## Abstract

Land ecosystems are important sources and sinks of atmospheric components. In turn, air pollutants affect the exchange rates of carbon and water fluxes between ecosystems and atmosphere. However, these biogeochemical processes are usually not well presented in the Earth system models, limiting the explorations of interactions between land ecosystems and air pollutants from the regional to global scales. Here, we develop and validate the interactive Model for Air Pollution and Land Ecosystems (iMAPLE) by upgrading the Yale Interactive terrestrial Biosphere model with process-based water cycles, fire emissions, wetland methane (CH<sub>4</sub>) emissions, and the trait-based ozone (O<sub>3</sub>) damages. Within the iMAPLE, soil moisture and temperature are dynamically calculated based on the water and energy balance in soil layers. Fire emissions are dependent on dryness, lightning, population, and fuel load. Wetland CH<sub>4</sub> is produced but consumed through oxidation, ebullition, diffusion, and plant-mediated transport. The trait-based scheme unifies O<sub>3</sub> sensitivity of different plant functional types (PFTs) with the leaf mass per area. Validations show correlation coefficients (*R*) of 0.59-0.86 for gross primary productivity (GPP) and 0.57-0.84 for evapotranspiration (ET) across the six PFTs at 201 flux tower sites, and yield an average *R* of 0.68 for CH<sub>4</sub> emissions at 44 sites. Simulated soil moisture and temperature match reanalysis data with the high *R* above 0.86 and low normalized mean biases (NMB) within 7%, leading to reasonable simulations of global GPP (*R*=0.92, NMB=1.3%) and ET (*R*=0.93, NMB=-10.4%) against satellite-based observations for 2001-2013. The model predicts an annual global area burned of 507.1 Mha, close to the observations of 475.4 Mha with a spatial *R* of 0.66 for 1997-2016. The wetland CH<sub>4</sub> emissions are estimated to be 153.45 Tg [CH<sub>4</sub>] yr<sup>-1</sup> during 2000-2014, close to the multi-model mean of 148 Tg [CH<sub>4</sub>] yr<sup>-1</sup>. The model also shows reasonable responses of GPP and ET to the changes in diffuse radiation, and yields a mean O<sub>3</sub> damage of 2.9% to global GPP. The iMAPLE model provides an advanced tool for studying the interactions between land ecosystem and air pollutants.

**Keywords:** carbon fluxes, water cycle, fire emissions, methane emissions, ozone damage, diffuse radiation.

57 **1. Introduction**

58 As an important component on the Earth, land ecosystems regulate global carbon and  
59 water cycles. Every year, the terrestrial ecosystem assimilates  $\sim 120$  Pg ( $1 \text{ Pg} = 10^{15} \text{ g}$ )  
60 carbon from atmosphere through vegetation photosynthesis (Beer et al., 2010).  
61 However, most of this carbon uptake returns to atmosphere due to plant and soil  
62 respiration (Sitch et al., 2015), as well as other perturbations such as biomass burning  
63 and biogenic emissions (van der Werf et al., 2010; Carslaw et al., 2010), leading to a net  
64 carbon sink of only  $\sim 2 \text{ Pg C yr}^{-1}$  during 1960-2021 (Friedlingstein et al., 2022).  
65 Meanwhile, land ecosystems affect atmospheric moisture and soil wetness through both  
66 physical (e.g., evaporation and runoff) and physiological (e.g., leaf transpiration and  
67 root hydrological uptake) processes. Observations show that transpiration accounts for  
68 80%-90% of the terrestrial evapotranspiration (ET) (Jasechko et al., 2013) and makes  
69 significant contributions to land precipitation especially over the tropical forests  
70 (Spracklen et al., 2012).

71

72 Different approaches have been applied to depict the spatiotemporal variations of  
73 ecosystem processes. The eddy covariance technique provides direct measurements of  
74 land carbon and water fluxes (Jung et al., 2011). However, the limited number and  
75 uneven distribution of ground sites results in large uncertainties in the upscaling of site-  
76 level fluxes to the global scale (Jung et al., 2020b). Satellite retrieval provides a unique  
77 tool for the continuous representations of land fluxes in both space and time (Worden  
78 et al., 2021). However, most of the ecosystem variables (e.g., gross primary productivity,  
79 GPP) can only be derived using available signals from remote sensing through  
80 empirical relationships (Madani et al., 2017). As a comparison, process-based models  
81 build physical parameterizations based on field and/or laboratory experiments and  
82 validate against the available *in situ* and satellite-based observations (Niu et al.,  
83 2011; Castillo et al., 2012). These models can be further applied at different spatial (from  
84 site to global) and temporal (from days to centuries) scales to identify the main drivers  
85 of the changes in carbon and water fluxes (Sitch et al., 2015). For example, a total of

86 17 vegetation models were validated and combined to predict the land carbon fluxes in  
87 the past century (Friedlingstein et al., 2022); the ensemble mean of these models  
88 revealed a steadily increasing land carbon sink from 1960 with the dominant  
89 contribution by CO<sub>2</sub> fertilization.

90  
91 While many studies quantified the ecosystem responses to the effects of CO<sub>2</sub>, climate,  
92 and human activities (Piao et al., 2009;Sitch et al., 2015), few have explored the  
93 interactions between air pollution and land ecosystems. Such biogeochemical processes  
94 become increasingly important in the Anthropocene period with significant changes in  
95 atmospheric compositions. For example, observations found that nitrogen and  
96 phosphorus constrain the CO<sub>2</sub> fertilization efficiency of global vegetation (Terrer et al.,  
97 2019), but such limiting effect is ignored or underestimated in most of the current  
98 models (Wang et al., 2020). Tropospheric ozone (O<sub>3</sub>) damages plant photosynthesis and  
99 stomatal conductance, inhibiting carbon assimilation and the ET from the land surface  
100 (Sitch et al., 2007;Lombardozzi et al., 2015). Atmospheric aerosols can enhance  
101 photosynthesis through diffuse fertilization effects (Mercado et al., 2009) but  
102 meanwhile decrease photosynthesis by reducing precipitation (Yue et al., 2017). In turn,  
103 ecosystems act as both the sources and sinks of atmospheric components. Biomass  
104 burning emits a large amount of carbon dioxide, trace gases, and particulate matter,  
105 further influencing air quality (Chen et al., 2021), ecosystem functions (Yue and Unger,  
106 2018), and global climate (Tian et al., 2022). Biogenic volatile organic compounds  
107 (BVOCs) are important precursors for both surface O<sub>3</sub> and secondary organic aerosols  
108 (Wu et al., 2020), which can feed back to affect biogenic emissions (Yuan et al., 2016)  
109 and carbon assimilation (Rap et al., 2018). Wetland methane (CH<sub>4</sub>) emissions account  
110 for the dominant fraction of natural sources of CH<sub>4</sub>, and are projected to increase under  
111 the global warming scenarios (Rosentreter et al., 2021;Zhang et al., 2017). On the other  
112 hand, stomatal uptake dominates the dry deposition of air pollutants over the vegetated  
113 land (Lin et al., 2020). Meanwhile, ET from forest results in the increase of water vapor  
114 in atmosphere (Spracklen et al., 2012), affecting the consequent rainfall and wet

115 deposition of particles.

116

117 Currently, numerical models are in general developed separately for atmospheric  
118 chemistry and ecosystem processes. The chemical transport models are usually driven  
119 with prescribed emissions of biomass burning (Warneke et al., 2023) and wetland  
120 methane (Heimann et al., 2020), while the ecosystem models often ignore the  
121 biogeochemical impacts of O<sub>3</sub> and aerosols (Friedlingstein et al., 2022). In an earlier  
122 study, we developed and validated the Yale Interactive terrestrial Biosphere (YIBs)  
123 model version 1.0 with the special focus on the interactions between atmospheric  
124 chemistry and land ecosystems (Yue and Unger, 2015). Thereafter, the YIBs model has  
125 been used offline to assess the O<sub>3</sub> vegetation damage (Yue et al., 2016), aerosol diffuse  
126 fertilization (Yue and Unger, 2017), BVOC emissions (Cao et al., 2021a), as well as  
127 coupled to other models to investigate the carbon-chemistry-climate interactions (Lei  
128 et al., 2020;Gong et al., 2021). The YIBs model has joined the multi-model  
129 intercomparison project of TRENDY since the year 2020 and showed reasonable  
130 performance in the simulation of carbon fluxes (Friedlingstein et al., 2020). However,  
131 the YIBs model failed to predict the typical hydrological variables such as ET and  
132 runoff due to the missing of carbon-water coupling modules. Furthermore, the model  
133 did not consider the nutrient limitation on plant photosynthesis and ignored some key  
134 exchange fluxes between land and atmosphere.

