Abstract. Wind-wave forecasts play a crucial role in the Great Lakes region towards ensuring the safety of communities, enhancement of the economy and protection of property. Modeling wind waves in closed and relatively shallow basins with complex bathymetry like the Great Lakes is a challenge that is successfully tackled by using variable-resolution triangular unstructured meshes. In this paper, we discuss recent advances in developing unstructured-mesh capabilities as part of the spectral wave model WAVEWATCH III, in the context of National Oceanic and Atmospheric Administration (NOAA) operational requirements such as model robustness, efficiency, and accuracy. We revisit the history of developments leading to the transition from rectilinear, to curvilinear grids, and finally to an unstructured mesh version of NOAA's operational Great Lakes wave-modeling system (GLWUv2.0). Our results describe the development of the operational GLWUv2.0, from mesh design and scalability analysis to validation and verification for hindcast of storm cases and reforecast using 4 months of retrospective simulations.

1 Introduction

The Great Lakes play a crucial role in the social, economic, and environmental fabric of the United States and Canada, supporting the livelihoods and well-being of millions of people. The region is home to approximately $1/10^{th}$ of the U.S. population (eight U.S. states of Illinois, Indiana, Michigan, Minnesota, New York, Ohio, Pennsylvania, and Wisconsin) and $1/4^{th}$ of the Canadian province of Ontario. Local communities rely on the Great Lakes for various purposes, including drinking water, industrial and agricultural activities, transportation, and recreation. The region further supports a range of economic sectors, including manufacturing, tourism, fishing, and shipping. Great Lakes waterways enable the transportation of goods and raw materials, supporting trade and commerce within the region and beyond.

Accurate wind wave forecasts play a crucial role in ensuring the safety of Great Lakes communities, protecting coastal
20 properties, and facilitating smooth maritime operations. As described in Alves et al. (2014) and Alves et al. (2023), the history
of forecasting in the Great Lakes region dates back to the establishment of NOAA's Great Lakes Environmental Research
Laboratory (GLERL) in 1974, which marked the beginning of systematic marine forecasting in this area. In collaboration with
researchers from the Ohio State University, GLERL pioneered the development of the first wave forecasting system, based
on a parametric, first-generation wave model, specifically tailored for the Great Lakes during the early 1980s (Schwab et al.,
25 1984). As advancements in wind-wave modeling progressed and third-generation models emerged in the late 1980s, GLERL,
in partnership with NOAA's Environmental Modeling Center (EMC), successfully co-developed a next-generation forecast
system. This system was integrated into NOAA's operational wave model framework, becoming an integral part of the suite of
operational environmental forecast models at the National Centers for Environmental Prediction (NCEP).

Upon the release of the third generation wave model WAVEWATCH III (Tolman, 1999) at EMC, GLERL and NCEP ini-
30 tiated the development of the next generation of wave forecast system for the Great Lakes Waves (GLW), incorporating key
requirements from forecasters and science operations officers (SOOs) from regional Weather Forecast Offices (WFOs). Two
years later in 2006, the first WW3-based GLW system was implemented operationally with three-hourly intervals. The model
grid was a single rectilinear grid with a resolution of ~ 4 km, with coverage of all five major Great Lakes basins (Erie-Saint
Clair, Ontario, Huron, Michigan, and Superior). Details are provided in Alves et al. (2014).

The next upgrade featuring a 2.5-km Lambert-conformal spatial grid took place in 2015, enhancing the forecast due to
35 a better representation of the basin-wide geographical features, particularly during rapidly changing conditions (Alves and
Chawla, 2015). This upgrade shed light on the importance of grid resolution, and the need for the implementation of more
accurate physics, especially in coastal environments (Alves et al., 2023). However, the existing system was not sufficiently
computationally efficient to resolve coastal areas with a uniform resolution grid. Meantime, the core WW3 model was equipped
40 with unstructured mesh capabilities and more advanced nearshore physical parameterizations including, but not limited to,
depth breaking, triad interaction, and reflection (Abdolali et al., 2020). The use of a single triangular mesh from coarse offshore
to fine nearshore resolution instead of multiple inter-nested grids with different resolutions showed a substantial improvement
in the workflow design, maintenance, computational efficiency, and accuracy.

In 2017, the GLW system was upgraded to an unstructured mesh (GLWUv1.0), with a 2.5 km resolution in deep water down
45 to 250 m in the nearshore. The added benefit as a result of better representation of wave transformation in the coastal areas
was recognized by the forecasters in the regions within this implementation (Alves et al., 2023). GLWUv1.0 used the explicit
numerical solver and the same parallelization algorithm as the structured and curvilinear grids, mainly due to operational
limitations. The approach had several limitations including restrictions on time stepping due to resolution and grid size, and a
maximum number of CPU threads dependent on the number of spectral components. With the advent of a new parallelization
50 algorithm and an implicit numerical solver, the model was made more efficient and accurate, allowing very large meshes
(Abdolali et al., 2020).

With the availability of appropriate resources, a recent GLWU implementation enabled taking advantage of such features,
with enhanced benefits that will be discussed below, providing a unique opportunity to improve the representation of nearshore

55 wave transformation, incorporating water level and current effects and resolving complicated geometries in shallow water
regions (Moghimi et al., 2020). In the past few decades, the noticeable increase in frequency and destructiveness of coastal
storms has led to a growing recognition of the need to couple wave models with other earth system models. This necessity
extends beyond just public awareness and warning systems, and its benefits encompass applications such as hindcasts for
climatologies, risk analyses for the insurance industry, and relevant data for tourism, investment sectors, and numerous other
stakeholders. The coupling of atmospheric, ocean wave, surge, and hydrological models on high-resolution numerical grids
60 has improved model accuracy by better representing nearshore/inland geometries and physics (Moghimi et al., 2020). This
breakthrough has expanded the limits of WW3 to be dynamically coupled with storm surge, hydrological, ice, and atmospheric
models and provides the opportunity to investigate nearshore wave climate (Bakhtyar et al., 2020). Moreover, the highly
efficient WW3 model allowed researchers to evaluate uncertainty via ensemble modeling (Abdolali et al., 2021).

