements from worldwide  
66 monitoring stations (e.g., Hernandez-Ceballos et al., 2015; Rodriguez-Perulero et al., 2019; Uhlar et al., 2020;  
67 Ajtic et al., 2021; Burakowska et al., 2021). Due to the cosmogenic origin of  $^7\text{Be}$ , surface air  $^7\text{Be}$  concentrations  
68 are found to be connected to the 11-year cycle of solar modulation (Leppänen et al., 2010; Zheng et al., 2021a).  
69 In addition,  $^7\text{Be}$  concentrations in the surface air are affected by different meteorological processes depending on  
70 locations, such as stratospheric intrusions (Jordan et al., 2003; Pacini et al., 2015; Yamagata et al., 2019),  
71 scavenging by precipitation (Chae and Kim, 2019; Kusmierczyk-Michulec et al., 2015), vertical transport in the  
72 troposphere (Aldahan et al., 2001; Ajtic et al., 2018; Zheng et al., 2021a) and large-scale atmospheric circulations  
73 (Hernández-Ceballos et al., 2022; Terzi and Kalinowski, 2017).

74 The ability of general circulation models (e.g., ECHAM5-HAM, ECHAM/MESSy and GISS ModelE) and  
75 chemical transport models (e.g., GEOS-Chem) to capture the main characteristics in  $^7\text{Be}$  and  $^{10}\text{Be}$  transport and  
76 deposition has been shown by previous studies (e.g., Heikkilä et al., 2008b; Koch and Rind, 1998; Field et al.,  
77 2006; Usoskin et al., 2009; Brattich et al., 2021; Spiegl et al., 2022). For example, Usoskin et al. (2009) found  
78 that the solar proton-induced  $^7\text{Be}$  production peak in 2005 is indistinguishable from unforced variability given the

79 amount of intrinsic variability through the comparison of GISS ModelE simulations and surface air measurements.  
80 By comparing the measurements with GEOS-Chem simulations over January-March 2003, Brattich et al. (2021)  
81 found that increased  $^7\text{Be}$  values in surface air samples in Northern Europe in early 2003 were associated with the  
82 instability of the Arctic polar vortex. They also showed that, while the model generally simulates well the month-  
83 to-month variation in surface  $^7\text{Be}$  concentrations, it tends to underestimate the observations (see their Table 2)  
84 partly due to the use of the default LP67 production rate for a solar maximum year (1958) in the GEOS-Chem  
85 model (Liu et al., 2001). In comparison with the LP67  $^7\text{Be}$  production rate (Liu et al., 2001; Brattich et al., 2021),  
86 the latest production models apply full Monte-Carlo simulations of the cosmic-ray-induced atmospheric nucleonic  
87 cascade (e.g., Poluianov et al., 2016; Masarik and Beer, 1999). LP67 shows the highest absolute  $^7\text{Be}$  and  $^{10}\text{Be}$   
88 production rates compared to other production models (Elsässer, 2013). P16 suggests that LP67 overestimates the  
89  $^7\text{Be}$  production by 30-50% compared to their production model (Poluianov et al., 2016). Furthermore, the LP67  
90 production rate implemented in GEOS-Chem is only validated for the year 1958, a year with a high solar  
91 modulation function (i.e., high solar activity) of 1200 MeV (Herbst et al., 2017). This highlights the problem of  
92 quantitatively comparing these uncorrected model outputs with measurements from other time periods. Some  
93 studies (e.g., Koch et al., 1996; Liu et al., 2016) have applied a scale factor to account for this solar modulation  
94 influence on LP67 production rate. However, this correction is not ideal as the varying solar modulation is  
95 latitudinally and vertically dependent. In earlier studies, the production of  $^{10}\text{Be}$  in GEOS-Chem was simply scaled  
96 to the  $^7\text{Be}$  production based on the ratio estimated from the surface measurements (Koch and Rind, 1998). In  
97 addition,  $^{10}\text{Be}$  as simulated by GEOS-Chem has not been evaluated so far. It is hence necessary to update the  
98 beryllium production rates in GEOS-Chem and assess the corresponding impacts on model simulation results.

99 In this study, we incorporate global  $^7\text{Be}$  and  $^{10}\text{Be}$  production rates from the recently published “CRAC:Be”  
100 (Cosmic Ray Atmospheric Cascade: Beryllium) model (Poluianov et al., 2016) into the GEOS-Chem model. We  
101 simulate  $^7\text{Be}$  and  $^{10}\text{Be}$  using GEOS-Chem with the following three production scenarios.

- 102 • Scenario I: production rate derived from the “CRAC:Be” model considering realistic geomagnetic  
103 cut-off rigidity (P16spa production rate)
- 104 • Scenario II: production rate derived from the “CRAC:Be” model considering an approximation of  
105 geomagnetic cut-off rigidities using a geocentric axial dipole (P16 production rate)
- 106 • Scenario III: default production rate in GEOS-Chem using an empirical approximation (LP67  
107 production rate)

108 Scenario I is treated as the standard simulation while the other two are sensitivity tests that also enable  
109 comparison to earlier studies. This paper is organized as follows. Section 2 introduces the GEOS-Chem model  
110 and three different  $^7\text{Be}$  and  $^{10}\text{Be}$  production rates, discusses the methodology and experiment design, and describes  
111 the observational data for model evaluations. In section 3, we first investigate the differences between three  
112 different production scenarios (section 3.1). Then, we evaluate model simulations of  $^7\text{Be}$  and  $^{10}\text{Be}$  with several  
113 published datasets of  $^7\text{Be}$  and  $^{10}\text{Be}$  measurements, in terms of absolute values (section 3.2-3.3), vertical profiles  
114 (section 3.4), and seasonal variations (section 3.6). The budgets and residence times of  $^7\text{Be}$  and  $^{10}\text{Be}$  are given in  
115 section 3.5. We also examine the  $^{10}\text{Be}/^7\text{Be}$  ratio in the model to assess its ability in capturing the stratosphere-  
116 troposphere exchange (section 3.7). Finally, we investigate the influence of including solar-induced production  
117 rate variability on  $^7\text{Be}$  simulations (section 3.8). Summary and conclusions are given in section 4.

## 118 2 Models and Data

### 119 2.1 GEOS-Chem model

120 GEOS-Chem is a global 3-D chemical transport model (<http://www.geos-chem.org>) that simulates trace  
121 gases and aerosols in both the troposphere and stratosphere (Eastham et al., 2014; Bey et al., 2001). It is driven  
122 by archived meteorological data. We use version 14.0.2 ([https://wiki.seas.harvard.edu/geos-chem/index.php/GEOS-Chem\\_14.0.2](https://wiki.seas.harvard.edu/geos-chem/index.php/GEOS-Chem_14.0.2)) to simulate the transport and deposition of atmospheric  $^7\text{Be}$  and  $^{10}\text{Be}$ . We  
123 drive the model with the Modern-Era Retrospective analysis for Research and Applications, Version 2 (MERRA-  
124 2) meteorological reanalysis (<http://gmao.gsfc.nasa.gov/reanalysis/MERRA-2/>; Gelaro et al., 2017). MERRA-2  
125 has a native resolution of  $0.5^\circ$  latitude by  $0.667^\circ$  longitude, with 72 vertical levels up to 0.01 hPa (80 km). Here  
126 the MERRA-2 data are re-gridded to  $4^\circ$  latitude by  $5^\circ$  longitude for input to GEOS-Chem for computational  
127 efficiency.

129 GEOS-Chem includes a radionuclide simulation option ( $^{222}\text{Rn}$ - $^{210}\text{Pb}$ - $^7\text{Be}$ - $^{10}\text{Be}$ ), which simulates transport  
130 (advection, convection, boundary layer mixing), deposition, and decay of the radionuclide tracers (e.g., Liu et al.,  
131 2001; Liu et al., 2004; Zhang et al., 2021a; Yu et al., 2018). The model uses the TPCORE algorithm of Lin and  
132 Rood (1996) for advection, archived convective mass fluxes to calculate convective transport (Wu et al., 2007),  
133 and the non-local scheme implemented by Lin and McElroy (2010) for boundary-layer mixing. As mentioned in  
134 the introduction section, the standard GEOS-Chem model uses the LP67  $^7\text{Be}$  and  $^{10}\text{Be}$  production rates. After  
135 production,  $^7\text{Be}$  and  $^{10}\text{Be}$  attach to ambient submicron aerosols ubiquitously and their behavior becomes that of  
136 aerosols until they are removed by wet deposition (precipitation scavenging) and dry deposition processes. Note  
137 that neither is the process of attachment explicitly represented nor is the aerosol size distribution considered in the  
138 model. In addition, the decay process is included for the short-lived  $^7\text{Be}$  with a half-life time of 53.2-day. The  
139 decay is minor for the long-living  $^{10}\text{Be}$ , which has a half-life time of 1.39 million years (e.g., Chmeleff et al.,  
140 2010).

141 Wet deposition includes rainout (in-cloud scavenging) due to stratiform and anvil precipitation (Liu et al.,  
142 2001), scavenging in convective updrafts (Mari et al., 2000), and washout (below-cloud scavenging) by  
143 precipitation (Wang et al., 2011). Scavenged aerosols from vertical layers above are allowed to be released to the  
144 atmosphere during re-evaporation of precipitation below cloud. In case of partial re-evaporation, we assume that  
145 half of the corresponding fraction of the scavenged aerosol mass is released at that level because some of the re-  
146 evaporation of precipitation are due to partial shrinking of the raindrops, which does not release aerosol (Liu et  
147 al., 2001). MERRA-2 fields of precipitation formation and evaporation are used directly by the model wet  
148 deposition scheme. Dry deposition is based on the resistance-in-series scheme of Wesely (1989). The process of  
149 sedimentation is not included in the model.

150 To quantify the stratospheric contribution to  $^7\text{Be}$  in the troposphere, we separately transport  $^7\text{Be}$  produced in  
151 the model layers above the MERRA-2 thermal tropopause (i.e., stratospheric  $^7\text{Be}$  tracer). This approach was  
152 previously used to study cross-tropopause transport of  $^7\text{Be}$  in GEOS-Chem (Liu et al., 2001; Brattich et al., 2021)  
153 and Global Modeling Initiative chemical transport models (Liu et al., 2016; Brattich et al., 2017). The  
154 Stratospheric fraction of  $^7\text{Be}$  is defined as the ratio of the stratospheric  $^7\text{Be}$  tracer concentration to the  $^7\text{Be}$   
155 concentration from the standard simulation.