135

136 In this study, we develop the interactive Model for Air Pollution and Land Ecosystems  
137 (iMAPLE) by coupling the process-based water cycle module from Noah-MP (Niu et  
138 al., 2011) to the carbon cycle in the YIBs (Figure 1). In addition, we update the original  
139 YIBs model with some major advances in the biogeochemical processes including  
140 dynamic fire emissions, wetland CH<sub>4</sub> emissions, nutrient limitations on photosynthesis,  
141 and the trait-based O<sub>3</sub> vegetation damage. The detailed descriptions of these updates  
142 are presented in the next section. The iMAPLE model is fully validated against  
143 available measurements in Section 3. The last section will summarize the model

144 performance and rethink the prospective directions for future development.

145

## 146 **2. Models and data**

### 147 **2.1 Main features of YIBs model**

148 The YIBs model is a process-based vegetation model predicting land carbon fluxes with  
149 dynamic changes in tree height, leaf area index, and carbon pools (Yue and Unger, 2015,  
150 thereafter YU2015). A total of nine plant functional types (PFTs) are considered  
151 including evergreen broadleaf forest (EBF), evergreen needleleaf forest (ENF),  
152 deciduous broadleaf forest (DBF), tundra, shrubland, C<sub>3</sub>/C<sub>4</sub> grassland, and C<sub>3</sub>/C<sub>4</sub>  
153 cropland. At each gridbox, a mixture of PFTs with each PFT fraction is used as model  
154 input, sharing the temperature or moisture information from the same soil column. Leaf  
155 photosynthesis is calculated using the well-established Michaelis-Menten enzyme-  
156 kinetics scheme (Farquhar et al., 1980) and is coupled to stomatal conductance with the  
157 modulations of air humidity and CO<sub>2</sub> concentrations (Ball et al., 1987). The model  
158 applies a two-leaf approach to distinguish the irradiating states for sunlit and shading  
159 leaves and adopts an adaptive stratification for the radiative transfer processes within  
160 canopy layers (Spitters, 1986). The gross carbon assimilation is further regulated by the  
161 optimized plant phenology, which is mainly dependent on temperature and light for  
162 deciduous trees (Yue et al., 2015) but temperature and/or moisture for shrubland and  
163 grassland (YU2015). The assimilated carbon is allocated among leaf, stem, and root to  
164 support autotrophic respiration and development, the latter of which is used to update  
165 plant height and leaf area (Cox, 2001). The input of litterfall triggers the carbon  
166 transition among 12 soil carbon pools and determines the magnitude of heterotrophic  
167 respiration with the joint effects of soil temperature, moisture, and texture (Schaefer et  
168 al., 2008). The net carbon uptake is then calculated by subtracting ecosystem respiration  
169 (plant and soil) and environmental perturbations (reforestation or deforestation) from  
170 the gross carbon assimilation (Yue et al., 2021). The YIBs model reasonably reproduces  
171 the observed spatiotemporal patterns of global carbon fluxes and makes contributions  
172 to the Global Carbon Project with the long-term simulations of land carbon sink in the

173 past century (Friedlingstein et al., 2020). The model specifically considers air pollution  
 174 impacts on land ecosystems (Figure 1), such as the ozone vegetation damage (Yue and  
 175 Unger, 2014) and aerosol diffuse fertilization effect (Yue and Unger, 2017). The YIBs  
 176 implements two different schemes for BVOCs emissions (Figure 1), including the  
 177 Model of Emissions of Gases and Aerosols from Nature (MEGAN, Guenther et al.,  
 178 2012) and the photosynthesis-dependent (PS\_BVOC) scheme (Unger et al., 2013).

179

## 180 **2.2 New processes in the iMAPLE model**

### 181 2.2.1 Process-based water cycles

182 The descriptions and units of all parameters used in this study are shown in Table S1.  
 183 We implement the hydrological module from Noah-MP into the iMAPLE model (Niu  
 184 et al., 2011). The water budget closure is achieved by constructing water-balance  
 185 equations among precipitation ( $P$ ,  $\text{Kg m}^{-2} \text{s}^{-1}$ ), evapotranspiration ( $ET$ ,  $\text{Kg m}^{-2} \text{s}^{-1}$ ),  
 186 runoff, and terrestrial water storage change ( $\Delta TWS$ ) on each grid cell as follows:

$$187 \quad P = ET + runoff + \Delta TWS \quad (1)$$

188 Here, hourly  $P$  from MERRA-2 reanalyses is used as the input.

189

190 We then divide  $ET$  into three portions including plant transpiration ( $TRA$ ), canopy  
 191 evaporation ( $ECAN$ ) and ground evaporation ( $EGRO$ ):

$$192 \quad ET = TRA + ECAN + EGRO \quad (2)$$

193 For vegetated grids,  $TRA$  is calculated as follows:

$$194 \quad TRA = \frac{\rho_{air} \cdot CP_{air} \cdot C_{tra} \cdot (e_{sat} - e_{ca})}{PC} \quad (3)$$

195 where  $\rho_{air}$  is air density,  $CP_{air}$  is heat capacity of dry air, and  $PC$  is the psychrometric  
 196 constant.  $e_{sat}$  is the saturated vapor pressure at the leaf temperature,  $e_{ca}$  is the vapor  
 197 pressure of the canopy air and  $C_{tra}$  is leaf transpiration conductance, which is  
 198 calculated based on the Ball-Berry scheme of stomatal resistance (Yue and Unger,  
 199 2015). Meanwhile,  $ECAN$  is calculated as follows:

$$200 \quad ECAN = \frac{\rho_{air} \cdot CP_{air} \cdot C_{canopy, evap} \cdot (e_{sat} - e_{ca})}{PC} \quad (4)$$

201 
$$C_{canopy,evap} = \frac{f_{wet} \cdot E_{VAI}}{R_{leaf,bdy}} \quad (5)$$

202 Here,  $C_{canopy,evap}$  is the latent heat conductance from the wet leaf surface to canopy  
 203 air.  $f_{wet}$  is the wet fraction of canopy, which is a fraction of the maximum canopy  
 204 precipitation interception capacity.  $E_{VAI}$  is the effective vegetation area index and  
 205  $R_{leaf,bdy}$  is the bulk leaf boundary resistance.  $EGRO$  is calculated as follows:

206 
$$EGRO = C_{ground,evap}(e_{sat,ground}RH - e_{ca}) \quad (6)$$

207 Here,  $C_{ground,evap}$  is the coefficient for latent heat at the ground,  $e_{sat,ground}$  is the  
 208 saturated vapor pressure at the ground and  $RH$  is the surface relative humidity.

209

210 Runoff includes surface ( $R_{srf}$ ) and subsurface ( $R_{sub}$ ) components:

211 
$$runoff = R_{srf} + R_{sub} \quad (7)$$

212 The surface runoff is calculated as follows:

213 
$$R_{srf} = Q_{soil,srf} - Q_{soil,in} \quad (8)$$

214 where  $Q_{soil,srf}$  is the incident water in the soil surface and is the sum of the  
 215 precipitation, snowmelt and dewfall.  $Q_{soil,in}$  is the infiltration into the soil, which is  
 216 derived from approximate solutions of Richards equations with considerations of the  
 217 spatial variations in precipitation and infiltration capacity. Here, we assume exponential  
 218 distributions of infiltration capacity in each grid cell following the approach by Schaake  
 219 et al. (1996):

220 
$$Q_{soil,in} = Q_{soil,srf} \frac{I_c}{Q_{soil,srf}\Delta t + I_c} \quad (9)$$

221 
$$I_c = W_d[1 - \exp(-K_{\Delta t}\Delta t)] \quad (10)$$

222 Here,  $I_c$  and  $W_d$  are the soil infiltration capacity of the model grid cell and the water  
 223 deficit of the soil column, respectively.  $K_{\Delta t}$  and  $\Delta t$  are the calibratable parameters and  
 224 model time step. We assume free drainage processes in the soil column bottom, thus the  
 225  $R_{sub}$  is calculated as follows:

226 
$$R_{sub} = \alpha_{slope} \cdot K_4 \quad (11)$$

227 where  $\alpha_{slope} = 0.1$  is the terrain slope index.  $K_4$  is the hydraulic conductivity in the  
 228 bottom soil layer parameterized following the scheme in Clapp and Hornberger (1978)  
 229 and is calculated using spatial soil profiles from Hengl et al. (2017).