This paper focuses on the latest operational implementation of the Great Lakes wave model GLWUv2.0, but also discusses
65 new features added to the wave model that benefit Earth systems coupling and ensemble forecasting. The sections are arranged
as follows. Section 3 provides an overview of the GLWUv2.0 implementation in operation in May 2023, including mesh design,
forcing characteristics, the end-to-end workflow design, retrospective simulations for two summer and two winter months, and
validation analysis. In Section 3, the performance of the unstructured WW3 was analyzed for ten hindcasted windy conditions
over the Great Lakes, highlighting the scalability of the domain decomposition algorithm and the effectiveness of the implicit
70 solver on high-resolution meshes. The contrasts, shown in Sections 2 and 3, manifest the lag between operation and core model
development front and define the path forward in the future of operational forecast. Concluding remarks and requirements for
future validation studies and support of better wave forecasts, in particular in the winter season and coastal areas, are provided
in Section 4.

2 Operational Implementation

75 The Great Lakes Wave Model (GLWUv2.0) currently provides guidance to twelve Weather Forecast Offices (WFOs) on six
domains, including the five Great Lakes region plus Lake Champlain. The system is forced by NOAA operational wind sources
(see below) and run on hourly forecast cycles daily, with twenty short-cycles out to 48 h and four long-cycles out to 150 h.
The core model, WAVEWATCH III, takes advantage of key features from the most recent advancements in the WW3v7 model
package outlined above, with some restrictions due to NOAA operational requirements (NCO, 2022), such as end-to-end
80 run-time, output formats, and Operational Readiness Test (ORT).

The WW3 model resolves the wave energy density spectrum with frequencies between 0.05 and 1.055 Hz, divided into 32
frequency bands with a geometric increment factor of 1.1, and 36 directions with 10° increments. In addition, wave physics
parameterizations include the Ardhuin et al.(2010) wind input and wave dissipation source-term (ST4), the Generalized Mul-
tiple Discrete Interactions Approximation (GMD) of Tolman (2014) for nonlinear wave-wave interaction (NL3, replacing the
85 Discrete Interaction Approximation (DIA) of Hasselmann et al. (1985)), JONSWAP bottom friction (BT1; Hasselmann et al.,
1973), depth-limited breaking based on the Battjes-Janssen formulation (DB1) (Battjes and Janssen, 1978). In order to take into

account ice, a simple ice blocking parameterization (IC0) with the discontinuous method is used, where a critical ice concentration in which the scheme switches between free propagation and blocking is $\epsilon_{c,0} = \epsilon_{c,n} = 0.7$. Due to NOAA operational requirements, a parallelization scheme known as "Card Deck" and the explicit numerical scheme are utilized, which limits performance due to restrictions on the number of allowed parallel threads, dependent on the discrete wave spectrum resolution, and on time stepping. In view of the latter, the global, spatial, spectral, and minimum source term WW3 time steps are set to 180, 60, 90 and 10 s, respectively.

2.1 Unstructured Mesh

In the GLWUv2.0, the $G0$ unstructured mesh is utilized for the five lakes with $\sim 253k$ nodes and $\sim 418k$ elements. A new feature in the latest implementation is the addition of a Lake Champlain mesh containing $\sim 30k$ nodes and $\sim 62k$ triangular elements, ranging in size from approximately 60 m in dynamic coastal regions to approximately 400 m in less dynamic offshore areas. Mesh resolution and corresponding histograms, highlighting the distribution of element size and significance of coastal elements in comparison to deep-water elements, are shown in Fig. 1. Mesh systems were tested to ensure they resolved key morphological features in all domains while remaining computationally feasible in a real-time operational environment.

2.2 Forcing Fields

The operational GLWUv2.0 forcing includes temporally variable wind speed and a stationary ice concentration at the initialization time step. A combination of various sources is used for wind due to operational limitations such as availability and spatial and temporal coverage. A flowchart of the forcing fields is shown in Figure 2.

The wind for Lakes Superior, Michigan, Huron, Erie, and Ontario are extracted from the National Digital Forecast Database (NDFD) with a spatial resolution of 2.5 km and variable temporal resolution up to 150-hour forecast (1-hourly out to 24 hours, 3-hourly for days 2-3, 6-hourly for days 4-6). The corresponding resolution of the sea ice concentration analysis for these five domains is 500 m (as opposed to 5 km in v1.0), obtained from the National Ice Center (NIC).

The Lake Champlain portion of the system is forced with atmospheric wind data from NCEP's High-Resolution Rapid Refresh (HRRR) (Dowell et al., 2022) with 3-km resolution for the first two days and switched to Global Forecast System (GFS) up to 150 hrs. The Lake Champlain ice coverage data is taken from National Weather Service Weather Forecast Office in Burlington, VT.

2.3 Workflow

The main characteristics of an end-to-end workflow in an operational environment are its robustness, predictability of potential unavailability of inputs with replaceable alternative options, and full automation, with no human intervention and following a strict run-time scheduling to ensure on-time delivery of guidance products. The three main steps of the GLWUv2.0 workflow, as shown in Fig. 3, are pre-processing, forecast, and post-processing jobs for two parallel jobs, one for the five Great Lakes (Superior, Michigan, Huron, Erie, and Ontario) and the other for Lake Champlain. The workflow runs every hour for 48 hrs