156 **2.2 <sup>7</sup>Be and <sup>10</sup>Be production models**

157 The GEOS-Chem currently use the LP67 production rates of <sup>7</sup>Be and <sup>10</sup>Be (Lal and Peters, 1967). These  
 158 production rates are calculated using an analytically estimated rate of nuclear disintegration (stars) in the  
 159 atmosphere (stars/g air/s), multiplied by the mean production yield of 0.045 atoms/star for <sup>7</sup>Be and 0.025  
 160 atoms/star for <sup>10</sup>Be (Lal and Peters, 1967). These rates are represented as a function of latitude and altitude for the  
 161 year 1958 and are not time varying.

162 Here we update the atmospheric <sup>7</sup>Be and <sup>10</sup>Be production rates in GEOS-Chem with the latest production  
 163 model: CRAC:Be model by P16 (Poluianov et al., 2016) using the solar modulation function record by Herbst et  
 164 al. (2017). The solar modulation function record is based on the local interstellar spectrum by Herbst et al. (2017),  
 165 which was also used in the production model. Given spatially and temporally resolved geomagnetic cut-off  
 166 rigidities, the P16 model allows the calculation of 3-dimensional, temporally variable <sup>7</sup>Be and <sup>10</sup>Be production  
 167 rates, which are necessary for input to atmospheric transport models. The P16 production model is regarded as  
 168 the latest and one of the most accurate production models for <sup>7</sup>Be and <sup>10</sup>Be and was used in recent general  
 169 circulation model simulations (e.g., Golubenko et al., 2021; Sukhodolov et al., 2017).

170 The production of <sup>7</sup>Be and <sup>10</sup>Be is calculated by an integral of the yield function of <sup>7</sup>Be and <sup>10</sup>Be ( $Y_i$ , atoms  
 171  $g^{-1} cm^2 sr$ ), and the energy spectrum of cosmic rays ( $J_i$ ,  $(sr sec cm^2)^{-1}$ ) above the cutoff energy  $E_c$ :

172 
$$Q(\Phi, h, P_c) = \sum_i \int_{E_c}^{\infty} Y_i(E, h) J_i(E, \Phi) dE$$

173 The  $i$  refers to different types of primary cosmic ray particles (e.g., proton, alpha and heavier particles). For  
 174 modelling the contribution of alpha and heavier particles to the total production, their nucleonic ratio in the local  
 175 interstellar spectrum was set to 0.353 (Koldobskiy et al., 2019). The yield function  $Y_i$  is a function of height ( $h$ )  
 176 and kinetic energy per incoming primary nucleon ( $E$ ) and is directly taken from P16. The energy spectrum of  
 177 cosmic rays  $J_i$  is a function of the kinetic energy ( $E$ ) and depends on the solar modulation function ( $\Phi$ ) (Herbst et  
 178 al., 2017).  $E_c$  is calculated as a function of the local geomagnetic rigidity cutoff ( $P_c$ ):

179 
$$E_c = E_r \left( \sqrt{1 + \left( \frac{Z_i P_c}{A_i E_r} \right)^2} - 1 \right)$$

180 where  $Z_i$  and  $A_i$  are the charge and mass numbers of particles, respectively.  $E_r$  is the rest mass of a proton (0.938  
 181 GeV).

182 The geomagnetic rigidity cutoff  $P_c$  is a quantitative estimation of the Earth's geomagnetic field shielding  
 183 effect (Smart and Shea, 2005). Cosmic ray particles with rigidity (momentum per unit charge of the particle)  
 184 higher than the geomagnetic cutoff rigidity value can enter the Earth's atmosphere. In several model simulations  
 185 of <sup>7</sup>Be and <sup>10</sup>Be (e.g., Heikkilä et al., 2008c; Field et al., 2006; Koch et al., 1996; Liu et al., 2001), the production  
 186 is calculated with a  $P_c$  simplified as a function of the geomagnetic latitude and geomagnetic dipole moment, called  
 187 the vertical Stoermer cut-off rigidity equation (see equation 5.8.2-2 in Beer et al., 2012). However, this is different  
 188 from the real geomagnetic cut-off rigidity inferred from the trajectories of particles with different energies using  
 189 real geomagnetic field measurements (e.g., Copeland, 2018) which also includes non-dipole moments of the field  
 190 (Beer et al., 2012) (Fig. S1). Earlier studies suggested that using the simple centered dipole models (e.g., Stoermer

191 cut-off rigidity) for cut-off rigidity approximation is limited as they can significantly distort the cut-off rigidity  
192 for some regions (e.g., low-latitude regions) (Pilchowski et al., 2010; Nevalainen et al., 2013)

193 Here we take the geomagnetic cutoff rigidity from Copeland (2018) that provides the cut-off rigidity at a  
194 fine interval (one degree) in both latitude and longitude. This production rate is denoted as P16spa. To investigate  
195 the effect of this more realistic representation of cut-off rigidity on  $^7\text{Be}$  and  $^{10}\text{Be}$  simulations, we also perform  
196 simulations where the cut-off rigidities are approximated by the Stoermer equation (denoted as P16). The  
197 influence of the geomagnetic field intensity variations can be considered negligible on annual and decadal  
198 timescales and are ignored here (e.g. Muscheler et al., 2007; Zheng et al., 2020). It should be mentioned that the  
199 LP67 production is based on an ideal axial dipole cut-off rigidity similar to the P16 production model.

200

### 201 **2.3 GEOS-Chem model experiments and evaluations**

202 An overview of the performed simulations is shown in Table S1. The simulation with the P16spa production rate  
203 is considered as the standard simulation while the simulations with the P16 and LP67 production rates are  
204 sensitivity tests. The simulation with the P16 production rate is conducted to evaluate the influence of a simplified  
205 approximation of cutoff rigidities resulting from a geocentric dipole. In earlier studies, the LP67 production rate  
206 was used for global model simulations of  $^7\text{Be}$  (e.g., Liu et al., 2016; Brattich et al., 2017; Liu et al., 2001; Koch  
207 et al., 1996). The purpose of performing the simulation with the LP67 production rate is to evaluate to what extent  
208 model simulations are biased when applying the default LP67 production. Since the LP67 production rate applies  
209 only for the year 1958 (with a solar modulation function of about 1200 MeV) and does not consider the influences  
210 of the solar variations (e.g., 11-year solar cycle), it underestimates the production rate for the period of 2008-2018  
211 that has an average solar modulation function of 500 MeV. To correct for this solar modulation influence, we  
212 follow the previous studies (e.g., Liu et al., 2016; Koch et al., 1996) by multiplying the model results by a scale  
213 factor of 1.39. It should be noted that this correction is not ideal as the effects of a varying solar modulation on  
214 cosmogenic radionuclide production rates depend on altitude and latitude. All simulations are performed from  
215 2002 to 2018 with the first six-year for spin-up to make sure the  $^{10}\text{Be}$  nearly reaches equilibrium in the atmosphere  
216 and the 2008-2018 period (11 years) for analysis. The simulations are conducted using a  $4^\circ$  latitude  $\times$   $5^\circ$  longitude  
217 resolution for computational efficiency (e.g., Liu et al., 2016; Liu et al., 2004).

218 To evaluate the model's ability to reproduce the variabilities in the observations, we use the statistical  
219 parameters: Spearman correlation coefficients and Root Mean Square Error (RMSE) (Chang and Hanna, 2004).  
220 Spearman rank correlation (R) (Myers et al., 2013) is used as it does not make any assumptions about the variables  
221 being normally distributed. It is less sensitive to outliers in the data compared to the commonly used Pearson  
222 correlation coefficients. The fraction of modeled concentrations within a factor of 2 of observations (FA2) is  
223 calculated, i.e., for which  $0.5 < X_{\text{model}}/X_{\text{observation}} < 2$ . Usually, if the scatter plot of the model and  
224 measurements is within a factor of 2 of observations, the model is considered to have a reasonably good  
225 performance (e.g., Heikkilä et al., 2008b; Brattich et al., 2021). For model comparison with surface air  
226 concentrations, the model value from the bottom grid box closest to the corresponding measurement site is  
227 selected.

228

## 229 2.4 <sup>7</sup>Be and <sup>10</sup>Be observational data for model validation

230 The annual mean <sup>7</sup>Be surface air concentration and deposition measurements are taken from a compilation by  
231 Zhang et al. (2021b). The compilation includes a total of 494 annual mean values for surface air <sup>7</sup>Be concentrations  
232 and 304 for <sup>7</sup>Be deposition fluxes. For the deposition measurements, most of them include both wet and dry  
233 deposition, while a few are collected only during rainfall events and thus include only wet deposition. It includes  
234 the data from:

- 235 • The Environmental Measurements Laboratory (EML,  
236 <https://www.wipp.energy.gov/namp/emllegacy/index.htm>) Surface Air Sampling Program (SASP),  
237 which began in the 1980s,
- 238 • The ongoing international monitor program Radioactivity Environmental Monitoring (REM) network  
239 (e.g., Hernandez-Ceballos et al., 2015; Sangiorgi et al., 2019),
- 240 • International Monitoring System (IMS) organized by the Comprehensive Nuclear-Test-Ban Treaty  
241 Organization (CTBTO) (e.g., Terzi and Kalinowski, 2017),
- 242 • Some additional datasets in publications not included in the above programs.

243 This compiled <sup>7</sup>Be dataset only includes those data covering more than 1 year to reduce the influence of inherent  
244 seasonal variations. We further include several recently published data for <sup>7</sup>Be surface air concentrations and  
245 deposition fluxes records that cover more than 1 year (Burakowska et al., 2021; Liu et al., 2022b; Kong et al.,  
246 2022).

247 The dataset used for investigating the seasonality of <sup>7</sup>Be surface air concentrations are mainly taken from a  
248 multiyear compilation dataset of IMS from Terzi and Kalinowski (2017). The seasonal <sup>7</sup>Be deposition data are  
249 taken from Courtier et al. (2017), Du et al. (2015), Dueñas et al. (2017), Hu et al. (2020), Lee et al. (2015), and  
250 Sangiorgi et al. (2019). The vertical profile of <sup>7</sup>Be concentrations is taken from the Environmental Measurements  
251 Laboratory (EML) High Altitude Sampling Program (HASP) spanning the years of 1962-1983. It should be noted,  
252 different from surface air measurements, the vertical air samples were usually collected during single-day flight  
253 campaigns.