230

231 Terrestrial water storage ( $TWS$ ) is the sum of groundwater storage ( $W_{gw}$ ), soil water  
232 content ( $W_{soil}$ ) and snow water equivalent ( $W_{snow}$ ):

$$233 \quad TWS = W_{gw} + W_{snow} + \sum_{i=1}^{N_{soil}} W_{soil} \quad (12)$$

234 Here, the soil module includes four layers ( $N_{soil} = 4$ ) and  $W_{soil}$  is calculated by the  
235 volumetric water content ( $W_i$ ) as follows:

$$236 \quad W_{soil} = \rho_{wat} \cdot W_i \cdot \Delta Z_i \quad \text{for } i = 1, 2, 3, 4 \quad (13)$$

237 where water density ( $\rho_{wat}$ ) = 1000 kg m<sup>-3</sup>, and  $\Delta Z_i = 0.1, 0.3, 0.6$  and 1m, respectively.

238 Hourly  $W_i$  depends on variations of soil water diffusion ( $D$ ) and hydraulic conductivity  
239 ( $K$ ) as follows:

$$240 \quad \frac{\partial W}{\partial t} = \frac{\partial}{\partial z} \left( D \frac{\partial W}{\partial z} \right) + \frac{\partial K}{\partial z} \quad (14)$$

241 Here,  $K$  and  $D$  are calculated following the parameterizations of Clapp-Hornberger  
242 curves (Clapp and Hornberger, 1978):

$$243 \quad \frac{K}{K_{sat}} = \left( \frac{W}{W_{sat}} \right)^{2b+3} \quad (15)$$

$$244 \quad D = K \cdot \frac{\partial \varphi}{\partial W} \quad (16)$$

$$245 \quad \frac{\varphi}{\varphi_{sat}} = \left( \frac{W}{W_{sat}} \right)^{-b} \quad (17)$$

246 where  $\varphi_{sat}$ ,  $W_{sat}$  and  $K_{sat}$  are saturated soil capillary potential, volumetric water  
247 content and hydraulic conductivity. Exponent  $b$  is an empirical constant depending  
248 on soil types. Soil moisture is calculated as the ratio of  $W_s$  to  $W_{sat}$ .

249

250 Soil temperature ( $T_s$ ) is calculated through physical processes as follows:

$$251 \quad \frac{\partial T_s}{\partial t} = \frac{1}{c} \frac{\partial}{\partial z} \left( K_T \frac{\partial T_s}{\partial z} \right) \quad (18)$$

252 Here  $K_T$  is soil specific heat capacity:

$$253 \quad K_T = K_e \cdot (K_s - K_{dry}) + K_{dry} \quad (19)$$

254 where  $K_e$ ,  $K_s$  and  $K_{dry}$  are Kersten values as a function of soil wetness, saturated soil  
255 heat conductivity and that under dry air conditions (Niu et al., 2011).  $C$  in Equation (13)

256 is the specific heat

$$257 \quad C = W_{lip} \cdot C_{lip} + W_{ice} \cdot C_{ice} + (1 - W_{sat}) \cdot C_{sat} + (W_{sat} - W) \cdot C_{air} \quad (20)$$

258 Here,  $W_{lip}$ ,  $C_{lip}$  and  $W_{ice}$ ,  $C_{ice}$  indicate water content and heat capacity on soil water  
259 and ice.  $C_{sat}$  and  $C_{air}$  are saturated and air heat capacity, which are empirical constants  
260 (Niu et al., 2011).

261

### 262 2.2.2 Dynamic fire emissions

263 We implement the active global fire parameterizations from Pechony and Shindell  
264 (2009) and Li et al. (2012) to the iMAPLE model. The fire emissions are determined  
265 by several key factors such as fuel flammability, natural ignitions, human activities, and  
266 fire spread. The fire count  $N_{fire}$  depends on flammability ( $Flam$ ), fire ignition (including  
267 both natural ignition rate  $I_N$  and anthropogenic ignition rate  $I_A$  and anthropogenic  
268 suppression ( $F_{NS}$ ):

$$269 \quad N_{fire} = Flam \times (I_N + I_A) \times F_{NS} \quad (21)$$

270  $Flam$  is a unitless metric representing conditions conducive to fire occurrence. It is  
271 parameterized as a function of vapor pressure deficit (VPD), precipitation (Prec), and  
272 leaf area index (LAI):

$$273 \quad Flam = VPD \times e^{-2 \times Prec} \times LAI \quad (22)$$

274  $I_N$  depends on the cloud-to-ground lightning and  $I_A$  can be expressed as:

$$275 \quad I_A = 0.03 \times PD \times k(PD) \quad (23)$$

276 where  $PD$  is population density. The empirical function of  $k(PD) = 6.8 \times PD^{-0.6}$  stands  
277 for ignition potentials by human activity. The fraction of non-suppressed fires  $F_{NS}$  is  
278 derived as:

$$279 \quad F_{NS} = 0.05 + 0.95 \times e^{-0.05 \times PD} \quad (24)$$

280

281 The burned area of a single fire ( $BA_{single}$ ) is typically taken to be elliptical in shape  
282 associated with length-to-breadth ratio ( $LB$ ), head-to-back ratio ( $HB$ ) and rate of fire  
283 spread ( $UP$ ) as follows:

$$284 \quad BA_{single} = \frac{\pi \times UP^2}{4 \times LB} \times \left(1 + \frac{1}{HB}\right)^2 \quad (25)$$

285 Then,  $LB$  and  $HB$  are related to changes of near-surface wind speed ( $U$ ) as follows:

$$286 \quad LB = 1 + 10 \times (1 - e^{-0.06 \times U}) \quad (26)$$

$$287 \quad HB = \frac{LB + (LB^2 - 1)^{0.5}}{LB - (LB^2 - 1)^{0.5}} \quad (27)$$

288 Meanwhile,  $UP$  is computed as the function of relative humidity ( $RH$ ):

$$289 \quad UP = UP_{max} \times f_{RH} \times f_{\theta} \times G(W) \quad (28)$$

290 Here,  $UP_{max}$  is the maximum fire spread rate depending on PFTs,  $f_{RH}$  and  $f_{\theta}$  represent  
 291 the dependence of fire spread on  $RH$  and on root-zone soil moisture, respectively.  $f_{\theta}$  is  
 292 simply set to 0.5 and  $f_{RH}$  is calculated as:

$$293 \quad f_{RH} = \begin{cases} 1, & RH \leq RH_{low} \\ \frac{RH - RH_{low}}{RH_{up} - RH_{low}}, & RH_{low} < RH < RH_{up} \\ 0, & RH \geq RH_{up} \end{cases} \quad (29)$$

294 In this study, we set  $RH_{low} = 30\%$  and  $RH_{up} = 70\%$  as the lower and upper thresholds of  
 295  $RH$  following the methods used in Li et al. (2012). If  $RH$  is higher than 70%, natural  
 296 fires will not occur or spread, and  $RH$  will no longer be a constraint for fire occurrence  
 297 and spread if  $RH \leq 30\%$ .  $G(W)$  is the limit of the fire spread:

$$298 \quad G(W) = \frac{LB}{1 + \frac{1}{HB}} \quad (30)$$

299 In general, the eccentricity of burned area is primarily influenced by near-surface wind  
 300 speed, while the rate of fire spread is jointly regulated by near-surface wind speed and  
 301 relative humidity. The shape of the fire is converted to a circular form when the near-  
 302 surface wind speed reaches zero, and burning ceases to propagate once the relative  
 303 humidity is above a specific threshold. The dependence of  $BA_{single}$  on  $U$  and  $RH$  is  
 304 shown in Figure S1.

305

306 Finally, the burned area ( $BA$ ) is represented as:

$$307 \quad BA = BA_{single} \times N_{fire} \quad (31)$$

308 The fire-emitted trace gases and aerosols ( $Emis$ ) are calculated as:

$$309 \quad Emis = BA \times EF \quad (32)$$

310 where  $EF$  is the emission factors for different species (such as black carbon and organic  
 311 carbon aerosols). It is important to note that the feedbacks from fire activities onto the

312 terrestrial ecosystem have not been considered in the current version of the iMAPLE  
 313 model due to the high complexity.

314

### 315 2.2.3 Wetland methane emissions

316 We implement the process-based wetland CH<sub>4</sub> emissions into the iMAPLE model. The  
 317 anthropogenic sources of CH<sub>4</sub> from Phase 6 of the Coupled Model Intercomparison  
 318 Project (CMIP6, <https://esgf-node.llnl.gov/projects/input4mips/>) are also used as input  
 319 for iMAPLE. For each soil layer, the flux of CH<sub>4</sub> ( $F_{CH_4}$ ) is calculated as the difference  
 320 between production ( $P_{CH_4}$ ) and consumptions, which include oxidation ( $O_{CH_4}$ ),  
 321 ebullition ( $E_{CH_4}$ ), diffusion ( $D_{CH_4}$ ), and plant-mediated transport through aerenchyma  
 322 ( $A_{CH_4}$ ) as follows:

$$323 \quad F_{CH_4} = P_{CH_4} - O_{CH_4} - E_{CH_4} - D_{CH_4} - A_{CH_4} \quad (33)$$

324 The net methane emission to the atmosphere is the sum of ebullition, diffusion and  
 325 aerenchyma transport from the top soil layer.