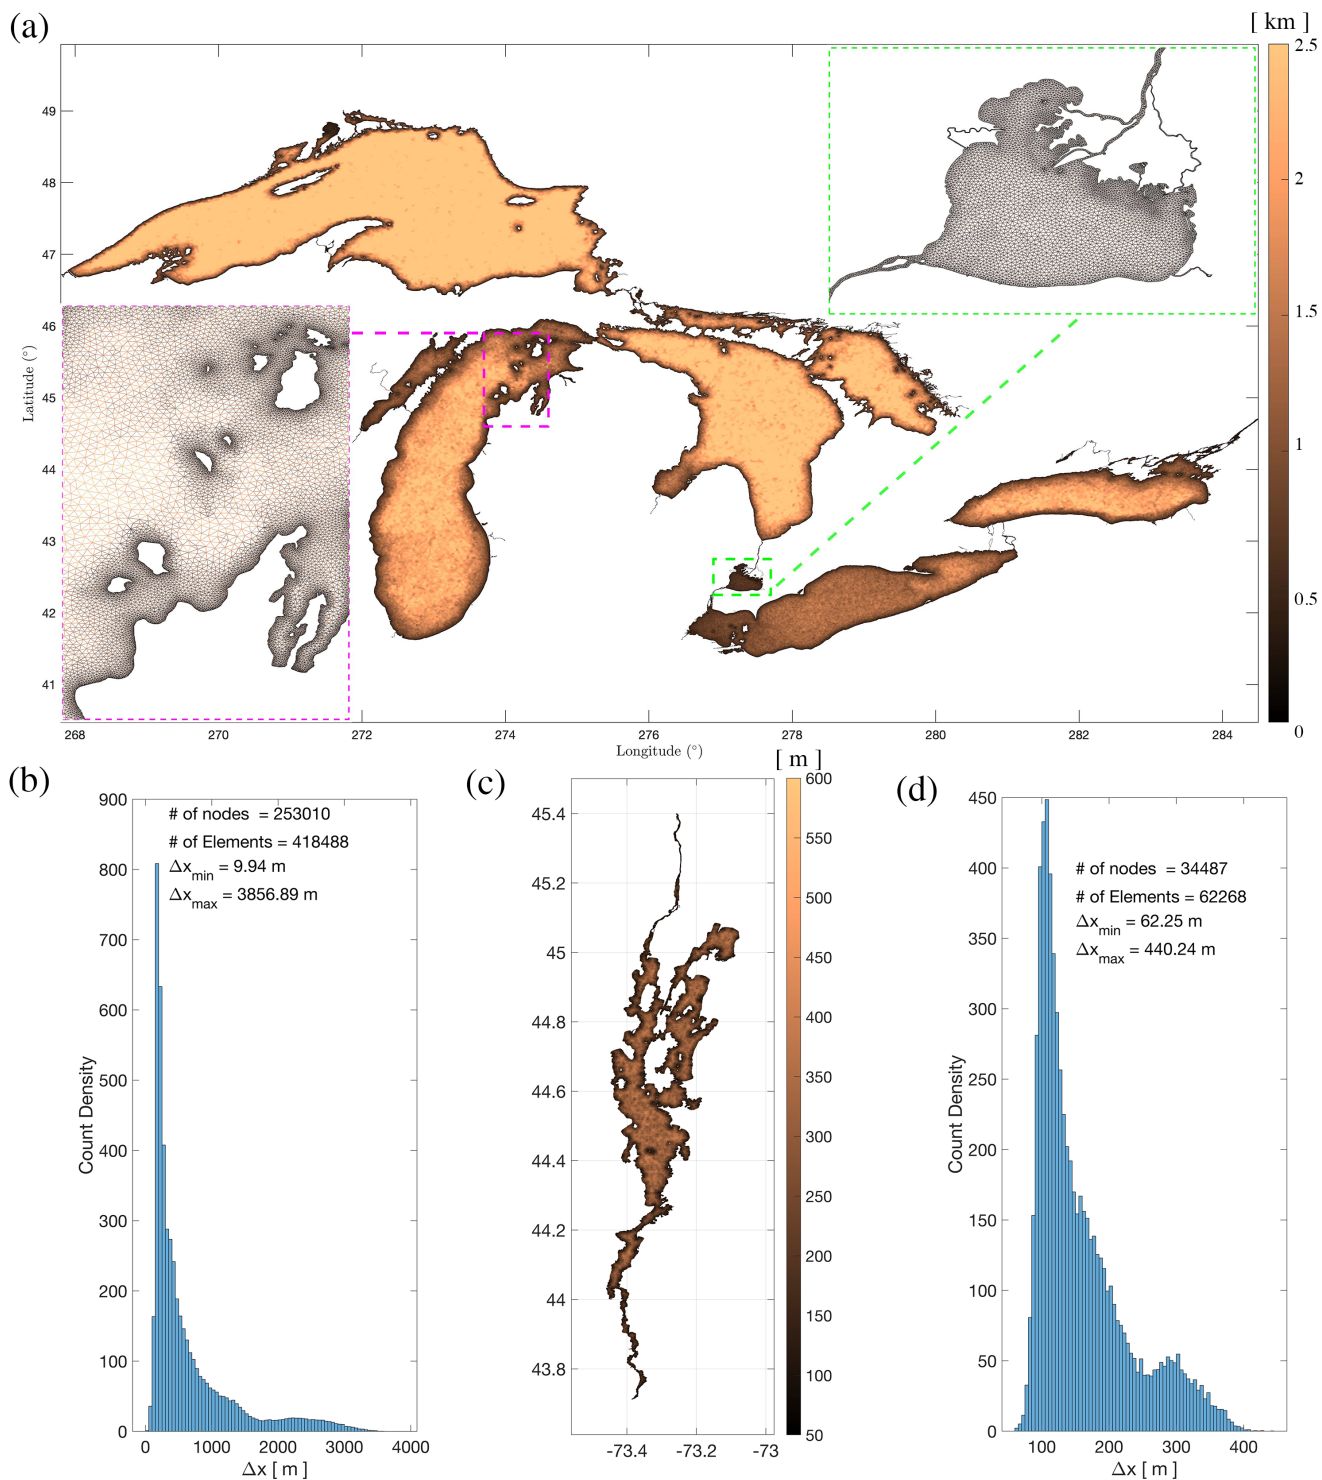

Figure 1. Great Lake Wave Unstructured v2.0 mesh resolutions: (a,b) five Great Lakes and (c,d) Lake Champlain.

Figure 2. Great Lake Wave Unstructured v2.0 atmospheric and ice forcing hierarchy.

in the short cycles and 150 hrs in long cycles, four times a day (01z, 07z, 13z, and 19z). Within the Great Lakes domain, the run-time is 24 minutes for the short cycle and 50 minutes for the long cycle. For Lake Champlain, the process completes in 17
 120 minutes in the short cycle and 27 minutes in the long cycle.