254 There are fewer <sup>10</sup>Be measurements compared to <sup>7</sup>Be. Here we compiled two datasets of published <sup>10</sup>Be  
255 surface air measurements (Table S2) (Aldahan et al., 2008; Liu et al., 2022a; Yamagata et al., 2019; Padilla et al.,  
256 2019; Rodriguez-Perulero et al., 2019; Huang et al., 2010; Méndez-García et al., 2022; Elsässer et al., 2011; Dibb  
257 et al., 1994) and deposition fluxes (Table S3) covering more than 1 year, to validate the model performance. The  
258 air samples are continuously collected by filters using a high-flow aerosol sampler. The sampling volume was  
259 approximately 700 m<sup>3</sup> of air for daily samples (e.g., Liu et al., 2022a) and between 3000 m<sup>3</sup> and 5000 m<sup>3</sup> for  
260 weekly samples (e.g., Yamagata et al., 2019). The deposition data include the precipitation samples (wet  
261 deposition) (Graham et al., 2003; Monaghan et al., 1986; Somayajulu et al., 1984; Heikkilä et al., 2008a; Raisbeck  
262 et al., 1979; Maejima et al., 2005) and ice core samples (wet and dry deposition) that cover the recent period  
263 (Heikkilä et al., 2008a; Zheng et al., 2021b; Pedro et al., 2012; Baroni et al., 2011; Aldahan et al., 1998; Berggren  
264 et al., 2009; Auer et al., 2009; Zheng et al., 2023b). The <sup>10</sup>Be vertical profile measurements are mainly taken from  
265 Dibb et al. (1994, 1992) and Jordan et al. (2003).

266

267 **3 Results and Discussions**

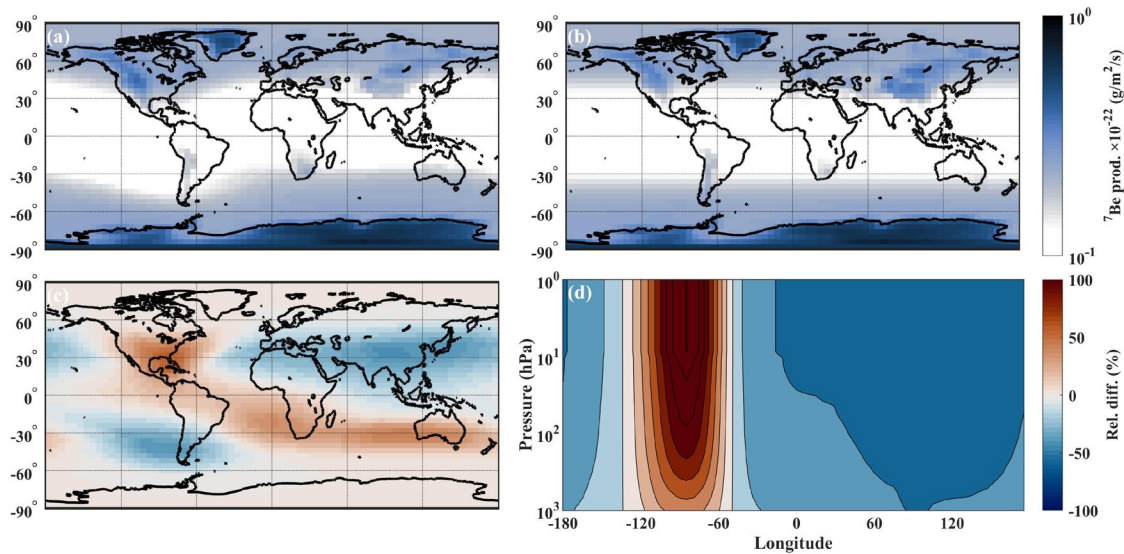

268 **3.1 <sup>7</sup>Be and <sup>10</sup>Be production rates**

269 Figure S2 shows the comparison between the <sup>7</sup>Be production rates from the LP67 and P16 models. Generally, the  
270 P16 production model shows a similar production distribution as the LP67 production rate, with a maximum <sup>7</sup>Be  
271 production over the polar stratosphere (~100 hPa). The LP67 production rate shows about 72% higher production  
272 rate compared to P16 in the stratosphere and 38% in the troposphere (Fig. S2c; Table S4). On a global average,  
273 the LP67 production rate is about 60% higher than that of P16 as shown in previous studies (Poluianov et al.,  
274 2016). The stratospheric production rate contributes about 67% to the total production rate for LP67 while it is  
275 about 62% for the P16 production rate for the year 1958.

276 The <sup>10</sup>Be<sub>LP67</sub> production rate in the GEOS-Chem model uses the identical source distribution as <sup>7</sup>Be with a  
277 scaling factor based on the estimates from surface air measurements (Koch and Rind, 1998). This leads to a  
278 constant <sup>10</sup>Be<sub>LP67</sub>/<sup>7</sup>Be<sub>LP67</sub> production ratio (0.55) throughout the entire atmosphere. However, as shown in many  
279 <sup>7</sup>Be and <sup>10</sup>Be production models (e.g., Poluianov et al., 2016; Masarik and Beer, 2009), <sup>7</sup>Be and <sup>10</sup>Be have different  
280 altitudinal production distributions. The P16 production shows an increasing <sup>10</sup>Be/<sup>7</sup>Be production ratio from  
281 higher altitude (0.35) to lower altitude (0.6) (Fig. S3). Using a constant <sup>10</sup>Be/<sup>7</sup>Be production ratio may thus result  
282 in large errors in the modeled <sup>10</sup>Be concentrations as well as <sup>10</sup>Be/<sup>7</sup>Be ratios. The stratospheric production of <sup>10</sup>Be  
283 contributes about 67% of the total production with LP67 while it is about 58% with the P16 production for the  
284 year 1958 (Table S4).

285 Figure 1 shows the comparison between <sup>7</sup>Be<sub>P16</sub> and <sup>7</sup>Be<sub>P16spa</sub> production rates for the period 2008-2018. The  
286 global production is similar for P16spa and P16 (Table S4). However, considering non-dipole moment influence  
287 on geomagnetic cut-off rigidity, <sup>7</sup>Be<sub>P16spa</sub> and <sup>10</sup>Be<sub>P16spa</sub> production rates in the Southern Hemisphere show ~11%  
288 higher production rates compared to the Northern Hemisphere (Table S4). This difference is not present when an  
289 axial dipole is assumed. Compared to P16 production rate, the <sup>7</sup>Be<sub>P16spa</sub> production rate shows 30-40% lower  
290 production over eastern Asia and southeastern Pacific, but 40-50% higher over North America and from  
291 subtropical South Atlantic to Australia (Fig. 1). <sup>10</sup>Be<sub>P16spa</sub> shows similar results as the <sup>7</sup>Be<sub>P16spa</sub>. These differences  
292 are not constant throughout the atmospheric column but generally increase with altitude (Fig. 1d).

293  
294

295

296 **Figure 1.** Upper panels: Spatial distribution of (a) P16spa and (b) P16  ${}^7\text{Be}$  production rates at 825 hPa over the period 2008-  
 297 2018. Lower panels: (c) Relative differences (%), i.e.,  $({}^7\text{Be}_{\text{P16spa}} - {}^7\text{Be}_{\text{P16}}) / {}^7\text{Be}_{\text{P16}} \times 100\%$ , between production rates with and  
 298 without considering the detailed spatial cut-off rigidity. (d) Relative differences (%) of the zonal mean production rates  
 299 between P16spa and P16 at  $30^\circ\text{N}$ .

300

### 301 3.2 ${}^7\text{Be}$ surface air concentrations and deposition fluxes

302 Figure 2 compares the simulated  ${}^7\text{Be}_{\text{P16spa}}$  averaged over 2008-2018 with the measurements. Due to the data  
 303 availability, the measurements do not necessarily cover the same period as model simulations. The model  
 304 deposition fluxes here include both dry and wet deposition. About 93.7% of modeled air  ${}^7\text{Be}_{\text{P16spa}}$  concentrations  
 305 agree within a factor of 2 with the observed values. The model also shows reasonable agreement with the measured  
 306 deposition fluxes (60.9% within a factor of 2) although the discrepancy between the modeled and observed  
 307 deposition fluxes is larger than that for surface air concentrations. The deposition fluxes are usually less well  
 308 monitored compared to the air  ${}^7\text{Be}$  samples and cover usually only shorter periods (e.g., one or two years). Further,  
 309 the limited model resolution applied here may not be able to capture meteorological conditions on local scales  
 310 (e.g., precipitation, convection, and tropopause folding) in some sites (e.g., Yu et al., 2018; Spiegl et al., 2022),  
 311 especially for coastal regions when the sub-grid scale orographic precipitation is important.

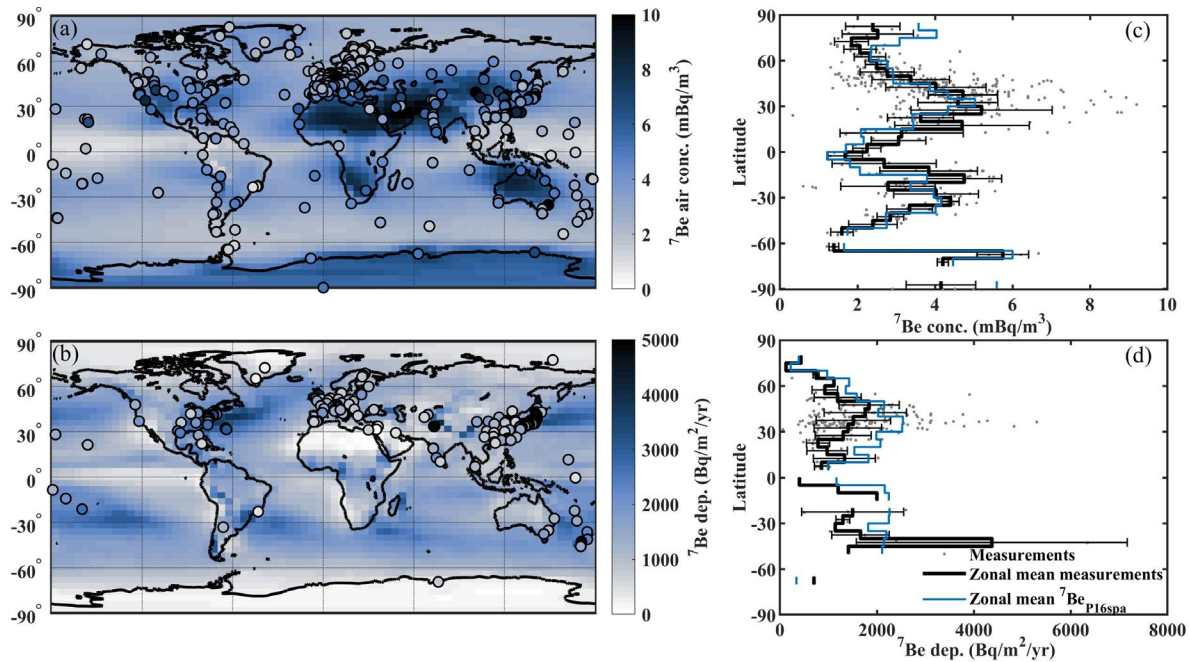

313

314 **Figure 2.** Scatter plot of modeled versus observed <sup>7</sup>Be surface air concentrations (left panel) and deposition fluxes (right  
 315 panel). The model values are averaged over the years of 2008-2018. The dashed lines are the factor of 2 of 1:1 line (straight  
 316 lines). The “FA2” indicates the fraction of modeled concentrations within a factor of 2 of observations while “RMSE” indicates  
 317 the root mean square error.