326

327 The production of CH<sub>4</sub> in soil depends on the quantity of carbon substrate and  
 328 environmental conditions including soil temperature  $T_s$ , pH, and wetland inundation  
 329 fraction  $f_{wetland}$  as follows:

$$330 \quad P_{CH_4} = R_h r f_{T_s} f_{pH} f_{wetland} \quad (34)$$

331 where  $R_h$  is the heterotrophic respiration estimated at the grid cell ( $mol\ C\ m^{-2}\ s^{-1}$ ).  $r$   
 332 represents the release ratio of methane and carbon dioxide (Wania et al., 2010). We  
 333 determine the dependence on  $T_s$  and soil pH in iMAPLE based on the parameterizations  
 334 from the TRIPLEX-GHG model (Zhu et al., 2014). The impact factor of soil  
 335 temperature  $f_{ST}$  can be calculated as follows (Zhang et al., 2002; Zhu et al., 2014):

$$336 \quad f_{ST} = \begin{cases} 0, & T_s < T_{min} \\ vt^{xt} \exp(xt(1-vt)), & T_{min} \leq T_s \leq T_{max} \\ 0, & T_s > T_{max} \end{cases} \quad (35)$$

$$337 \quad vt = (T_{max} - T_s)/(T_{max} - T_{opt}) \quad (36)$$

$$338 \quad xt = [\log(Q_{10})(T_{max} - T_{opt})]^2 (1.0 + at^{0.5})^2 / 400.0 \quad (37)$$

$$339 \quad at = 1.0 + 40.0 / [\log(Q_{10})(T_{max} - T_{opt})] \quad (38)$$

340  $T_{min}$ ,  $T_{max}$ , and  $T_{opt}$  represents the lowest, highest and optimum temperature for the  
 341 process of methane production and oxidation, respectively. In this study, the  $T_{min} =$   
 342  $0^{\circ}\text{C}$ ,  $T_{max} = 45^{\circ}\text{C}$  and  $T_{opt} = 25^{\circ}\text{C}$  (Zhu et al., 2014).

343

344 For the temperature-dependence, the  $Q_{10}$  relationships are applied as follows:

$$345 \quad Q_{10} = r_b Q_b^{\frac{T_s - T_{base}}{10}} \quad (39)$$

346 Here  $r_b$  is set to 3.0 and  $Q_b$  is 1.33 with a base temperature ( $T_{base}$ ) of  $25^{\circ}\text{C}$  (Zhu et al.,  
 347 2014;Paudel et al., 2016). The inundation fraction of wetland at each cell describes the  
 348 proportion of anaerobic conditions (Zhang et al., 2021). We ignore the impact of redox  
 349 potential (Eh) because global observations are not available and the Eh-related  
 350 processes are poorly characterized in current models (Wania et al., 2010).

351

352 The oxidation of  $\text{CH}_4$  is a series of aerobic activities related to temperature and  $\text{CH}_4$   
 353 concentrations:

$$354 \quad O_{\text{CH}_4} = [\text{CH}_4] f_{Ts} f_{\text{CH}_4} \quad (40)$$

355 where  $[\text{CH}_4]$  is the methane amount in each soil layer ( $\text{g cm}^{-2} \text{ layer}^{-1}$ ).  $f_{\text{CH}_4}$  is the  
 356  $\text{CH}_4$  concentration factor representing a Michaelis-Menten kinetic relationship:

$$357 \quad f_{\text{CH}_4} = \frac{[\text{CH}_4]}{[\text{CH}_4] + K_{\text{CH}_4}} \quad (41)$$

358 where  $K_{\text{CH}_4} = 5 \mu\text{mol L}^{-1}$  is the half-saturation coefficient with respect to  $\text{CH}_4$  (Walter  
 359 and Heimann, 2000). For temperature-dependence of oxidation, the  $Q_{10}$  relationship  
 360 with  $r_b = 2.0$ ,  $Q_b = 1.9$ , and  $T_{base} = 12^{\circ}\text{C}$  is adopted (Zhu et al., 2014;Paudel et al., 2016).

361

362 The diffusion of  $\text{CH}_4$  follows the Fick's law with dependence on  $\text{CH}_4$  concentrations  
 363 and the molecular diffusion coefficients of  $\text{CH}_4$  in the air ( $D_a = 0.2 \text{ cm}^2 \text{ s}^{-1}$ ) and water  
 364 ( $D_w = 0.00002 \text{ cm}^2 \text{ s}^{-1}$ ) respectively (Walter and Heimann, 2000). For each soil layer  
 365  $i$ , the diffusion coefficient  $D_i$  can be calculated as follows :

$$366 \quad D_i = D_a \times (R_{sand} \times 0.45 + R_{silt} \times 0.2 + R_{clay} \times 0.14) \times f_{tort} \times S_{poro} \times (1 -$$

$$367 \quad WFPS_i) + D_w \times WFPS_i \quad (42)$$

368 where  $R_{sand}$ ,  $R_{silt}$ ,  $R_{clay}$  is the relative content of sand, silt, and clay in the soil,  $f_{tort} =$   
369 0.66 is tortuosity coefficient,  $S_{poro}$  is soil porosity, and  $WFPS$  represents the pore space  
370 full of water (Zhuang et al., 2004).

371

372 The ebullition of  $CH_4$  occurs when  $CH_4$  concentration is above the threshold of 0.5  
373  $mol\ CH_4\ m^{-3}$  (Walter et al., 2001). Since the process of ebullition occurs in a very short  
374 time, the bubbles will generate at once and all the flux will be released to atmosphere  
375 if the concentration reaches the threshold. The plant-mediated transport of  $CH_4$  through  
376 aerenchyma is dependent on the concentration gradient of  $CH_4$  and plant-related factors  
377 (Zhu et al., 2014). The  $A_{CH_4}$  is determined by the oxidation factor for roots and the  
378 aerenchyma factor for plants. The baseline value of the oxidation factor in roots is 0.5,  
379 with a regulatory range from 0.2 to 1.0 determined by the wetland plant types. The plant  
380 aerenchyma factor is calculated by the ratio of the plant root length density (typical  
381 value:  $2.1\ cm\ mg^{-1}$ ) and the root cross-sectional area (typical value:  $0.0013\ cm^2$ ), along  
382 with a plant root to atmosphere diffusion factor for methane which is modulated by  
383 plant type within a range of 0 to 1 (Zhang et al., 2002).

384

#### 385 2.2.4 The down regulation on photosynthesis

386 We implement the down regulation parameterization from Arora et al. (2009) to indicate  
387 the nutrient limitations on leaf photosynthesis. A down-regulating factor  $\varepsilon$  is calculated  
388 as a function of  $CO_2$  concentrations ( $C$ ) as follows:

$$389 \quad \varepsilon(C) = \frac{1 + \gamma_{gd} \ln(C/C_0)}{1 + \gamma_g \ln(C/C_0)} \quad (43)$$

390 where  $C_0$  is a reference  $CO_2$  concentration set to 288 ppm. The values of  $\gamma_{gd} = 0.42$  and  
391  $\gamma_g = 0.90$  are derived from multiple measurements to constrain the  $CO_2$  fertilization.  
392 Then the down-regulated photosynthesis is calculated by scaling the original value with  
393 the factor of  $\varepsilon$ .

394

#### 395 2.2.5 Trait-based $O_3$ vegetation damaging scheme

396 The YIBs model considers  $O_3$  vegetation damage using the flux-based scheme proposed

397 by Sitch et al. (2007) (thereafter S2007), which determines the damaging ratio  $F$  of  
 398 plant photosynthesis as follows:

$$399 \quad F = a_{PFT} \times \max\{f_{O_3} - t_{PFT}, 0\} \quad (44)$$

400 Here, the  $f_{O_3}$  denotes O<sub>3</sub> stomatal flux (nmol m<sup>-2</sup> s<sup>-1</sup>) defined as:

$$401 \quad f_{O_3} = \frac{[O_3]}{r + \left[ \frac{k_{O_3}}{g_p \times (1-F)} \right]} \quad (45)$$

402 where  $[O_3]$  represents the O<sub>3</sub> concentrations at the reference level (nmol m<sup>-3</sup>).  $r$  is the  
 403 sum of boundary and aerodynamic resistance between leaf surface and reference level  
 404 (s m<sup>-1</sup>).  $g_p$  is the potential stomatal conductance for H<sub>2</sub>O (m s<sup>-1</sup>).  $k_{O_3} = 1.67$  is a  
 405 conversion factor of leaf resistance for O<sub>3</sub> to that for water vapor. The level of O<sub>3</sub>  
 406 damage is then determined by the PFT-specific sensitivity  $a_{PFT}$  and threshold  $t_{PFT}$ ,  
 407 which are different among PFTs.