2.3.1 Pre-processing job

This serial job retrieves wind and ice inputs from other operational models like HRRR, GFS or analysis from NDFD, NIC, and the Burlington Weather Forecast Office. In case the current cycle is not available, a look back option fills the forcing from the previous forecast cycles. If the ice field is not provided, the previous forecast cycle ice field is used. Within this step, the
 125 grib2 files are cropped for GLWU coverage, interpolated on the computational grid, and saved in NetCDF format. The WW3 pre-processing executable (*ww3_prnc*) converts the inputs into binary format. The run-times for pre-processing step are 3 and 4 minutes for short and long cycles for the five lakes and 8 and 13 minutes for short and long cycles for Lake Champlain, respectively.

2.3.2 Forecast job

130 This parallel job performs two simulations for the five lakes (on 16 nodes, each node with 64 cores) and Lake Champlain (on 8 nodes) simultaneously. Note that the reason for the separation into two domains is to load balance between the two domains in which Lake Champlain requires more iterations (due to CFL criteria). The run-time for the five lakes is 9 and 24 minutes for

short and long cycles, while Lake Champlain takes 5 and 10 minutes, respectively. Binary point and gridded outputs are stored during the simulation.

135 2.3.3 Post-processing job

This serial job generates NetCDF and grib2 outputs on 500 *m* and 2.5 *km* resolutions while point outputs are generated in NetCDF format (spectral outputs and time series of wave statistics). These data are transferred to the Advanced Weather Interactive Processing System (AWIPS) and NOAA Operational Model Archive and Distribution System (NOMAD) for use by WFOs and the public. The runtime of this step is 12 and 22 minutes for short and long cycles for the five lakes and 3 minutes
140 for Lake Champlain.

2.3.4 Validation and verification job

Once the field and point outputs are prepared during the post-processing phase, and real-time observations from buoys are gathered and subjected to quality checks, a comparative analysis of the results is conducted. This analysis involves generating statistical summaries, including time series plots for parameters such as wind speed, wind direction, significant wave height,
145 peak period, and mean wave direction. Additionally, graphical representations such as linear regression plots and Taylor diagrams are generated, along with tables containing relevant statistics.

2.4 Validation and Verification

The long cycle runs with 6-day re-forecasts simulations (4 times/day) for the GLWUv2.0 system are validated against in-situ measurements at 25 locations as shown in Figure 4. The model performance has been evaluated during two summer months
150 (June and July 2022) where observations were available. Note that the temporarily deployed buoy in Lake Champlain was available during this period, which was one of the criteria for the selection of the retrospective run period.

Two months of simulations (January and February 2022) were conducted to evaluate the model results that included the higher resolution ice and assess model performance with previously reported observed wave artifacts at the ice edge by WFOs. The buoys are removed during wintertime to avoid damage to the gauges, therefore, only qualitative checks were performed.
155 The ice season outputs were provided to the eyewitnesses forecasters at WFOs to make sure they match their observations.

The physical parameters in the wave model were tuned to minimize the statistical metrics of significant wave height, keeping the first forecast day close to the observations. As shown in Fig. 5, the model score in terms of bias, absolute bias, standard deviation, and root mean square error deteriorate with longer forecast lead time, which introduced less accuracy and more uncertainty in the forcing field.

160 Looking closer at trend between forcing wind and downstream wave model output in Fig. 6, the linear regression plot is shown for results separated for percentile ranges of <50, 75, 90, 95 and > 99 for up to six daily forecast. It is clearly shown the wind (U_{10}) was overestimated in NDFD for small values (< 50 percentile) and then underestimated each day for larger values since the forecast was initiated. On the other hand, the wave model outputs were close to 1:1 for the first day with slight