318 Figure 3 shows the spatial distribution and zonal mean of measurements in comparison with the model  
 319 simulated <sup>7</sup>Be<sub>P16spa</sub> surface air concentrations and deposition fluxes. Generally, the model captures the spatial  
 320 distribution of <sup>7</sup>Be air concentrations and deposition fluxes. The “latitudinal pattern” of surface air <sup>7</sup>Be  
 321 concentrations differs from that of <sup>7</sup>Be production rate, reflecting the effects of atmospheric transport and  
 322 deposition processes. The model suggests high <sup>7</sup>Be air concentrations mainly over the dry regions (Fig. 3a) due  
 323 to low wet deposition rates (e.g., desert regions over Northern Africa, Arabian Peninsula, central Australia, and  
 324 Antarctica) and over high-altitude regions (e.g., Tibetan Plateau). The model captures the observed latitudinal  
 325 peaks in surface air concentrations over the subtropics and mid-latitudes (Fig. 3c around 30°N-40°N and 30°S -  
 326 40°S). These peaks are consistent with the high stratospheric contribution (~25-30%) at mid-latitudes (Fig. S4).  
 327 The model overestimates <sup>7</sup>Be air concentrations over the Arctic (70°N-90°N, Fig. 3c) by about 30%-40%. By  
 328 contrast, high <sup>7</sup>Be deposition fluxes are observed at mid-latitudes due to the influence of the high precipitation  
 329 (wet deposition) and strong stratosphere-troposphere exchange (Fig. 3d). In the Northern Hemisphere, the model  
 330 simulated deposition fluxes peak at a lower latitude (~30°N) relative to the observations (~45°N). These modeled  
 331 spatial distributions of the air concentrations and deposition rates of <sup>7</sup>Be also agree generally well with previous  
 332 model simulations (e.g., Heikkilä and Smith, 2012).

333

334

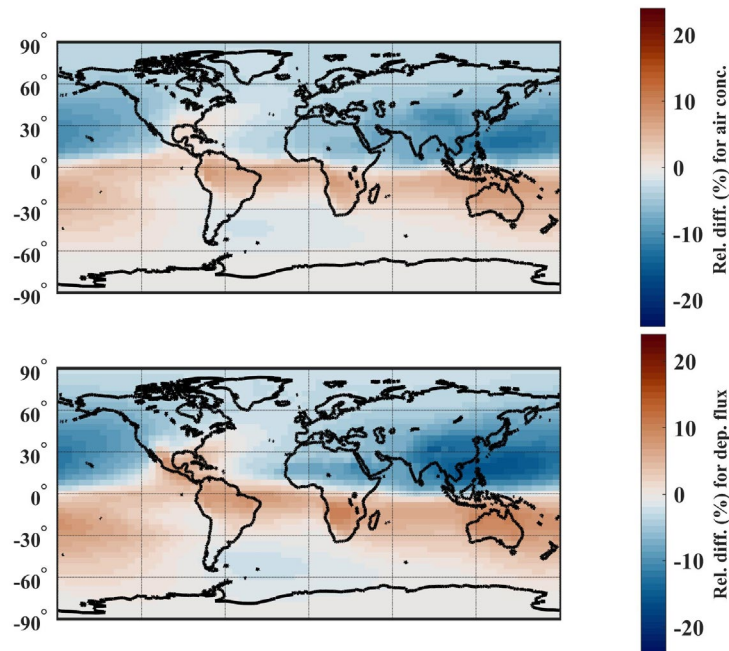

335 **Figure 3.** Left column: (a) modeled  ${}^7\text{Be}_{\text{P16spa}}$  surface air concentrations ( $\text{mBq}/\text{m}^3$ ) and (b) deposition fluxes ( $\text{Bq}/\text{m}^2/\text{yr}$ )  
 336 averaged over the period 2008-2018. Color-coded dots denote  ${}^7\text{Be}$  measurements. Right column: zonal mean of (c) observed  
 337  ${}^7\text{Be}$  surface air concentrations and (d) deposition fluxes (black lines, for each  $5^\circ$  latitude bin) compared with the model  
 338 simulation using the P16spa production rate (blue lines). Dots are individual measurements. The error bars indicate one  
 339 standard deviation. The outliers, defined as more than three scaled median absolute deviations (MAD) away from the median,  
 340 are excluded from the calculation. The observations are averaged over the years available.

341 The modelled  ${}^7\text{Be}_{\text{P16spa}}$  air concentrations show better agreements (smaller RMSE and higher FA2 values)  
 342 with the measurements in comparison to  ${}^7\text{Be}_{\text{LP67}}$  (Fig. S5).  ${}^7\text{Be}_{\text{LP67}}$  tends to overestimate the absolute values of  
 343  ${}^7\text{Be}$  and  ${}^{10}\text{Be}$  concentrations. This is caused by i) the overestimation of  ${}^7\text{Be}$  production rate by LP67 for a given  
 344 solar modulation function and ii) using a simple scale factor to account for the solar modulation influence on the  
 345 LP67  ${}^7\text{Be}$  production rate.

346 We also examine whether using the dipole-approximation of the cut-off rigidity or real cut-off rigidity (P16  
 347 and P16spa, respectively) in the production model leads to significantly different results (Fig. 4). Although large  
 348 differences in the production model are observed between P16spa and P16 production rates (up to 40-50%  
 349 differences over eastern Asia and southern Pacific), such differences are reduced in surface air concentrations and  
 350 deposition fluxes due to transport and deposition processes, as expected. The  ${}^7\text{Be}_{\text{P16sap}}$  air concentrations show  
 351 higher values ( $\sim 7\%$ ) over  $10^\circ\text{S}$ - $40^\circ\text{S}$  and lower values ( $\sim 12\%$ ) over the east Asian region (Fig. 4) compared to  
 352  ${}^7\text{Be}_{\text{P16}}$ . These differences are higher for the deposition fluxes with up to 10% higher over the  $10^\circ\text{S}$ - $40^\circ\text{S}$  and up to  
 353 18% lower over the east Asian region (Fig. 4). Since the total deposition flux reflects precipitation scavenging  
 354 through the tropospheric column, it tends to be more sensitive to  ${}^7\text{Be}$  air concentrations at higher altitudes and  
 355 downward transport of  ${}^7\text{Be}$  from the stratosphere. Indeed, model results suggest that deposition fluxes have a  
 356 higher stratospheric fraction compared to the surface air concentrations (Fig. S4). The  ${}^7\text{Be}_{\text{P16spa}}$  deposition fluxes  
 357 show better agreement with measurements than those of  ${}^7\text{Be}_{\text{P16}}$  (Fig. S5). The comparison for  ${}^{10}\text{Be}$  shows similar  
 358 results as  ${}^7\text{Be}$  except with less than 10% differences. For  ${}^{10}\text{Be}$  deposition fluxes in Antarctica and Greenland, this  
 359 influence is less than 3%. This is because the dominant contribution of  ${}^{10}\text{Be}$  is from the stratosphere where the  
 360 hemispheric production differences are diminished by the long stratospheric residence time of  ${}^{10}\text{Be}$ . However, it  
 361 does not suggest that the cut-off rigidity including the non-dipole influence could be ignored for  ${}^{10}\text{Be}$  depositions  
 362 in polar regions, as the spatial pattern of cut-off rigidities was very different in the past time, e.g., during the

363 Laschamps geomagnetic field minimum around 41,000 years before the present (Gao et al., 2022). Further studies  
364 are warranted to investigate this spatial cut-off rigidity influence on  $^{10}\text{Be}$  in more detail.  
365

366  
367 **Figure 4.** Relative differences (percentage) of surface air concentrations (upper panel) and deposition fluxes (lower panel)  
368 between  $^7\text{Be}_{\text{P16spa}}$  and  $^7\text{Be}_{\text{P16}}$  for the period 2008-2018, i.e.,  $(^7\text{Be}_{\text{P16spa}} - ^7\text{Be}_{\text{P16}}) / ^7\text{Be}_{\text{P16}} \times 100\%$ .

369

### 370 3.3 $^{10}\text{Be}$ surface air concentrations and deposition fluxes

371 Figure 5 shows the comparison between modeled annual mean  $^{10}\text{Be}_{\text{P16spa}}$  surface air concentrations (or deposition  
372 fluxes) averaged over 2008-2018 and measurements. The  $^{10}\text{Be}_{\text{P16spa}}$  shows similar spatial distributions as  $^7\text{Be}_{\text{P16spa}}$   
373 because both radionuclides share the same transport and deposition processes. The model underestimates the  
374 measured  $^{10}\text{Be}$  surface air concentrations and deposition fluxes at some sites (Fig. 5b, 5d). This may be attributed  
375 to the influence of resuspended dust with  $^{10}\text{Be}$  attached, which could typically contribute 10%-35% to the air  $^{10}\text{Be}$   
376 concentrations (Monaghan et al., 1986). It should be mentioned that  $^7\text{Be}$  decays in the dust because of its short  
377 half-life, and therefore does not contribute to the surface air  $^7\text{Be}$  concentrations. Indeed, data where a careful  
378 examination of the recycled dust  $^{10}\text{Be}$  in samples was conducted (e.g., Monaghan et al., 1986), or from locations  
379 that are less influenced by recycled dust  $^{10}\text{Be}$  (e.g., Polar regions; dots in Fig. 5b-5d), show better agreement with  
380 the model simulations. This suggests the importance of considering the dust contribution when measuring the air  
381  $^{10}\text{Be}$  samples. The model also shows relatively good agreement with most  $^{10}\text{Be}$  deposition data from polar ice  
382 cores (marked as dots in Fig. 5d) within a factor of 2.

