Abstract. We describe the development of the tangent linear (TL) and adjoint models of the MPAS-CO₂ transport model, which is a global online chemical transport model developed upon the non-hydrostatic Model for Prediction Across Scales-Atmosphere (MPAS-A). The primary goal is to make the model system a valuable research tool for investigating atmospheric carbon transport and inverse modeling. First, we develop the TL code, encompassing all CO₂ transport processes within the MPAS-CO₂ forward model. Then, we construct the adjoint model using a combined strategy involving re-calculation and storage of the essential meteorological variables needed for CO₂ transport. This strategy allows the adjoint model to undertake long-period integration with moderate memory demands. To ensure accuracy, the TL and adjoint models undergo vigorous verifications through a series of standard tests. The adjoint model, through backward-in-time integration, calculates the sensitivity of atmospheric CO₂ observations to surface CO₂ fluxes and the initial atmospheric CO₂ mixing ratio. To demonstrate the utility of the newly-developed adjoint model, we conduct simulations for two types of atmospheric CO₂ observations: tower-based *in situ* CO₂ mixing ratio and satellite-derived column-averaged CO₂ mixing ratio (X_{CO_2}). A comparison between the sensitivity to surface flux calculated by the MPAS-CO₂ adjoint model with its counterpart from Carbon Tracker-Lagrange (CT-L) reveals spatial agreement but notable magnitude differences. These differences, particularly evident for X_{CO_2} , might be attributed to the two model systems' differences in simulation configuration, spatial resolution, and treatment of vertical mixing processes. Moreover, this comparison highlights the substantial loss of information in the atmospheric CO₂ observations due to CT-L's spatial domain limitation. Furthermore, the adjoint sensitivity analysis demonstrates that the sensitivities to both surface flux and initial CO₂ conditions spread out throughout the entire northern hemisphere within a month. MPAS-CO₂ forward, TL, and adjoint models stand out for their calculation efficiency and variable-resolution capability, making them competitive in computational cost. In conclusion, the successful development of the MPAS-CO₂ TL and adjoint models, and their integration into the MPAS-CO₂ system, establish the possibility of using MPAS's unique features in atmospheric CO₂ transport sensitivity studies and in inverse modeling with advanced methods such as variational data assimilation.

1 Introduction

Estimating CO₂ fluxes through inverse modeling, using atmospheric chemical transport models and atmospheric CO₂ measurements, is an important approach for understanding the global carbon budget. Beyond providing seasonal flux estimates that are useful for understanding the magnitude and phase of photosynthesis and respiration, it provides annual mean flux estimates that shed light on the key processes driving the response to climate change. When these annual mean CO₂ estimates are adjusted to account for lateral fluxes (e.g., due to rivers, or the transport of crops and wood products), it gives an independent means of validating carbon stock change estimates from the terrestrial biogeochemical models and inventories (Byrne et al., 2023). However, atmospheric transport models, which play a key role in inverse modeling, remain a significant source of uncertainty on both regional and global scales (Schuh et al., 2019, 2022; Hurtt et al., 2022).

Two classes of chemical transport models – online and offline – are commonly used for simulating atmospheric CO₂ transport. Offline models, such as TM5 (Krol et al., 2005; Meirink et al., 2006), PCTM (Kawa et al., 2004; Baker et al., 2006) and GEOS-Chem (Kopacz et al., 2009), solve the tracer continuity equation using winds and vertical mixing fields computed from an independent run of a meteorological model or from a meteorological analysis. Online models, such as WRF-Chem (Grell et al., 2011), OLAM (Walko and Avissar, 2008; Schuh et al., 2021), and MPAS-CO₂ (Skamarock et al., 2012; Zheng et al., 2021), integrate chemistry, transport and meteorology simultaneously. Although offline models typically have lower computational costs, the separation of chemistry/transport from meteorology leads to a loss of information regarding atmospheric processes occurring at time scales shorter than the meteorological model output frequency (Grell et al., 2005). In comparison, online models, owing to their simultaneous integration of meteorology and chemistry, have the potential to improve transport accuracy, particularly for vertical transport of chemistry. Recent advances in computer power and parallelization have greatly reduced the computational cost of online transport models, making them increasingly more accessible and practical for atmospheric CO₂ research.