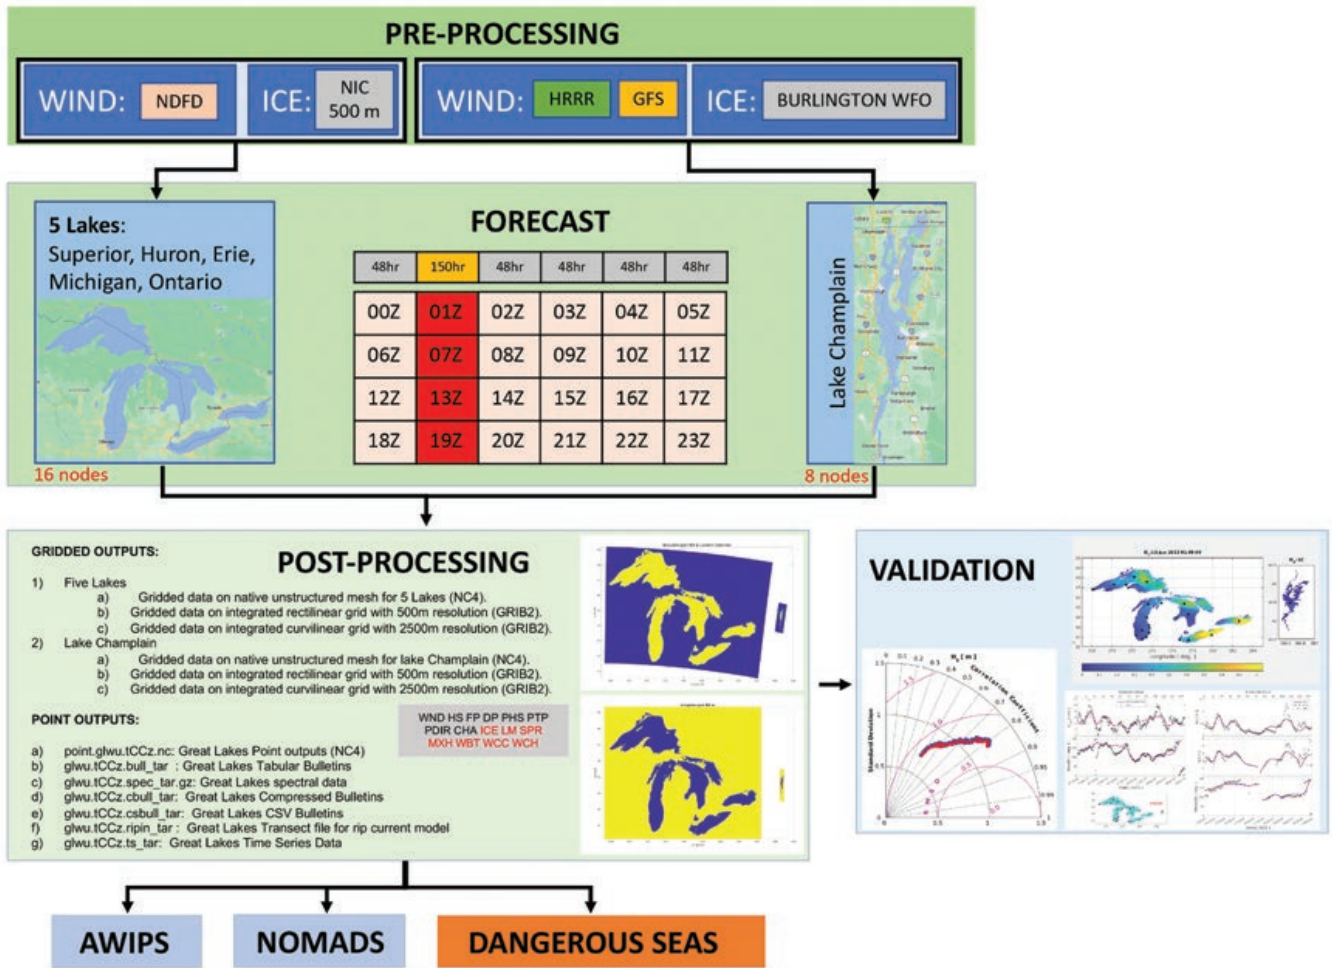

Figure 3. Great Lake Wave Unstructured v2.0 workflow at NOAA NCEP Central Operation (NCO).

underestimation for the larger waves (panel b). Note that unless a dynamic forecast lead time dependent correction is applied on the wind field, the wave models cannot be tuned for the whole duration of the forecast, and the results would deviate from observations as forecast lead time increases. The pattern propagation (under/overestimation) from wind to wave model is due to the nature of wind-wave generation and the direct impact of wind on waves.

Last, the performance of the NDFD winds and WW3 waves at 25 in-situ observations were assessed as a function of forecast lead time and summarized in the Taylor diagrams shown in Fig. 7, in terms of normalized standard deviation (σ), root mean square deviation ($RMSD$), and correlation coefficient (CC). For U_{10} (top panel), as forecast lead time passes, the $RMSD$ increases from 0.7 to 0.9 while σ and CC drop from 0.98 and 0.74 to 0.5 and 0.32, respectively. On the other hand, a similar pattern is observed for H_s (bottom panel), with a slight change in $RMSD$ (0.7-0.8) whereas σ and CC drop from 1.23 and 0.8 to 0.7 and 0.5, respectively.

Figure 4. The location of meteorological and wave observations, obtained from the National Data Buoy Center (NDBC) locations for model validation (© Google Earth, earth.google.com/web/)

2.5 Dangerous Seas

175 In addition to the wave model core upgrade, GLWUv2.0 features seven additional field outputs in order to be utilized in the Dangerous Seas Project over the Great Lakes Region. This project is a bilateral collaborative agreement between NOAA (EMC-OPC) and the Environment and Climate Change Canada (ECCC), to enhance scientific and operational cooperation between Canada and the United States. In this effort, a Dangerous Sea is defined as a combination of wave height, period, steepness, breaking waves, crossing seas, and rapidly changing sea state (time rate of change) that causes navigational risk
180 (speed and course) and, or leading to, the potential loss of vessel, cargo, or crew. Mariners should avoid dangerous seas at all costs. The project has started with the Great Lakes, a basin responding to mostly the wind impact on the water surface, and will migrate the work to the open ocean where wave patterns are more complex. Additional details on this will be made available in a separate article in the future.

Figure 5. Wave model performance for hourly H_s forecast versus lead time in terms of bias, absolute bias, standard deviation (σ), and root mean square error ($RMSE$).