383

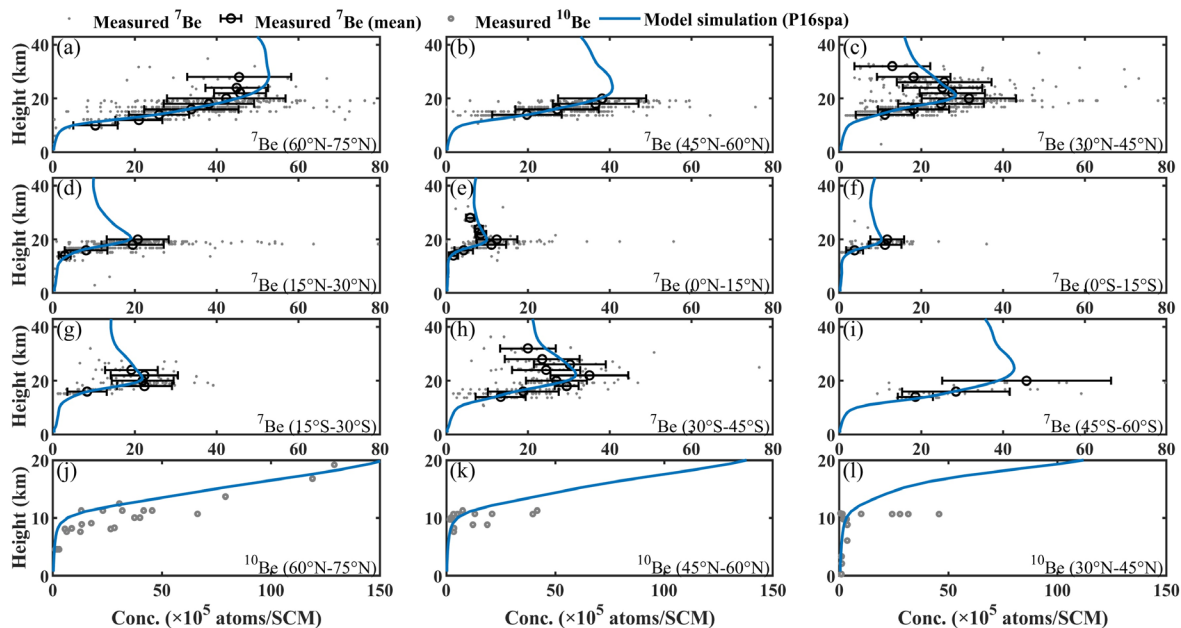

384  
 385 **Figure 5.** Left column: the modeled annual mean  $^{10}\text{Be}_{\text{P16spa}}$  (a) surface air concentrations and (b) deposition fluxes averaged  
 386 over 2008-2018 overplotted with measurements (color-coded dots). Right column: (c)-(d) the scatter plot between model  
 387 results and measurements for (c) surface air concentrations and (d) deposition fluxes. The dots in (c-d) indicate measurements  
 388 with careful examination of dust  $^{10}\text{Be}$  contributions or from the polar regions which are not influenced by dust  $^{10}\text{Be}$ . The  
 389 crosses indicate the samples without examining dust contributions. The FA2 and RMSE are calculated only using the dust-  
 390 free samples (dots). Blue and orange colors indicate the results using P16spa and LP67 production rates, respectively.

391

### 392 3.4 Vertical profiles of $^7\text{Be}$ and $^{10}\text{Be}$

393 Figure 6 shows the simulated annual zonal mean vertical profiles of  $^7\text{Be}_{\text{P16spa}}$  and  $^{10}\text{Be}_{\text{P16spa}}$  concentrations  
 394 compared with those from aircraft measurements in the troposphere and stratosphere from the EML/HASP. The  
 395 measurements cover different regions and specific meteorological conditions; hence they should only provide a  
 396 range in which the model results should lie. Following previous modelling studies (Heikkilä et al., 2008b; Koch  
 397 et al., 1996), we compare model zonal mean values in each  $15^\circ$  latitude band with the corresponding observations.

398 The simulated  $^7\text{Be}_{\text{P16spa}}$  profiles agree well with the measurements, especially capturing the peaks at  $\sim 20$ - $22$   
 399 km at mid- and low- latitudes (e.g., Fig. 6c, 6e, 6h). The feature that  $^7\text{Be}$  increases with altitude without a peak at  
 400 22 km at northern high latitudes ( $60^\circ\text{N}$ - $75^\circ\text{N}$ ) is also captured by the model (Fig. 6a). The  $^7\text{Be}_{\text{P16spa}}$  shows high  
 401 concentrations in the polar stratosphere and low values over the equatorial stratosphere (Fig. S6), mainly reflecting  
 402 the latitudinal distribution of the production. This “latitudinal structure” is modulated for  $^{10}\text{Be}_{\text{P16spa}}$  in the  
 403 stratosphere as  $^{10}\text{Be}$  is better mixed than  $^7\text{Be}$  due to its slow decay together with relatively long residence time in  
 404 the stratosphere (Waugh and Hall, 2002). Both  $^7\text{Be}$  and  $^{10}\text{Be}$  show very low concentrations in the tropical upper  
 405 troposphere, reflecting the frequent injection of air from the lower troposphere in wet convective updrafts, where  
 406 aerosols are efficiently scavenged (Fig. S6).

407  
 408 **Figure 6.** Comparison of the vertical profile between measurements (circles) and model zonal mean  ${}^7\text{Be}_{\text{p16spa}}$   
 409 and  ${}^{10}\text{Be}_{\text{p16spa}}$  concentrations for each latitudinal band ( $15^\circ$ ) over the period 2008-2018. The  ${}^7\text{Be}$  (circle with  
 410 error bar) observations (from the EML/HASP) are averaged for the altitude band of every 2 km where more than  
 411 5 samples are available. We exclude the outlier from the calculation, which is defined as more than three scaled  
 412 median absolute deviations (MAD) away from the median. The  ${}^{10}\text{Be}$  profile measurements are mainly taken  
 413 from Dibb et al. (1994, 1992) and Jordan et al. (2003).

414  
 415 The model also reasonably simulated  ${}^{10}\text{Be}$  concentration vertical profiles compared with observations, with  
 416 a tendency to underestimate observations in the stratosphere (Fig. 6j-6l). A previous general circulation model  
 417 study by also showed too low model stratospheric  ${}^{10}\text{Be}$  compared to measurements. They attributed this  
 418 underestimation to too short stratospheric air residence time in the model, which prevents  ${}^{10}\text{Be}$  concentrations  
 419 from accumulating sufficiently in the stratosphere. However, this may not be the case in our study, as the  
 420 stratospheric air residence time in the MERRA-2 reanalysis agrees reasonably with the observations (Chabrilat  
 421 et al., 2018). Another explanation is that the  ${}^{10}\text{Be}$  production rate may be underestimated in the stratosphere.  ${}^7\text{Be}$   
 422 is less affected by this process than  ${}^{10}\text{Be}$  because of its short half-life compared to its stratospheric residence time  
 423 (Delaygue et al., 2015).

424  
 425 **3.5 Global budgets and residence time**

426 Table 1 shows the global budgets for  ${}^7\text{Be}$  and  ${}^{10}\text{Be}$  over the period of 2008-2018. About 22.1% of tropospheric  
 427  ${}^7\text{Be}$  is lost by radioactive decay, 76.2% by convective and large-scale precipitation, and 1.7% by dry deposition.  
 428 The wet deposition contributes to about 97% of total deposition for  ${}^7\text{Be}$  and  ${}^{10}\text{Be}$  (Table 1; Fig. S7), which is  
 429 slightly higher than the  $\sim 93\%$  contribution in previous model studies (Heikkilä et al., 2008b; Koch et al., 1996;  
 430 Spiegl et al., 2022). The global mean tropospheric residence time of  ${}^7\text{Be}$  is about 21 days, which is comparable to  
 431 those reported by previous model studies: 18 days by Heikkilä et al. (2008b) and 21 days by Koch et al. (1996)

432 and Liu et al. (2001). This also agrees with the residence time of about 22-35 days estimated from the observed  
 433 deposition fluxes and air concentrations at 30°N - 75°N (Bleichrodt, 1978). The averaged tropospheric residence  
 434 time of <sup>10</sup>Be is about 24 days, which is consistent with the 20 days suggested by Heikkilä et al. (2008b).

435

436 **Table 1.** Global budgets of <sup>7</sup>Be and <sup>10</sup>Be averaged over the period 2008-2018 in GEOS-Chem using P16spa.

437

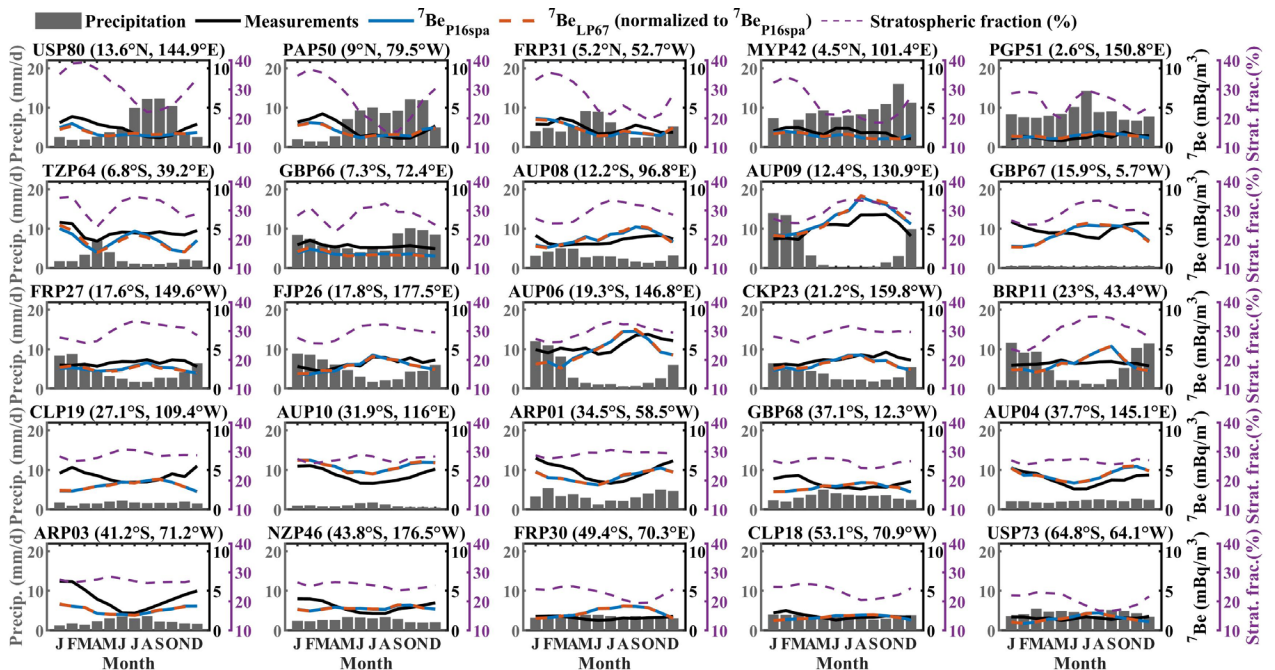

### 438 3.6 Seasonality in <sup>7</sup>Be and <sup>10</sup>Be

439 The seasonality of <sup>7</sup>Be is influenced by a) the amount of precipitation; b) the stratosphere-troposphere exchange  
 440 processes; and c) the vertical transport of <sup>7</sup>Be in the troposphere. The roles of these factors may vary depending  
 441 on location. We compare the seasonal variations of modeled <sup>7</sup>Be<sub>P16spa</sub> and <sup>7</sup>Be<sub>LP67</sub> concentrations with  
 442 measurements from a dataset compiled by Terzi and Kalinowski (2017) with the data covering more than 6 years  
 443 (Fig. 7). It should be noted that the model <sup>7</sup>Be results and MERRA-2 precipitation rates are averaged over the  
 444 years of 2008-2018 while the measurements are based on the data availability over the period 2001-2015.