408

409 In iMAPLE, we implement the trait-based O<sub>3</sub> vegetation damaging scheme to unify the  
 410 inter-PFT sensitivities (Ma et al., 2023):

$$411 \quad a_{PFT} = \frac{a}{LMA} \quad (46)$$

412 Here, a unified plant sensitivity  $a$  (nmol<sup>-1</sup> g s) is scaled by leaf mass per area (LMA, g  
 413 m<sup>-2</sup>) to derive the sensitivity of a specific PFT ( $a_{PFT}$ ). Accordingly, the damaging  
 414 fraction  $F$  is modified as follows:

$$415 \quad F = a \times \max\left\{ \frac{f_{O_3}}{LMA} - t, 0 \right\} \quad (47)$$

416 Here  $t$  (nmol g<sup>-1</sup> s<sup>-1</sup>) is a unified flux threshold for O<sub>3</sub> vegetation damage. The  $f_{O_3}$  in  
 417 Equation (45) is fed into Equation (47) so as to build a quadratic equation for  $F$ . We  
 418 solve the quadratic equation and select the  $F$  value within the range of [0, 1]. The  
 419 updated scheme considers the dilution effects of O<sub>3</sub> dose through leaf cross-section by  
 420 incorporating LMA. Plants with high LMA (e.g., ENF and EBF) usually have low  
 421 sensitivities, and those with low LMA (e.g., DBF and crops) are more sensitive to O<sub>3</sub>  
 422 damages. The unified sensitivity  $a$  is set to 3.5 nmol<sup>-1</sup> g s and threshold  $t$  is set to 0.019  
 423 nmol g<sup>-1</sup> s<sup>-1</sup> by calibrating simulated  $F$  values with literature-based measurements (Ma  
 424 et al., 2023).

425

### 426 **2.3 Design of simulations**

427 We perform four sensitivity experiments with the iMAPLE model. The baseline (BASE)  
428 simulation considers the two-way coupling between carbon and water cycles, so that  
429 the prognostic soil meteorology drives canopy photosynthesis and evapotranspiration.  
430 A sensitivity run named BASE\_NW is set up by turning off the water cycle in the  
431 iMAPLE model. In this simulation, the soil moisture and soil temperature are adopted  
432 from the Modern-Era Retrospective Analysis for Research and Applications, Version 2  
433 (MERRA-2) reanalyses (Gelaro et al., 2017). The third and fourth runs turn on the O<sub>3</sub>  
434 vegetation damage effect using either the LMA-based scheme (O3LMA) or the S2007  
435 scheme (O3S2007). Surface hourly O<sub>3</sub> concentrations are adopted from the chemical  
436 transport model simulations used in our previous study (Yue and Unger, 2018). For all  
437 simulations, the iMAPLE model is driven with the hourly surface meteorology at a  
438 spatial resolution of 1°×1° from the MERRA-2 reanalyses, including surface air  
439 temperature, air pressure, specific humidity, wind speed, precipitation, snowfall,  
440 shortwave and longwave radiation. We run the model for the period of 1980-2021 using  
441 the initial conditions of the equilibrium soil carbon pool, tree height, and water fluxes  
442 from a spin-up run of 200 years driven with perpetual forcing for the year 1980.

443

444 The iMAPLE model is driven with observed CO<sub>2</sub> concentrations from Mauna Loa  
445 (Keeling et al., 1976) and the land cover fraction of nine PFTs derived by combining  
446 satellite retrievals from both Moderate Resolution Imaging Spectroradiometer (MODIS)  
447 (Hansen et al., 2003) and Advanced Very High Resolution Radiometer (AVHRR)  
448 (Defries et al., 2000). For fire emissions, we use Gridded Population of the World  
449 version 4 (<https://sedac.ciesin.columbia.edu/data/collection/gpw-v4>) to calculate  
450 human ignition and suppression. The lightning ignition is calculated using the flash rate  
451 from Very High Resolution Gridded Lightning Climatology Data  
452 CollectionVersion1 ([https://ghrc.nsstc.nasa.gov/uso/ds\\_details/collections/lisvhrcC.ht](https://ghrc.nsstc.nasa.gov/uso/ds_details/collections/lisvhrcC.html)  
453 ml). For wetland CH<sub>4</sub> emissions, we use the 2000-2020 global dataset of Wetland Area

454 and Dynamics for Methane Modeling (WAD2M) derived from static datasets and  
455 remote sensing (Zhang et al., 2021), global soil pH from Hengl et al. (2017), and  
456 gridded soil texture from Scholes et al. (2011). For the LMA-based O<sub>3</sub> damage scheme,  
457 we use gridded LMA from the trait-level dataset of TRY (Kattge et al., 2011) developed  
458 by extending field measurements with a random forest model (Moreno-Martínez et al.,  
459 2018).

460

#### 461 **2.4 Data for validations**

462 We use observational datasets to validate the biogeochemical processes and related  
463 variables simulated by the iMAPLE model. For simulated carbon and water fluxes, site-  
464 level observations are collected from 201 sites from the FLUXNET network (Table S2  
465 and Figure 2). Among these sites, 95 have the ENF tree species as the major PFT and  
466 106 are dominated by non-tree species especially shrubland. Most (71%) of the sites  
467 are located at the middle latitudes (30°-60°N) of the Northern Hemisphere (NH),  
468 especially in the U.S. and Europe. Compared to the previous evaluation in YU2015, we  
469 have many more sites in the tropics (22 in this study vs. 5 in YU2015), Asia (20 in this  
470 study vs. 1 in YU2015), and in the Southern Hemisphere (28 in this study vs. 7 in  
471 YU2015) in this study. We also use the global gridded observations of GPP from the  
472 satellite retrievals including the solar-induced chlorophyll fluorescence (SIF) product  
473 GOSIF (Li and Xiao, 2019) and the Global land surface satellite (GLASS) product  
474 (Yuan et al., 2010). The global observations of ET are adopted from the benchmark  
475 product of FLUXCOM (Jung et al., 2020a) and the satellite-based GLASS product. For  
476 the dynamic fire module, we use monthly observed area burned from the Global Fire  
477 Emission Database version 4.1 with small fires (GFED4.1s) during 1997-2016 (van der  
478 Werf et al., 2010; Randerson et al., 2012). For methane emissions, we use site-level  
479 measurements of CH<sub>4</sub> fluxes from the FLUXNET-CH<sub>4</sub> network (Delwiche et al., 2021).  
480 We exclude the monthly records with missing data at more than half of the days and  
481 calculate the long-term mean fluxes for the seasonal cycle. In total, we select 44 sites  
482 with at least six months of data available for the validations (Table S3).

483

### 484 **3. Model evaluations**

#### 485 3.1 Site-level evaluations

486 Simulated GPP shows correlation coefficients (R) of 0.59-0.86 for the six main PFTs  
487 with varied sample numbers (Figure 3). The highest R is achieved for ENF, though the  
488 model underestimates the mean GPP magnitude by 20.62% for this species. On average,  
489 simulated GPP is lower than observations for most PFTs. Compared to previous  
490 evaluation of the YIBs model (YU2015), iMAPLE with coupled water cycle improves  
491 the R of GPP simulations for ENF (from 0.65 to 0.86) and grassland (from 0.7 to 0.8)  
492 but worsens the predictions for other species such as EBF (from 0.65 to 0.59). The main  
493 cause of this degradation is the application of MERRA-2 reanalyses in the iMAPLE  
494 simulations instead of the site-level meteorology used in the YU2015. The biases in the  
495 meteorological input may cause uncertainties in the simulation of GPP fluxes (Ma et  
496 al., 2021). In addition, the mismatch of vegetation cover and soil properties between  
497 the site location and the 1°×1° grid in the simulation may further contribute to the  
498 modeling biases.