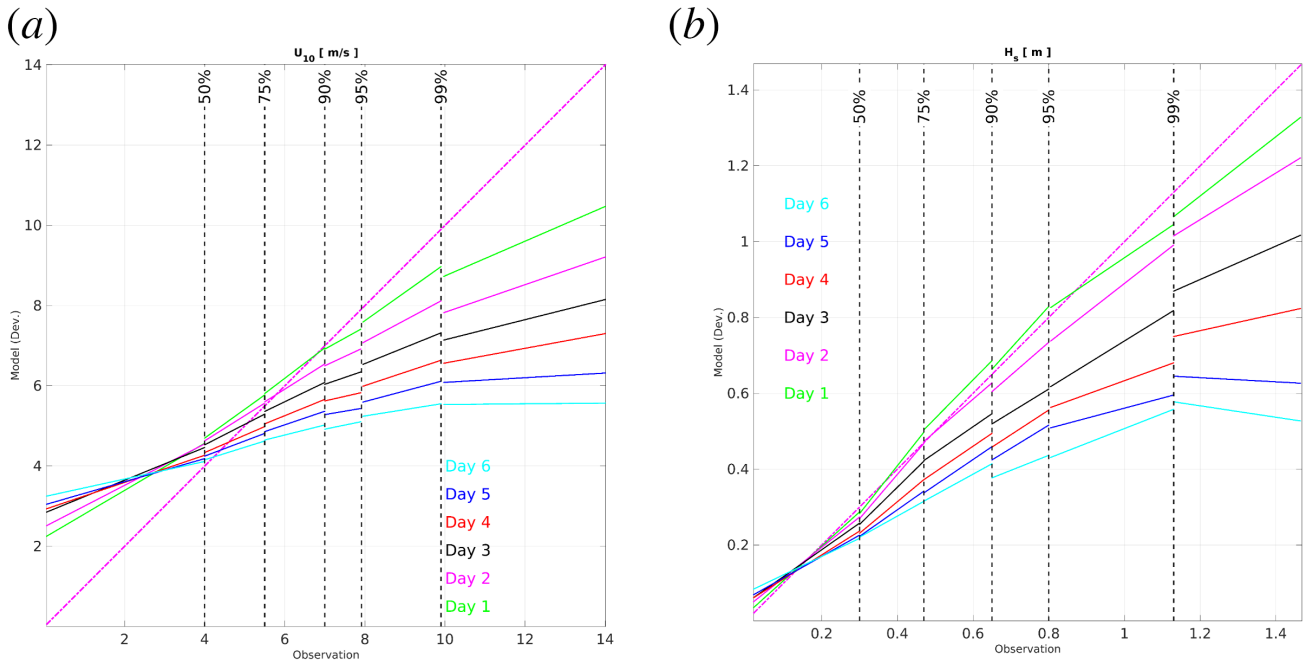

Figure 6. Linear regression plot for wind speed (a) and significant wave height (b) for the daily forecast lead times, separated for <50, 75, 90, 95 and > 99 percentiles.

3 Future Implementations

185 In this section, key features of the core WW3 model left out from GLWUv2.0 due to operational restrictions are tested in support of future upgrades. The aim is to highlight the performance and efficiency benefits of new model features in meshes of one order of magnitude larger than the one used in operation (G_0) with high resolution ($\sim 5\text{-}10\text{ m}$) in coastal regions. A validation study is performed on three unstructured meshes (G_0 , G_1 , and G_2) for ten stormy conditions (T_1, \dots, T_{10}) in the Great Lakes from June 27 to October 26, 2016. The atmospheric forcing is provided by the HWRF model (Tallapragada et al.,
 190 2015) covering Lake Michigan and Lake Superior. The G_0 mesh, which is used in the operational GLWUv1.0 and GLWUv2.0 systems, is compared with two other meshes of higher resolutions. The top row of Figure 8 shows the grid resolutions with an inset magnified view on the northeast side of Lake Michigan. The meshes are finer near the shore and at locations with irregular bathymetry to ensure the complicated coastline and geometries, which have a significant influence on wave transformations, are better represented in the model.

195 A snapshot of the significant wave height field on the G_0 mesh and the percentage difference for G_1 and G_2 meshes are shown in the bottom row. In addition to a quantitative comparison, the atmospheric and wave model outputs are validated at six available stationary buoy stations. The performance of the atmospheric and wave models at the six buoy locations are summarized in Taylor diagrams shown in Fig. 9, in terms of normalized standard deviation (σ), root mean square deviation

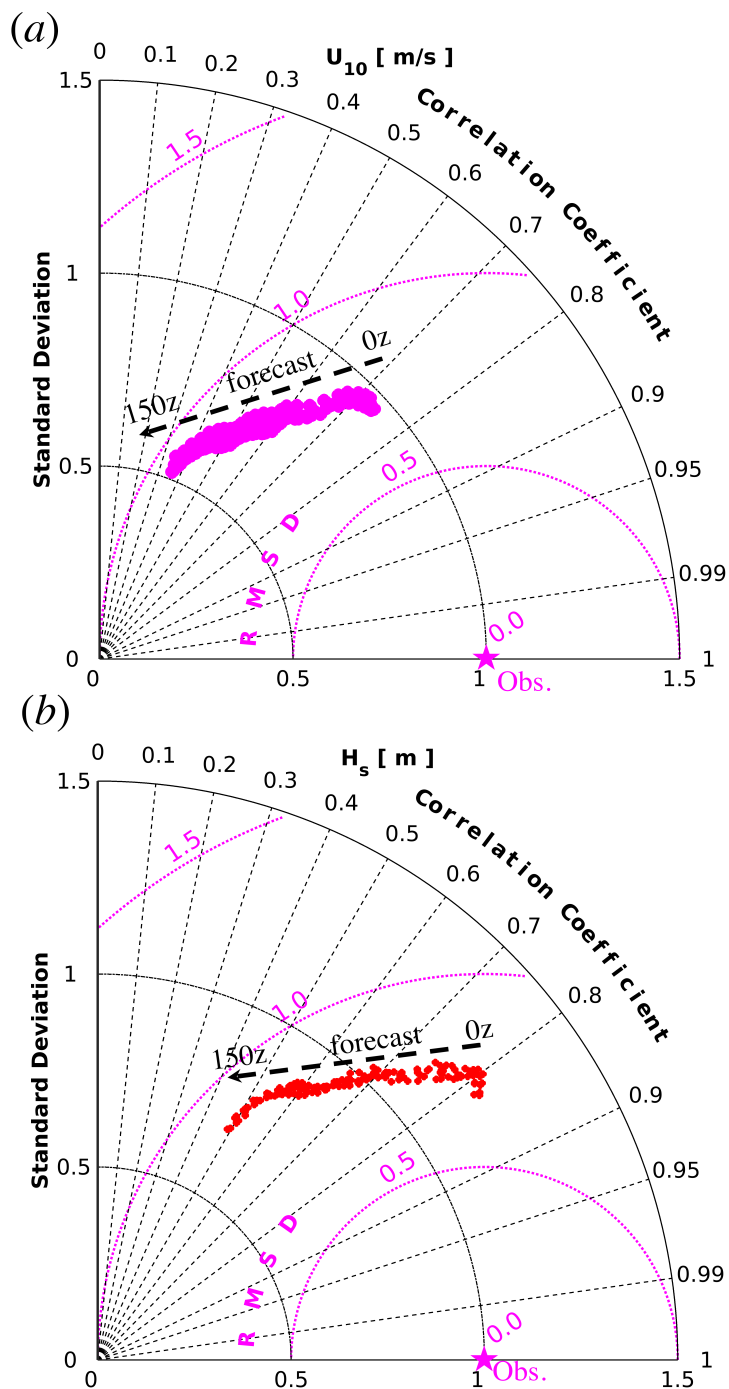

Figure 7. Taylor diagram for (a) wind speed (U_{10}) and (b) significant wave height (H_s) in terms of the Pearson correlation coefficient, normalized root mean square deviation ($RMSE$), and standard deviation σ . The black arrow shows the statistics in forecast hour (for June–July 2022).