445

446 **Figure 7.** Seasonal cycle of simulated and measured surface air  $^7\text{Be}$  concentrations, MERRA-2 total precipitation ( $4^\circ \times 5^\circ$  bar  
 447 graph), and modeled stratospheric contributions to surface air. The plots are arranged based on the site latitudes. The model  
 448 results using the LP67 production rate are normalized to the ones using the P16spa production rate.

449

450 **Figure 7.** (continued)

451 In the Southern Hemisphere from  $25^\circ\text{S}$ - $40^\circ\text{S}$ , the  $^7\text{Be}$  concentration peak is observed in austral summer  
 452 (December-February), resulting from the combined influence of stratospheric intrusions and strong vertical  
 453 transport during this season (Villarreal et al., 2022; Zheng et al., 2021a; Koch et al., 1996). The summer peak is  
 454 also observed at northern mid-latitudes. This “summer peak” feature is well simulated by the model at some sites  
 455 (e.g., KWP40 ( $29.3^\circ\text{N}$ ,  $47.9^\circ\text{E}$ ), AUP04 ( $37.7^\circ\text{S}$ ,  $145.1^\circ\text{E}$ ) and AUP10 ( $31.9^\circ\text{S}$ ,  $116^\circ\text{E}$ ) shown in Fig. 7) but not

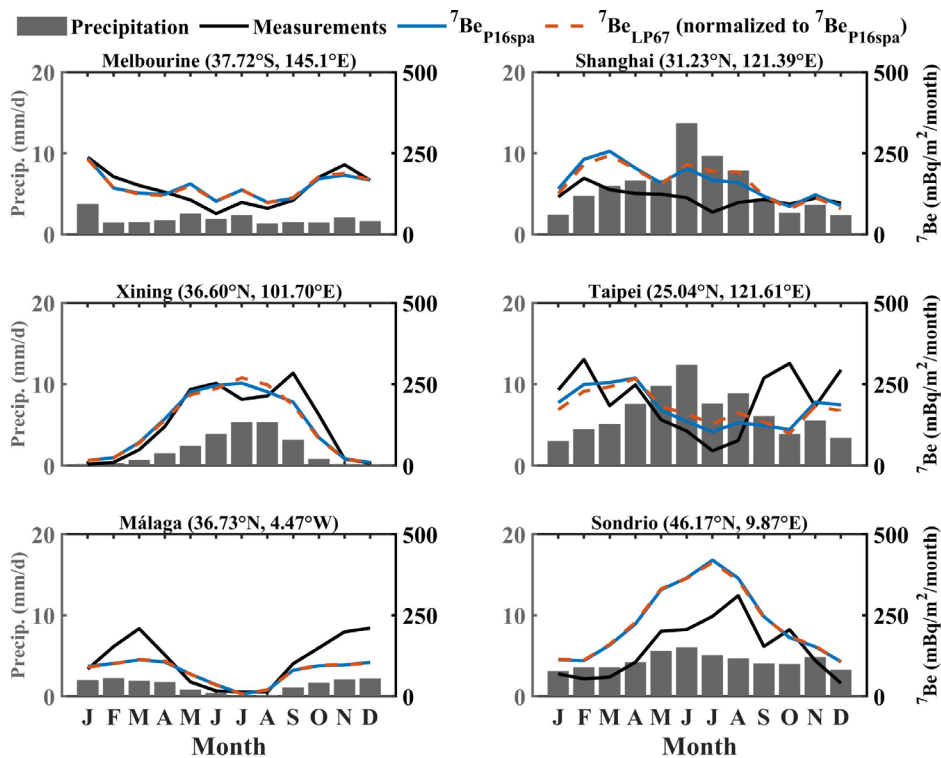

456 at others (e.g., GBP68 (37.1°S, 12.3°W) and PTP53 (37.7°N, 25.7°W) in Fig. 7). This may not be related to  
 457 stratospheric intrusion in the model as the simulated stratospheric contributions (Fig. S4) agree fairly well with  
 458 estimates inferred from measurements, i.e., ~25% on annual average at northern mid-latitude surface (Dutkiewicz  
 459 and Husain, 1985; Liu et al., 2016). Hence this could be due to the errors in vertical transport (e.g., convection)  
 460 during the summer season.

461 The sites at northern high-latitudes (>50°N) show spring peaks that are well simulated by the model (e.g.,  
 462 ISP3 (64.1°N, 21.9°W)). This spring peak coincides with high stratospheric contributions, reflecting the influence  
 463 of stratospheric intrusions. The influence of precipitation changes is also seen at several sites, especially in  
 464 locations with high precipitation rates (e.g., monsoon regions). For example, two sites from Japan (JPP38 (36.3°N,  
 465 139.1°E) and JPP37 (26.5°N, 127.9°E) in Fig. 7) show summer minima coinciding with the high precipitation,  
 466 even with relatively high stratospheric contributions in the same month.

467 The seasonal variation of stratospheric contribution is quite similar for the sites located in the Northern  
 468 Hemisphere, with a high contribution in spring and a low contribution in fall. This is consistent with the estimates  
 469 based on air samples that indicate stratospheric contributions varying from ~40% in spring to ~15% in fall at  
 470 latitudes 38°N-51°N (Dutkiewicz and Husain, 1985).

471 Generally, the model simulates well the annual cycle of surface air <sup>7</sup>Be concentrations for most sites in terms  
 472 of amplitude and seasonality (Fig.7). For a few sites (e.g., DEP33 (47.9°N, 7.9°E)), the model captures the  
 473 observed seasonality but not the correct absolute values. This could be partly due to the coarse resolution of the  
 474 model. The <sup>7</sup>Be<sub>LP67</sub> is normalized to <sup>7</sup>Be<sub>P16spa</sub> as we focus on the comparison of seasonal variability between these  
 475 simulations. The very similar features (differences within 1%) between all simulations using different production  
 476 rates indicate a dominant influence of the meteorological conditions on the seasonal variations of the air <sup>7</sup>Be  
 477 concentrations.

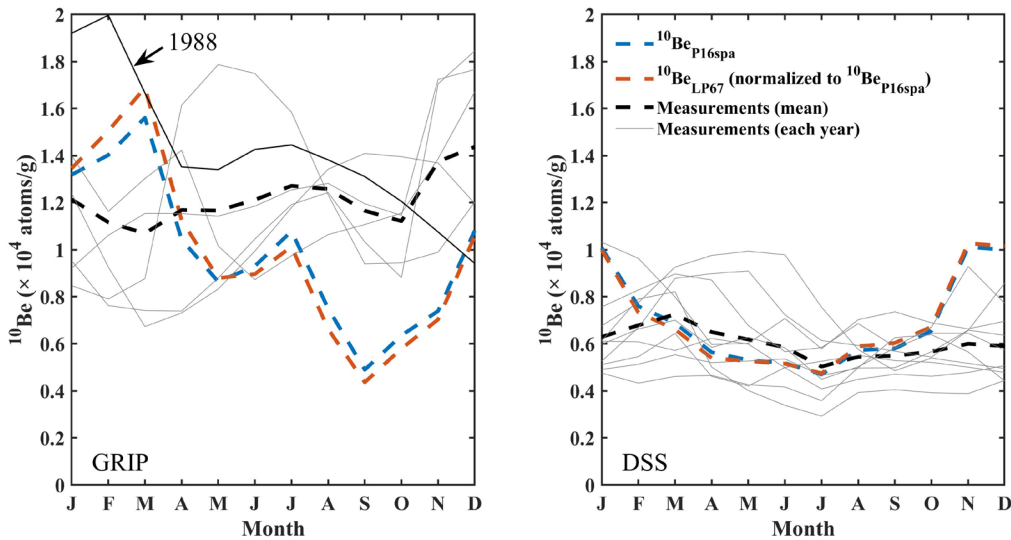

478

479 **Figure 8.** Seasonal cycle of simulated (color lines) and measured (black line)  $^7\text{Be}$  deposition fluxes together with MERRA-2  
 480 total precipitation ( $4^\circ \times 5^\circ$ , bar graph). The model results using the LP67 production rate are normalized to the ones using the  
 481 P16spa production rate.

482 Figure 8 compares model results with the seasonal  $^7\text{Be}$  deposition flux observations over the overlapping  
 483 periods. Usually, high precipitation leads to high  $^7\text{Be}$  deposition fluxes (e.g., Du et al., 2015). Interestingly, low  
 484 deposition fluxes are observed during the summer season in Taipei (Lee et al., 2015; Huh et al., 2006) coinciding  
 485 with high precipitation. This feature is well-captured in the model. Taipei has a typhoon season in summer when  
 486 strong precipitation can occur in a very short period. The atmospheric  $^7\text{Be}$  could be removed quickly at the early  
 487 stage of the precipitation event while at the later stage there is little  $^7\text{Be}$  left in the air that can be removed  
 488 (Ioannidou and Papastefanou, 2006).