499

500 Simulated ET matches observations with correlation coefficients of 0.57-0.84 at the  
501 FLUXNET sites (Figure 4). Relatively better performance is achieved for ENF (R=0.83)  
502 and grassland (R=0.84), for which the model yields good predictions of GPP as well.  
503 In contrast, low correlations and high biases are predicted for shrubland and cropland.  
504 For the shrubland sites, different land types (e.g., closed shrublands, permanent  
505 wetlands, and woody savannas) share the same parameters in the iMAPLE model,  
506 resulting in the biases in depicting the site-specific carbon and water fluxes. For  
507 cropland, the prognostic phenology of grass species is applied in the model due to the  
508 missing of plantation information for individual sites. Even with these deficits, the  
509 iMAPLE model in general captures the spatiotemporal variations of GPP and ET at  
510 most sites.

511

512 We further compare the simulated wetland CH<sub>4</sub> fluxes from the BASE experiment with  
513 observations at the FLUXNET-CH<sub>4</sub> sites. Similar to the carbon flux sites, most of these  
514 CH<sub>4</sub> flux sites are located in the NH (Figure 5a). However, different from the carbon  
515 fluxes which usually range from 0 to 15 g C m<sup>-2</sup> day<sup>-1</sup>, the CH<sub>4</sub> fluxes show a wide  
516 range across several orders of magnitude from 10<sup>-2</sup> to 10<sup>3</sup> g [CH<sub>4</sub>] m<sup>-2</sup> yr<sup>-1</sup> (Figure 5b).  
517 Such a large contrast requires a more realistic configuration of model parameters to  
518 distinguish the large gradient among sites. For example, US-Tw1 and US-Tw4 are two  
519 nearby sites within a distance of 1 km, where our simulations give a CH<sub>4</sub> flux of 14.35  
520 g[CH<sub>4</sub>] m<sup>-2</sup> yr<sup>-1</sup> during 2011-2017. However, average CH<sub>4</sub> flux shows a difference of  
521 3.7 times with 66.31 g[CH<sub>4</sub>] m<sup>-2</sup> yr<sup>-1</sup> in US-Tw1 and 18.16 g[CH<sub>4</sub>] m<sup>-2</sup> yr<sup>-1</sup> in US-Tw4  
522 during 2011-2017. In the model, these two sites share the same land surface properties  
523 because they are located on the same grid. On average, simulated CH<sub>4</sub> fluxes are  
524 correlated with observations at a moderate R of 0.68 and a normalized mean bias (NMB)  
525 of -28%.

526

### 527 3.2 Grid-level evaluations

528 The coupling of Noah-MP module enables the dynamic prediction of soil parameters  
529 by the iMAPLE model. We compare the simulated soil moisture and soil temperature  
530 from the BASE experiment with MERRA-2 reanalyses (Figure 6). Both simulations  
531 (Figure 6a) and observations (Figure 6b) show low soil moisture over arid and semi-  
532 arid regions with the minimum in North Africa. The model also captures the high soil  
533 moisture in tropical rainforest. However, the prediction underestimates soil moisture in  
534 boreal regions in NH (Figure 6c). On the global scale, simulated soil moisture matches  
535 observations with a high R of 0.86 and a low NMB of -6.9%. These statistical metrics  
536 are further improved for the simulated soil temperature with the R of 0.99 and NMB of  
537 0.5% against observations (Figure 6f). The simulation reproduces the observed spatial  
538 pattern with a uniform warming bias.

539

540 Driven with the prognostic soil moisture and temperature, the iMAPLE model predicts

541 reasonable land carbon and water fluxes (Figure 7). Simulated GPP (Figure 7a)  
542 reproduces observed patterns (Figure 7b) with high values in the tropical rainforest,  
543 moderate values in the boreal forests, and low values in the arid regions. On the global  
544 scale, our simulations yield a total GPP of 129.8 Pg C yr<sup>-1</sup>, similar to the observed  
545 amount of 125.4 Pg C yr<sup>-1</sup>. The predicted GPP is higher than observations over the  
546 tropical rainforest (Figure 7c). However, such overestimation may instead be an  
547 indicator of biases in the ensemble observations, which are derived from the empirical  
548 models instead of direct measurements (Yuan et al., 2010;Running et al., 2004). Our  
549 site-level evaluations show that iMAPLE predicts reasonable GPP values at the EBF  
550 sites (Figure 3). Despite this inconsistency, the model yields a high R of 0.92 and a  
551 small NMB of 1.3% for GPP against observations on the global scale (Figure 7c).  
552 Simulated ET (Figure 7d) matches the observations (Figure 7e) with high values in the  
553 tropical rainforest and secondary high values in the boreal forest. In general, the  
554 prediction is lower than observations except for the eastern U.S. and eastern China  
555 (Figure 7f). On average, the iMAPLE model shows the R of 0.93 and NMB of -10.4%  
556 in the simulation of ET compared to the ensemble of observations.

557

558 We further compare the simulated GPP with (BASE) or without (BASE\_NW) dynamic  
559 water cycle (Figure 8). Relative to the simulations driven with MERRA-2 soil moisture  
560 and temperature, the iMAPLE model coupled with Noah-MP water module predicts  
561 very similar GPP over the hotspot regions such as tropical rainforest and boreal forest  
562 (Figure 8a). However, the coupled model predicts lower GPP for grassland in the tropics  
563 (e.g., South America and central Africa) but higher GPP in arid regions (e.g., South  
564 Africa and Australia). Since the baseline GPP is very low in arid regions, the relative  
565 changes are even larger than 100% over those areas. These GPP differences are mainly  
566 driven by the changes in soil moisture, which increases over the arid regions with the  
567 dynamic water cycle (Figure 6c). The reduction of soil moisture in the high latitudes of  
568 NH shows limited impacts on the predicted GPP, likely because the boreal ecosystem  
569 is more dependent on temperature than moisture (Beer et al., 2010).

570

### 571 3.3 Ecosystem perturbations to air pollution

572 Within the iMAPLE framework, the land ecosystem perturbs atmospheric components  
573 through the emissions from biomass burning, wetland CH<sub>4</sub>, and BVOCs. We compare  
574 the simulated burned fraction and fire-emitted organic carbon (OC) emissions with  
575 observations from GFED4.1s (Figure 9). The largest burned fraction is predicted over  
576 the Sahel region and countries of Angola and Zambia, surrounding the low center of  
577 Congo rainforest. Moderate burnings could be found in northern Australia and eastern  
578 South America. Most of these hotspots are located on the grassland and shrubland in  
579 the tropics, where the high temperature and limited rainfall promotes regional fire  
580 activities. The model reasonably captures the observed fire pattern with a spatial  
581 correlation of 0.66 and NMB of 6.05% (Figure 9c), though the model overestimates the  
582 area burned in South Africa. The predicted fire area is used to derive biomass burning  
583 emissions of air pollutants (e.g., carbon monoxide, nitrogen oxides, black carbon,  
584 organic carbon, sulfur dioxide) with the specific emission factors (Tian et al., 2023).  
585 Furthermore, we compare fire-emitted OC from the model with GFED4.1s. The spatial  
586 pattern of OC emissions is similar to that of burned area. The simulations yield a total  
587 of 16.8 Tg yr<sup>-1</sup> for the global fire-emitted OC, slightly higher than the amount of 16.4  
588 Tg yr<sup>-1</sup> from GFED4.1s with some overestimations in tropical Africa (Figure 9f).

589

590 The wetland emissions of CH<sub>4</sub> show hotspots over tropical rainforests (Figure 10a),  
591 where the dense soil carbon provides abundant substrates for emissions and the warm  
592 climate promotes the emission rates. The secondary hotspots are located at the boreal  
593 regions in the NH. This spatial pattern is very similar to the map of wetland CH<sub>4</sub>  
594 emissions predicted by an ensemble of 13 biogeochemical models (Saunois et al., 2020).  
595 On the global scale, the total wetland emission is 153.45 Tg [CH<sub>4</sub>] yr<sup>-1</sup> during 2000-  
596 2014, close to the average of 148±25 Tg [CH<sub>4</sub>] yr<sup>-1</sup> for 2000-2017 estimated by the  
597 multiple models. As a comparison, anthropogenic source of CH<sub>4</sub> show the high amount  
598 in China and India due to the large emissions from fossil fuels and agriculture (Figure

599 10b). On the global scale, the wetland emissions are equivalent to 45.3% of the total  
600 anthropogenic emissions. As important factors driving CH<sub>4</sub> emissions, heterotrophic  
601 respiration shows higher values over tropical regions and eastern China with a total  
602 amount of 73.2 Pg C yr<sup>-1</sup> (Figure 10c), and relative high wetland coverages are found  
603 in boreal Asia and Amazon (Figure 10d).