(*RMSD*), and correlation coefficient (*CC*) for the observation and model outputs for wind speed (top panel), significant wave
200 height (middle panel) and peak period (bottom panel).

The wind speed has normalized standard deviations in the range of 1-1.3, *RMSD* between 0.5-0.8 with a correlation
coefficient of nearly 0.8 for all the buoys. On the other hand and for all the grids, the significant wave height has $\sigma = 1 - 1.3$,
RMSD = 0.42 – 0.6, and *CC* = 0.86 – 0.94. The peak period has a similar normalized standard deviation, with *RMSD* =
0.6 – 0.81 and *CC* = 0.75 – 0.88. These results show a slight improvement for the intermediate (*G1*) and high-resolution grids
205 (*G2*) with the implicit scheme relative to the operational grid (*G0*) with the explicit scheme. Note that a significant improvement
is not expected due to the deepwater location of the available buoys, which are not expected to benefit from higher resolutions
nearer the coast. (Time series of wind speed U_{10} , wind direction (Fig.AA1), significant wave height (H_s), peak period (T_p), and
mean wave direction from buoy observation and HWRF/WW3 models in Fig.AB1 are provided in supplementary materials).

Our findings highlight a noteworthy improvement in model output achieved by increasing the grid resolution, with particu-
210 larly remarkable enhancements observed in the nearshore region. The finer details of sub-scale geographical features that were
previously absent in the coarse meshes are now captured in the higher-resolution simulations. This discovery underscores the
importance of higher-resolution grids in accurately representing coastal morphology features. These significant differences in
model output hold the promise of qualitative improvements that can be of great importance for nearshore hazards forecasting
and prediction. Forecasters in the region have a crucial need for such advancements to enhance their ability to predict and
215 mitigate potential coastal hazards effectively.

However, to observe a more pronounced impact of mesh resolution, especially for the ten stormy conditions studied, a com-
parable increase in atmospheric forcing resolution, coupled with changes in water level and current fields, becomes essential.
The reason behind this requirement is that the wave climate in enclosed basins is primarily influenced by locally generated
wind-seas. During this study, the same wind field was interpolated on all three grids without considering water levels and
220 current fields. In addition, due to the lack of coastal observations, where the dominant waves might interact with the bottom,
the statistics of the three simulations show nearly equal performances. Looking solely at the comparison plots with the existing
in-situ observations underestimates the importance of high-resolution bathymetric features because the gauges are far away
from any geographical feature like offshore islands that would show the resolution effect on wave transformation interacting
with those features (see conclusion remarks for the needs for the future improvements on high-resolution grids).

The model performance has been evaluated on NCEP's HPC's for the pre-existing parallelization algorithm in WW3 (*CD*)
225 with its explicit equation solver and the newer Domain Decomposition (*DD*) algorithm with the implicit solver on three
unstructured triangular meshes. The grid resolutions are compared in Fig. 8. The *G0* mesh is designed for operational imple-
mentation. The criteria for the *G0* mesh design were mainly computational efficiency and limited available resources in view
of the requirements of the *CD* parallelization and explicit propagation schemes. Therefore, the *G0* grid is relatively small with
230 nearly 250K nodes and a minimum resolution of 250 m in coastal areas. In contrast, a moderate (*G1* with 750K nodes) and a
large grid (*G2* with 2.40M nodes) with ~ 5 m minimum resolution were designed to distinguish the computational limits of
each parallelization algorithm and solver scheme.

The scalability performance is shown in Fig. 10 in terms of non-dimensional computational speed, revealing linear growth in the model performance for various model options and grids for implicit (solid lines) and explicit (dashed lines) schemes. It is clearly shown that the $G0$ grid (black lines) has one order of magnitude faster performance with the implicit scheme compared to the explicit scheme and faster than real-time computation for any given number of CPU cores for both solver schemes. However, increasing the number of grid nodes to 750 k and decreasing the minimum resolution to 5 m led to a significant slowdown in the model performance for the explicit solvers (dashed blue) due to the ineffectiveness of CD parallelization and model CFL constraint embedded in the explicit scheme on triangular unstructured grids.

Such limitations have confronted WW3 users applying larger grids with very high resolution for a long time. The shown slowdown in performance is more evident for the $G2$ mesh (dashed red), where the model computational wall time dropped under real-time (horizontal solid line). On the other hand, the implicit scheme (solid lines), allows to resolve the physical processes in nearshore regions with the prescribed higher grid resolution in an efficient way. For example, the $G2$ mesh with the DD scheme has nearly the same performance of $G0$ mesh with the explicit scheme, in spite of having nearly ten times more nodes. In addition, the DD algorithm does not have any limit in terms of the number of CPU cores allocations, unlike the CD algorithm. Therefore, larger grids can be distributed on a larger number of computational cores, free from the NSPEC limit (number of spectral components) imposed in the CD algorithm (vertical solid line). This computational performance breakthrough is a valuable contribution from our work to research and operational applications using the WW3 model.

4 Conclusions

This article presents an overview of the implementation of GLWUv2.0, encompassing workflow design and validation studies for the duration of 4 months re-forecast, so-called retro-respective simulations. The validation includes a qualitative comparison during the summer season and a qualitative analysis for the ice season when no buoys were available in the Great Lakes. The article also acknowledges the limitations and challenges encountered in the operational environment, which restricted the utilization of the most advanced components of the wave model.

In addition to GLWUv2.0 implementations, the model scalability was evaluated on three unstructured meshes, with 250K ($G0$), 750k ($G1$), and 2.4M ($G2$) nodes with minimum resolutions of 250, 20, and 5 m, respectively. The scalability analysis shows the efficiency of the implicit numerical solver as opposed to the explicit solver, constrained by CFL criteria. In addition, the limitless Domain Decomposition (DD) parallelization will support the use of large meshes in operational environments, where simulation time mandates the design process. In order to show the accuracy of the model during storm conditions, the aforementioned unstructured meshes were compared during ten selected stormy conditions.