489 To examine the ability of model to simulate  $^{10}\text{Be}$  in polar regions, we compare model results with two sub-  
 490 annual ice cores records (Fig. 9): the GRIP record from Greenland (1986-1990) (Heikkilä et al., 2008c) and the  
 491 DSS record from Antarctica (2000-2009) (Pedro et al., 2011a). It should be noted that the direct measurements  
 492 from ice cores are concentrations in the ice (atoms/g). To calculate deposition fluxes, the ice concentrations are  
 493 multiplied with ice accumulation rates. However, for sub-annual accumulations, this bears large uncertainties.  
 494 Therefore, we calculate the modeled  $^{10}\text{Be}$  concentrations for the selected sites using the model deposition fluxes  
 495 at the selected sites timed by ice density and then divided by the corresponding model precipitation rates.

496 **Figure 9.** Seasonal cycle of simulated  $^{10}\text{Be}$  deposition fluxes (2008-2018) and measured  $^{10}\text{Be}$  deposition fluxes in GRIP (1986-  
 497 1990) and DSS (2000-2009) ice cores. The solid lines (grey) refer to seasonal variations of the measurements for each year.  
 498 The black solid line indicates seasonal data of measurements in the year 1988. The dashed lines indicate the averaged seasonal  
 499 variations of measured  $^{10}\text{Be}$  (black),  $^{10}\text{Be}_{\text{P16spa}}$  (blue), and  $^{10}\text{Be}_{\text{LP67}}$  (red) concentrations.  
 500

501 Firstly, there is no consistent seasonal cycle in the GRIP  $^{10}\text{Be}$  measurement, indicating a strong role of local  
 502 meteorology. The model does not reproduce the mean seasonal cycle partly because the model was not run for the  
 503 exact same period. However, we note that the measurements for the year 1988 show an annual cycle similar to  
 504 that in the model, suggesting that the model  $^{10}\text{Be}$  seasonality falls within the range of the observations. For the  
 505 DSS site, the model simulates the austral winter minima but not the austral fall maxima (February-April). These  
 506 model biases could be due to the limited model resolution and local effects (e.g., ice redistribution due to wind  
 507 blow) that are not resolved by the model. Such discrepancies were also reported by previous model studies using  
 508 the ECHAM5-HAM general circulation model ( $2.8^\circ \times 2.8^\circ$ ) over the overlap period (Heikkilä et al., 2008c; Pedro

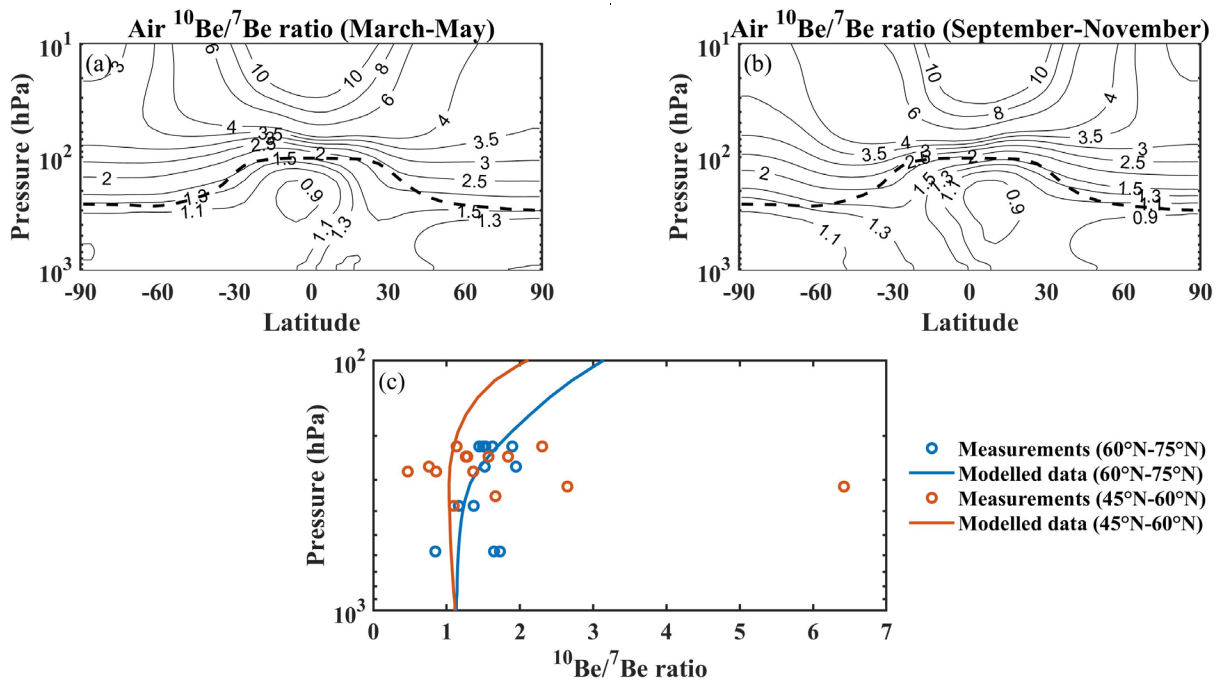

509 et al., 2011b). Global model simulations at higher resolutions or using a regional model could help improve the  
 510 agreements between model results and measurements at Greenland and Antarctica. However, it should be kept in  
 511 mind that local surface processes can cause a high degree of spatial variability in the impurity concentrations in  
 512 ice cores even on short distances (Gfeller et al., 2014), which cannot be resolved in climate models.

513

### 514 3.7 $^{10}\text{Be}/^7\text{Be}$ ratio

515 Figure 10 shows the modeled zonal mean  $^{10}\text{Be}/^7\text{Be}$  ratios during boreal spring (March-May) and austral  
 516 spring (September-November), respectively, when the stratosphere-troposphere exchange is strong in either of  
 517 the two hemispheres. Also shown are the comparison of the altitudinal profile of the  $^{10}\text{Be}/^7\text{Be}$  ratio with  
 518 measurements from three aircraft missions (Jordan et al., 2003). The model  $^{10}\text{Be}/^7\text{Be}$  ratio generally lies within  
 519 the ranges of measurements. Due to the decay of the  $^7\text{Be}$  and long residence time in the stratosphere, the  $^{10}\text{Be}/^7\text{Be}$   
 520 ratio is higher ( $>1.5$ ) in the stratosphere and increase over the altitude, with a maximum ( $>10$ ) in the tropical  
 521 stratosphere. During the period without strong stratospheric intrusion (e.g., autumn season in Northern  
 522 Hemisphere, Fig.10b), the monthly  $^{10}\text{Be}/^7\text{Be}$  ratio near the surface is around 0.9~1. This surface  $^{10}\text{Be}/^7\text{Be}$  ratio  
 523 could be up to 1.4 when the strong stratosphere-troposphere exchange happens (e.g., spring season in Northern  
 524 Hemisphere, Fig. 10a).

525

526

527 **Figure 10.** Upper panels: simulated  $^{10}\text{Be}/^7\text{Be}$  ratio in spring (March-May) (a) and autumn (September-November) (b) averaged  
 528 over the years 2008-2018. Lower panel (c): comparison between the annual averaged model  $^{10}\text{Be}/^7\text{Be}$  ratios (lines) and those  
 529 from measurements (circles; Jordan et al., 2003). The comparison is shown for the latitude bands of 60°N-75°N and 45°N-  
 530 60°N, respectively.

531 Figure 11 compares model surface air  $^7\text{Be}$  and  $^{10}\text{Be}$  concentrations and  $^{10}\text{Be}/^7\text{Be}$  ratios with monthly mean  
 532 observations in Tokyo (Yamagata et al., 2019) during the period of 2008-2014. Here we mainly focus on the  
 533 relative variations, and  $^7\text{Be}$  and  $^{10}\text{Be}$  data are normalized. The model captures the observed variability in Tokyo  
 534 well. The  $^7\text{Be}$  and  $^{10}\text{Be}$  show a peak in early spring (March-May) while the  $^{10}\text{Be}/^7\text{Be}$  ratio shows a wider peak

535 over March-July. The summer minima of  $^7\text{Be}$  and  $^{10}\text{Be}$  are due to strong scavenging associated with the  
 536 monsoon/typhoon season precipitation. While the  $^{10}\text{Be}/^7\text{Be}$  ratio is independent of precipitation scavenging, the  
 537 peaks of  $^{10}\text{Be}/^7\text{Be}$  coincide well with the enhancements of stratospheric contribution in the model. This indicates  
 538 that the  $^{10}\text{Be}/^7\text{Be}$  ratio is a better indicator of the vertical transport and stratospheric intrusion influences than  
 539 either tracer alone.

540  
 541 **Figure 11.** Comparison of monthly mean  $^7\text{Be}$  (top panel),  $^{10}\text{Be}$  (middle panel) concentrations, and  $^{10}\text{Be}/^7\text{Be}$  ratio (bottom  
 542 panel) between model results and measurements for the Tokyo station over the period 2008-2014. Noted that all  $^7\text{Be}$  and  $^{10}\text{Be}$   
 543 values are normalized to focus on variability. The dashed black line bridges the gap in each record.