604

605 Isoprene emissions from the two schemes in the iMAPLE model show similar spatial  
606 distributions with the hotspots over tropical rainforest (Figure 11), where the warm  
607 climate and abundant light are favorable for the biogenic emissions. Compared to the  
608 MEGAN scheme, the PS\_BVOC scheme yields higher emissions in the tropical  
609 rainforest and boreal forest, but lower emissions for the shrubland and grassland in  
610 semiarid regions (Figure 11c). Such differences are attributed to the varied processes as  
611 well as the emission factors. Our earlier study showed that PS\_BVOC scheme predicts  
612 stronger trends in isoprene emissions than MEGAN (Cao et al., 2021a), because the  
613 former considers both CO<sub>2</sub> fertilization and inhibition effects while the latter considers  
614 only the inhibition effects. On the global scale, isoprene emissions are 550 Tg yr<sup>-1</sup> with  
615 PS\_BVOC (Figure 11a) and 611 Tg yr<sup>-1</sup> with MEGAN (Figure 11b). These amounts are  
616 higher than the ensemble mean of 448 Tg yr<sup>-1</sup> from the CMIP6 models (Cao et al.,  
617 2021b), but in general within the range of 412-601 Tg yr<sup>-1</sup> as summarized by Carslaw  
618 et al. (2010).

619

#### 620 3.4. Air pollution impacts on ecosystem fluxes

621 We assess the damaging effects of surface O<sub>3</sub> to GPP with two schemes (O3LMA –  
622 BASE and O3S2007 - BASE) (Figure 12). Simulated GPP losses show similar patterns  
623 with high damages in eastern U.S., western Europe, and eastern China, where surface  
624 O<sub>3</sub> level is high due to the anthropogenic emissions. Limited GPP damages are  
625 predicted in the tropics though with abundant forest coverage due to the low level of  
626 O<sub>3</sub> pollution. Compared to the S2007 scheme, predicted GPP loss is further alleviated  
627 in tropical rainforest with the LMA-based scheme, because the latter scheme

628 determines lower O<sub>3</sub> sensitivity for evergreen trees due to their higher content of  
629 chemical resistance with the larger LMA value (Ma et al., 2023). On the global scale,  
630 the average GPP loss is -2.9% with the LMA scheme and -3.2% with the S2007 scheme.  
631 Such damage to GPP is weaker than the estimate of -4.8% in Ma et al. (2023) because  
632 of the differences in O<sub>3</sub> concentrations, vegetation types, and photosynthetic parameters.  
633

634 Atmospheric aerosols cause perturbations to both direct and diffuse radiation, which  
635 have different efficiencies in enhancing plant photosynthesis. Here, we separate the  
636 diffuse (diffuse fraction > 0.75) and direct (diffuse fraction < 0.25) components using  
637 observed diffuse fraction and solar radiation at six FLUXNET sites, and aggregate the  
638 GPP and ET fluxes for different radiation periods at certain intervals (Figure 13). At the  
639 six selected sites, observed GPP is higher and grows faster with more diffusive light  
640 than that under the direct light conditions (Figure 13a-13f). Simulations in general  
641 reproduce such feature with the comparable variability. In the earlier study, simulated  
642 diffuse fertilization efficiency for GPP (changes of GPP per unit diffuse radiation) was  
643 well validated against observations at more than 20 sites (Yue and Unger, 2018). Such  
644 amelioration of GPP suggests that moderate aerosol loading is beneficial for ecosystem  
645 carbon uptake (Yue and Unger, 2017). However, the dense aerosol loading may instead  
646 weaken plant photosynthesis due to the large reduction in direct radiation.

647

648 We further evaluate the ET responses to diffuse and direct radiation from the iMAPLE  
649 model (Figure 13g-13l). Although ET is slightly higher at the diffusive condition, the  
650 growth rates are weaker than that of GPP. The main cause of such difference is related  
651 to the varied light dependence of ET components, which consist of canopy evaporation  
652 and transpiration. Transpiration is tightly coupled with photosynthesis and will increase  
653 by diffuse radiation at a similar rate. However, evaporation is more dependent on light  
654 quantity which will decrease with the extinction of aerosols. As a result, the weakened  
655 evaporation in part offsets the increased transpiration, leading to the smaller growth rate  
656 of ET than the responses of photosynthesis and the consequent enhancement in water

657 use efficiency (Wang et al., 2023). The iMAPLE model reasonably captures the lower  
658 growth rates of ET than GPP in response to diffuse radiation at the selected sites.

659

#### 660 **4. Conclusions and discussion**

661 We develop the iMAPLE model by coupling Noah-MP water module with YIBs  
662 vegetation model. Validations show that iMAPLE predicts reasonable distribution of  
663 soil moisture and soil temperature. Driven with these prognostic soil conditions and  
664 meteorology from reanalyses, the model reasonably reproduces the observed  
665 spatiotemporal variations of both GPP and ET fluxes at 201 sites and on the global scale.  
666 We further update the biogeochemical processes in iMAPLE to extend the model's  
667 capability in quantifying interactions between air pollution and land ecosystems. The  
668 model reasonably predicts wetland CH<sub>4</sub> emissions at 44 sites and yields the similar  
669 global map of CH<sub>4</sub> emissions compared to an ensemble of 13 biogeochemical models.  
670 In addition, predicted biomass burning and biogenic emissions are consistent with  
671 either satellite retrievals or results from other models. We assess the impacts of surface  
672 O<sub>3</sub> and aerosols on ecosystem fluxes. The LMA-based scheme links the O<sub>3</sub> sensitivity  
673 with vegetation LMA and predicts a global map of GPP loss that is consistent with the  
674 traditional scheme using the PFT-specific sensitivity. The updated scheme effectively  
675 reduces modeling uncertainties by decreasing the number of parameters for O<sub>3</sub>  
676 sensitivity and provides an option to apply the advanced LMA map from remote sensing.  
677 The model also reproduces the observed responses of GPP and ET to diffuse radiation  
678 with a lower growth rate for ET than GPP.

679

680 There are several limitations in the current version of iMAPLE. First, it does not include  
681 the dynamic nutrient cycle. Although we implement the down regulation from Arora et  
682 al. (2009) to constrain CO<sub>2</sub> fertilization, this limitation is dependent only on the ambient  
683 CO<sub>2</sub> concentrations and could not represent the heterogeneous distribution of nutrients.  
684 As a result, the model could not reveal the biogeochemical effects of nitrogen and  
685 phosphorus deposition on land ecosystems. Second, the feedback of fire activities to

686 ecosystems is ignored. The iMAPLE model considers the impacts of fuel load on area  
687 burned at each modeling time step. However, these fire perturbations do not in turn  
688 change the vegetation distribution and composition. The vegetation model does not  
689 consider the competition among PFTs, so that fire perturbations are not allowed to  
690 change vegetation coverage. As a result, the interactions between fire and ecosystems  
691 are underestimated in the current model framework, potentially leading to  
692 overestimations of wildfire activity due to remaining fuel loads.” Third, iMAPLE does  
693 not consider the dynamic changes in wetland area for CH<sub>4</sub> emissions. Although the  
694 Noah-MP module predicts runoff and underground water, the changes of hydrological  
695 cycles are not connected with wetland area in the model. Instead, a prescribed wetland  
696 dataset is applied to reduce the possible uncertainties but meanwhile limits the  
697 explorations of CH<sub>4</sub> changes in the historical and future periods. Meanwhile, the  
698 iMAPLE model considers only dynamic soil water and temperature down to the 2-m  
699 level, which may affect the interactions between climate and the land terrestrial  
700 ecosystem especially during drier conditions. These limitations will be the focuses of  
701 model development in the next step.

702

703 The iMAPLE model inherits the good capability of the original YIBs model in the  
704 simulations of carbon cycle. Furthermore, iMAPLE upgrades the YIBs model with  
705 carbon-water coupling and more biogeochemical processes. With the iMAPLE model,  
706 we could assess the changes of carbon and water fluxes, as well as their coupling, in  
707 response to environmental perturbations (e.g., climate change, air pollution, land cover  
708 change). Meanwhile, by coupling iMAPLE with climate and/or chemical models, we  
709 could further quantify the changes of meteorology and atmospheric components in  
710 response to the biogeochemical and biogeophysical processes. For example, Lei et al.  
711 (2022) revealed the strong vegetation feedback to global surface O<sub>3</sub> during the drought  
712 periods using the YIBs model coupled to a chemical transport model. Xie et al. (2019)  
713 found a significant increase in atmospheric CO<sub>2</sub> concentrations due to O<sub>3</sub>-induced  
714 vegetation damage using the YIBs model coupled with a regional climate-chemistry

715 model. Gong et al. (2021) estimated a surface warming in polluted regions due to the  
716 ozone-vegetation feedback using the YIBs model coupled with a global climate-  
717 chemistry model. These studies indicate that the iMAPLE model could be used either  
718 offline or online with other models to explore the interactions among climate, chemistry,  
719 and ecosystems.