The article explores studies that offer insights into future improvements in wave forecasting. It emphasizes the need for refining grid resolution and modernizing numerical models to achieve significant enhancements. Additionally, considering coastal-scale phenomena, interactions with other Earth system models such as circulation, sea-ice, atmosphere and hydrological models is crucial for a comprehensive understanding of coastal dynamics. The role of coastal observations in model validation is highlighted, requiring remote sensing techniques such as coastal altimetry and new in-situ data collection technologies such

as drifter buoys, HF radars, particularly during the ice season when conventional field observation is not possible. Improving our understanding of the wave climate in diverse environments (i.e., interacting with ice, vegetation, rocky beaches, and coastal structures) through more observations and with more accurate numerical models will help to better evaluate and design coastal protection with nature-based solutions, so-called Engineering with Nature, to improve coastal resilience.

270 *Code availability.* The current version of GLWUv2.0 modeling system, including the workflow, the WW3 model, and input files to produce the results, shown in this paper, can be accessed at the Zenodo archive: <https://doi.org/10.5281/zenodo.8341987> under the Lesser GNU Public License v3.

Acknowledgements. The author wishes to thank Dr. Robert E. Jensen for the fruitful discussions on the future of wave modeling/observations in the Great Lake area. The authors acknowledge the NOAA's Great Lakes Environmental Research Laboratory (GLERL) for providing the bathymetry and coastline of the Lake Champlain and buoy #45195 observations, Dr. Greg Mann from the National Weather Service, Detroit office for providing 10 storm cases, the forecast officers at the Great Lakes WFOs for their feedback during the evaluation period, particularly during ice season, when eyewitnesses were the only source of validation, EMC Engineering and Implementation Branch and NCEP Central Operation (NCO) for their help during GLWUv2.0 transition to operations.

Figure A1. Atmospheric Model validation at the buoy locations, HWRf (blue) versus observations (black): (top) Wind speed; (bottom) Wind direction.

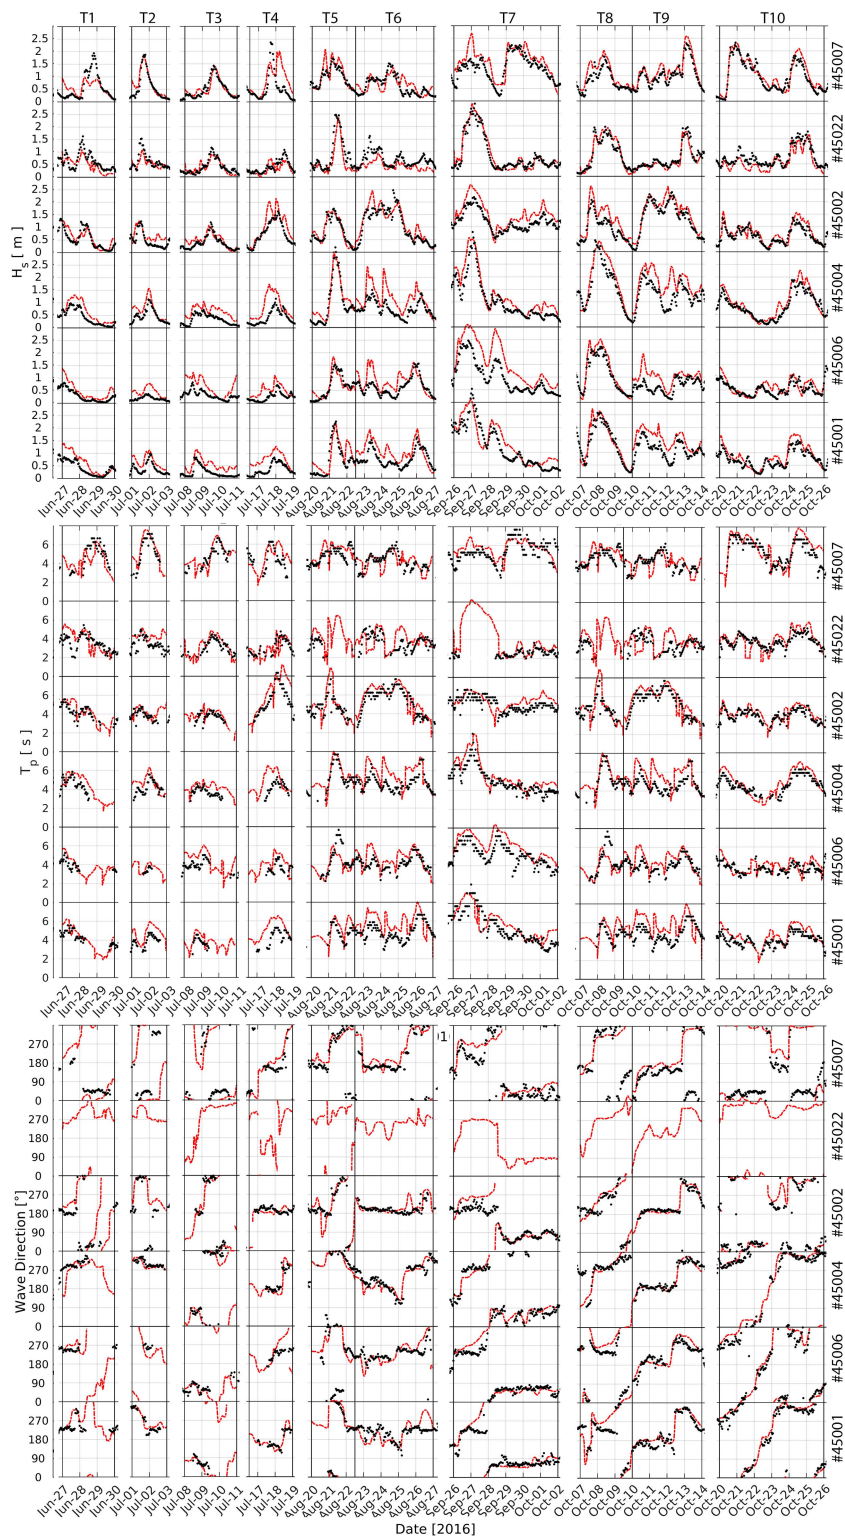

Figure B1. Wave Model validation at the buoy locations, WW3 (red) versus observations (black): (top) Significant wave height; (middle) Peak Period; (bottom) Wind direction.