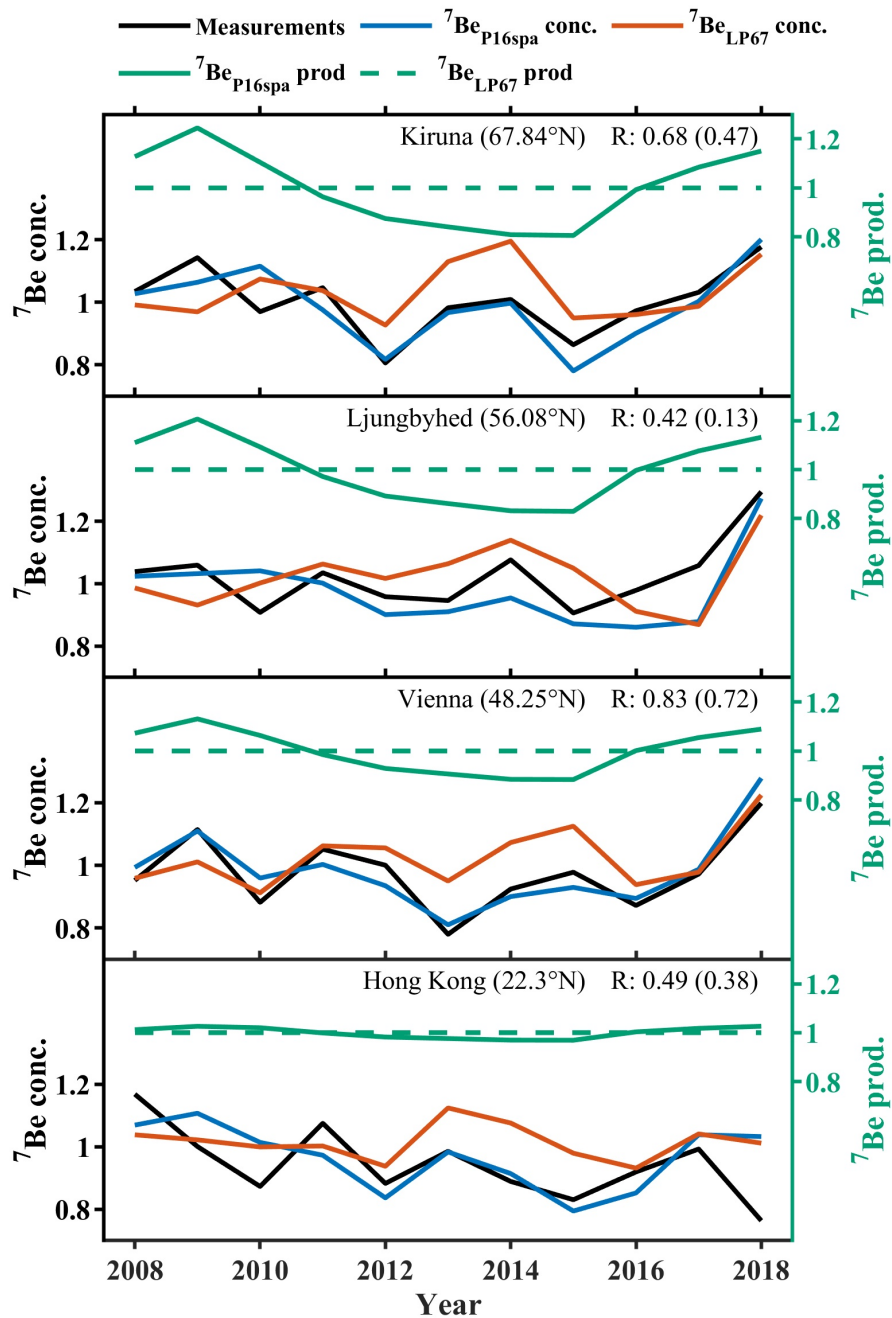

### 544 3.8 Solar modulation influences

545 Here we examine the ability of model to simulate the inter-annual variability of  $^7\text{Be}$  surface air concentrations,  
 546 especially whether the model can simulate the solar modulation influence using the updated production model.  
 547 Figure 12 shows the comparison of model simulated annual mean surface air  $^7\text{Be}$  concentrations with  
 548 measurements during 2008-2018 from four sites: Kiruna, Ljungbyhed, Vienna and Hong Kong (Kong et al., 2022;  
 549 Zheng et al., 2021a). The tropospheric  $^7\text{Be}$  production rate from each site is also plotted for comparison as  
 550 measured annual mean surface air  $^7\text{Be}$  concentrations are predominantly influenced by the local tropospheric  $^7\text{Be}$   
 551 production signal (Zheng et al., 2021a).

552 The model  $^7\text{Be}_{\text{P16spa}}$  surface air concentrations show a better agreement with annual  $^7\text{Be}$  measurements  
 553 (higher R-value) compared to  $^7\text{Be}_{\text{LP67}}$  concentrations at all surface sites (Fig. 12). The variability in the  
 554 measurements (Kiruna, Ljungbyhed, and Vienna) agrees well with the trend in production, suggesting a dominant  
 555 influence of solar modulation during this period. This is further supported by strong deviations between  $^7\text{Be}_{\text{P16spa}}$   
 556 and  $^7\text{Be}_{\text{LP67}}$  as no solar influence is considered in  $^7\text{Be}_{\text{LP67}}$ . This also emphasizes the importance of including solar  
 557 modulation of the  $^7\text{Be}$  and  $^{10}\text{Be}$  production in modeling studies, especially for high-latitude regions. The mismatch  
 558 of measurements and production at Kiruna from 2012 to 2015, together with the similar year-to-year variability

559 between  ${}^7\text{Be}_{\text{P16spa}}$  and  ${}^7\text{Be}_{\text{LP67}}$ , suggests the meteorological influence is dominant at Kiruna for this period. This  
 560 also suggests that meteorological influences can suppress the solar signal in the  ${}^7\text{Be}$  and  ${}^{10}\text{Be}$  observations.

561  
 562 **Figure 12.** Comparison of annual mean model surface air  ${}^7\text{Be}$  concentrations with measurements from 2008–2018. Also shown  
 563 are the model tropospheric  ${}^7\text{Be}$  production (purple lines) at each station. All data are normalized by being divided by the mean  
 564 over the first five years. The linear spearman correlation coefficient R-value is between  ${}^7\text{Be}_{\text{P16spa}}$  and measurements while the  
 565 value in the bracket is between  ${}^7\text{Be}_{\text{LP67}}$  and measurements.

#### 566 4 Summary and conclusions

567 We have incorporated the  ${}^7\text{Be}$  and  ${}^{10}\text{Be}$  production rates derived from the CRAC:Be model considering realistic  
 568 spatial geomagnetic cut-off rigidities (P16spa) into the GEOS-Chem global chemical transport model, enabling  
 569 the model output to be quantitatively comparable with the measurements. In addition to the standard simulation

570 using P16spa production rate, we further conducted two sensitivity simulations: one with the default production  
571 rate in GEOS-Chem based on an empirical approach (LP67), and one with production rate from the CRAC:Be but  
572 considering only geomagnetic cut-off rigidities for a geocentric axial dipole (P16). On global average, the LP67  
573 production rate is 60% higher compared to those of P16 and P16spa. On the other hand, the P16 production rate  
574 shows some regional differences (up to 50%) compared to the P16spa production rate.

575 In comparison with a large amount of air and deposition flux measurements, the model  ${}^7\text{Be}_{\text{P16spa}}$  shows good  
576 agreements with respect to surface air concentrations (93.7% of data within a factor of 2) and reasonably good  
577 agreements regarding deposition fluxes (60.9% of data within a factor of 2). The model simulates well the surface  
578 air concentration peaks in the subtropics associated strong downward transport from the stratosphere. This  
579 agreement is better than those using the default production  ${}^7\text{Be}_{\text{LP67}}$  and the  ${}^7\text{Be}_{\text{P16}}$  production with simplified axis  
580 symmetric dipole cut-off rigidity. The  ${}^7\text{Be}_{\text{LP67}}$  simulation tends to overestimate the absolute value of  ${}^7\text{Be}$  and  ${}^{10}\text{Be}$ .  
581 The  ${}^7\text{Be}_{\text{P16}}$  simulation tends to produce a positive bias ( $\sim 18\%$ ) for the  ${}^7\text{Be}$  deposition fluxes in East Asia region,  
582 nevertheless, no large bias is found for  ${}^7\text{Be}$  surface air concentrations. The surface deposition fluxes are more  
583 sensitive to the production in the mid- and upper-troposphere due to the effect of precipitation scavenging  
584 throughout the troposphere.

585 For the first time, the ability of GEOS-Chem to simulate  ${}^{10}\text{Be}$  is also assessed with measurements. The model  
586  ${}^{10}\text{Be}_{\text{P16spa}}$  results agree well with  ${}^{10}\text{Be}$  observational data that were evaluated for dust influences or from the regions  
587 less influenced by dust (e.g., polar regions), while underestimating most samples that were not corrected for dust  
588 influences. This highlights the importance of examining the dust contribution to  ${}^{10}\text{Be}$  measurements when using  
589 these data to evaluate models.

590 Independent of the production models, surface  ${}^7\text{Be}$  and  ${}^{10}\text{Be}$  concentrations from all three simulations show  
591 similar seasonal variations, suggesting a dominant meteorological influence. The model generally simulates well  
592 the annual cycle of  ${}^7\text{Be}$  surface air concentrations and deposition fluxes at most sites in terms of amplitude and  
593 seasonality. The model fails to capture the “summer peak” in a few sites likely due to errors in convective transport  
594 during summer.

595 The model  ${}^{10}\text{Be}/{}^7\text{Be}$  ratios also lie within the measurements, suggesting the stratosphere-troposphere  
596 exchange process is reasonably represented in the model. The mismatch of the peaks between  ${}^7\text{Be}({}^{10}\text{Be})$  and  
597  ${}^{10}\text{Be}/{}^7\text{Be}$  ratios at the Tokyo site suggests that the  ${}^{10}\text{Be}/{}^7\text{Be}$  ratio is a better indicator of the vertical transport and  
598 stratospheric influences than either tracer alone as the ratio is independent of precipitation scavenging.

599 Finally, we demonstrate the value and importance of including time-varying solar modulation in  ${}^7\text{Be}$  and  
600  ${}^{10}\text{Be}$  production rates for model simulations of both tracers. It significantly improves the agreement of interannual  
601 variations between the model and measurements, especially at those surface sites from mid- and high- latitudes.  
602 The mismatch of trends in modeled  ${}^7\text{Be}$  production rate and observed air concentrations at Kiruna from 2012-  
603 2015 also suggests that the solar signal can be suppressed by meteorological influences.

604 In summary, we have shown that with the state-of-the-art P16spa production rate, the ability of GEOS-Chem  
605 to reproduce the  ${}^7\text{Be}$  and  ${}^{10}\text{Be}$  measurements (including interannual variability of  ${}^7\text{Be}$ ) is significantly improved.  
606 While uncertainties in transport and deposition processes play a major role in the model performance, reduced  
607 uncertainties in the production rates, as demonstrated in this study, allow us to use  ${}^7\text{Be}$  and  ${}^{10}\text{Be}$  tracers as better  
608 tools for evaluating and testing transport and scavenging in global models. We recommend using the P16spa  
609 (versus default LP67) production rate for GEOS-Chem simulations of  ${}^7\text{Be}$  and  ${}^{10}\text{Be}$  in the future.

610

611 *Author contributions.* MZ initiated the study. MZ performed the analysis and interpretation with contributions  
612 from HL and FA. MZ conducted the GEOS-Chem model simulations with the help from MW and ZL. All authors  
613 discussed the results and edited the manuscript.

614

615 *Competing interests.* The authors declare that there is no conflict of interest.

616

617 *Data and Code availability.* Observational data for model validation are available in the references described in  
618 section 2.3. The two compiled  $^{10}\text{Be}$  observation datasets are available in the Supplementary Information. The  
619 GEOS-Chem v14.0.2 model code, GEOS-Chem model output and  $^7\text{Be}$  and  $^{10}\text{Be}$  production rates are available at  
620 Zenodo repository (<https://doi.org/10.5281/zenodo.8372652>; Zheng et al., 2023a).