1183 **Figure 1** The illustration of biogeochemical processes in the iMAPLE version 1.0  
 1184 model. The carbon cycle is connected with water cycle, wildfire emissions, biogenic  
 1185 volatile organic compounds (BVOCs) emissions, wetland methane emissions, and is  
 1186 affected by air pollutants including aerosols and ozone. The bold arrows indicate the  
 1187 directions of fluxes and air pollutants. The thin arrows indicate the influential pathways  
 1188 among different components. The dependences on key parameters are shown for some  
 1189 processes. Red fonts indicate new or updated processes in iMAPLE relative to the YIBs  
 1190 model. For detailed parameterizations please refer to section 2.2.

 1208  
 1209

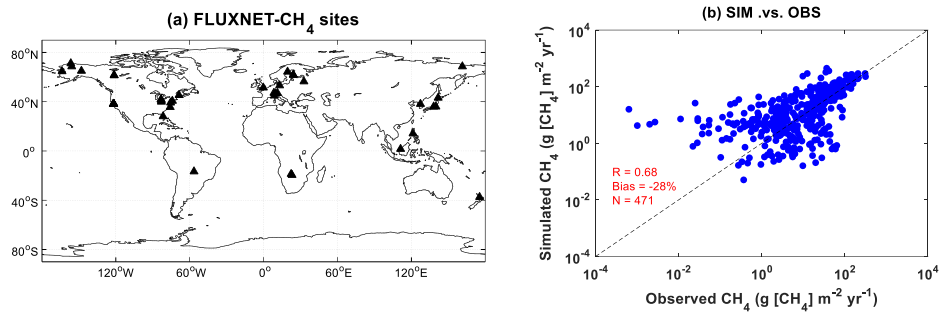

**Figure 3** Comparisons between observed and simulated monthly GPP from 201 FLUXNET sites. Each point indicates the average value of one month at a site. The red line represents linear regression between observations and simulations from the BASE experiment. The correlation coefficient (R), normalized mean bias and numbers of points/months (N) are shown on each panel. The comparisons are grouped into six PFTs including EBF, ENF, DBF, Shrub, Grass, and Crop. The unit is  $\text{g C m}^{-2} \text{ day}^{-1}$ .

1210  
 1211  
 1212  
 1213

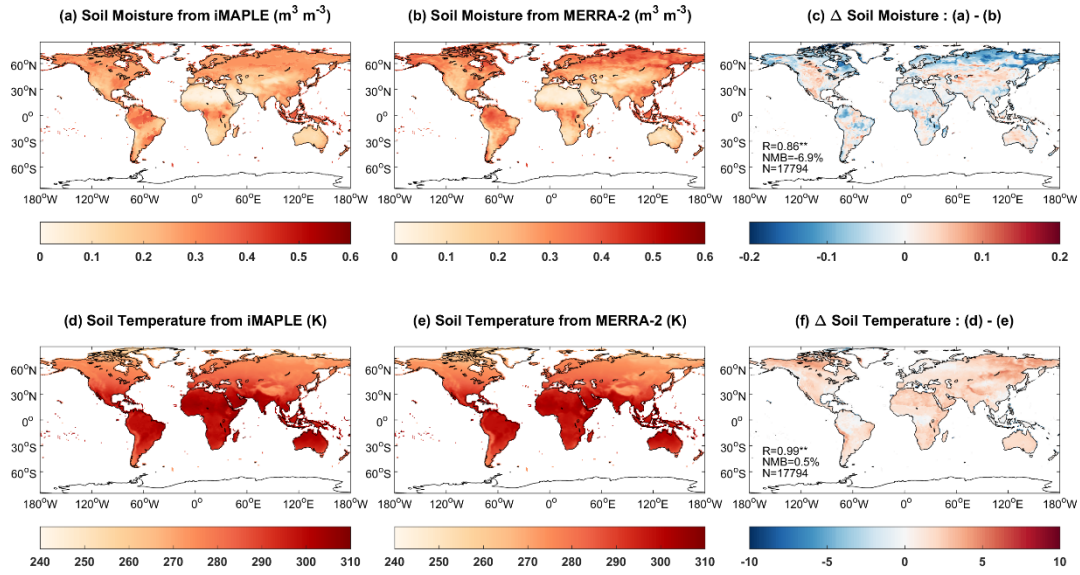

**Figure 4** The same as Figure 3 but for ET. The unit is mm month<sup>-1</sup>.

1214

1215 **Figure 5** (a) Spatial distribution of global FLUXNET-CH<sub>4</sub> sites and (b) comparisons between  
 1216 observed and simulated monthly methane flux from the BASE experiment. Filled triangles indicate  
 1217 sites with at least six months observations of wetland CH<sub>4</sub> fluxes. Each point represents average  
 1218 value of monthly methane emission at one site. The correlation coefficient (R), normalized mean  
 1219 bias and numbers of points/months (N) are shown on the right panel. The unit is g [CH<sub>4</sub>] m<sup>-2</sup> yr<sup>-1</sup>.  
 1220

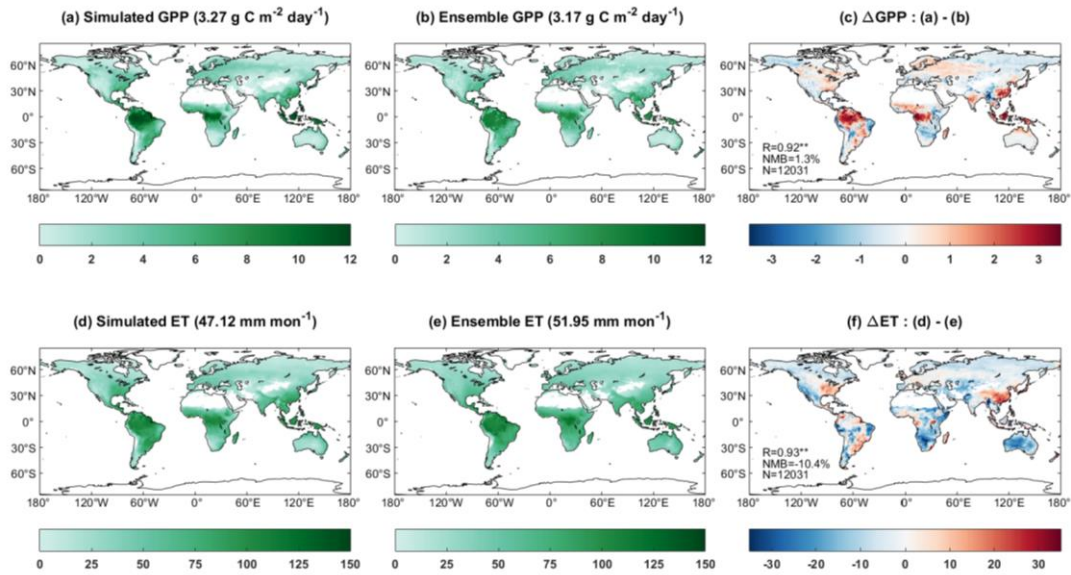

1221

1222 **Figure 6** Comparisons of simulated (a) soil moisture ( $\text{m}^3 \text{m}^{-3}$ ) and (d) soil temperature (K) from the  
 1223 iMAPLE model with (b, e) the MERRA-2 reanalyses. Both simulations from the BASE experiment  
 1224 and observations from MERRA-2 reanalyses are averaged for the period of 1980-2020. The spatial  
 1225 difference, correlation coefficient (R), normalized mean bias (NMB) between simulations and  
 1226 observations and numbers of points (N) are shown on (c) and (f), respectively.

**Figure 13** Observed and simulated responses of site-level (a-f) GPP and (g-l) ET to diffuse and direct radiation at the FLUXNET sites. Photosynthetically active radiation (PAR) reaching the surface are divided into diffuse (diffuse fraction > 0.75) and direct (diffuse fraction < 0.25) radiation at six FLUXNET sites with more than 10 years of observations. Observations (simulations) are grouped over PAR bins of  $40 \text{ W m}^{-2}$  with errorbars (shadings) indicating standard deviations of GPP and ET for each bin. The red (blue) and magenta (green) represent observed and simulated responses of GPP and ET to diffuse (direct) radiation. Units of GPP and ET are  $\text{g C m}^{-2} \text{ day}^{-1}$  and  $\text{mm hr}^{-1}$ , respectively.