A number of studies have demonstrated that transport model accuracy can be improved by increasing the model's horizontal resolution (Feng et al., 2016; Agusti-Panareda et al., 2019). Because global high-resolution CO₂ transport simulations are computationally demanding, limited-area models (regional models) are often used instead (Pillai et al., 2012; Lauvaux et al., 2012; Zheng et al., 2018). However, regional models introduce the lateral boundary condition, posing challenges for CO₂ inverse modeling (Zheng et al., 2019; Rayner et al., 2019). As a global online chemical transport model, MPAS-CO₂ (Zheng et al., 2021) avoids the lateral boundary condition problem. Like OLAM (Schuh et al., 2021), MPAS-CO₂ uses a global variable-resolution mesh to facilitate local grid refinement for high-resolution simulations in specific regions without incurring prohibitively high computational costs and avoiding the disadvantages of lateral boundary conditions.

The primary objective of this study is to develop the tangent linear (TL) and adjoint (AD) models associated with the global online transport model MPAS-CO₂ (Zheng et al., 2021). Adjoint model techniques have been widely used in both meteoro-

logical and atmospheric greenhouse gas research (Errico, 1997; Courtier et al., 1994; Giering et al., 2006; Meirink et al., 2008; Henze et al., 2007; Tian and Zou, 2021), and play critical roles in variational data assimilation and sensitivity analyses (Baker et al., 2006; Zheng et al., 2018; Tian and Zou, 2020).

60 The subsequent sections of this paper provide an overview of the MPAS-CO₂ forward model developed in Zheng et al. (2021) (Section 2), and the development and verification of the TL and AD models based on the forward model (Sections 3 & 4). The utility of the newly developed AD model is demonstrated with adjoint sensitivity analyses in Section 5. Finally, a summary and conclusions are given in Section 6.

2 MPAS-CO₂ forward model

65 Zheng et al. (2021) documented the development of MPAS-CO₂, verifying its mass conservation and assessing its accuracy. Hereafter, we refer to MPAS-CO₂ as the forward model, whose TL and AD model counterparts we develop in the present paper. A brief description of the forward model is provided here; see Zheng et al. (2021) for comprehensive details. The forward model characterizes CO₂ transport through the continuity equation:

$$\frac{\partial(\tilde{\rho}q_{co_2})}{\partial t} = -(\nabla \cdot \tilde{\rho}q_{co_2} \mathbf{V})_{\zeta} + F_{bl} + F_{cu} \quad (1)$$

70 where q_{co_2} is CO₂ dry air mixing ratio, $\tilde{\rho} = \rho_d/(\partial\zeta/\partial z)$, ρ_d is dry air density, ζ is the vertical coordinate, z is geometric height, t is time, and $\mathbf{V} = (u, v, w)$ is the velocity vector (u , v , and w are the zonal, meridional, and vertical wind components, respectively). The meteorological variables, such as wind velocity and dry air density, are updated simultaneously with CO₂ by the model's dynamical core and physics parameterizations. The left-hand side (LHS) of Eq. (1) is the total CO₂ time tendency ($\partial(\tilde{\rho}q_{co_2})/\partial t$). The first term on the right-hand side (RHS) represents the contributions to CO₂ time tendency from the advection. The second (F_{bl}) and third (F_{cu}) terms of RHS represent the contribution from the vertical mixing by the planetary boundary layer (PBL) and cumulus convective transport parameterizations, respectively. Advection of CO₂ in MPAS-CO₂ is handled in the model's dynamical core and can be expressed as Eq. (2), where the first two terms on the RHS represent the horizontal advection, and the third term represents the vertical advection:

$$(\nabla \cdot \tilde{\rho}q_{co_2} \mathbf{V})_{\zeta} = \left[\frac{\partial(\tilde{\rho}uq_{co_2})}{\partial x} + \frac{\partial(\tilde{\rho}vq_{co_2})}{\partial y} \right]_{\zeta} + \frac{\partial(\tilde{\rho}wq_{co_2})}{\partial \zeta} \quad (2)$$

80 CO₂ vertical mixing by the PBL parameterization is implemented based on the YSU scheme (Hong et al., 2006) and can be expressed as:

$$\left[\frac{\partial q_{co_2}}{\partial t} \right]_{bl} = \frac{\partial}{\partial z} \left[K_h \left(\frac{\partial q_{co_2}}{\partial z} \right) - \overline{(w'q'_{co_2})_h} \left(\frac{z}{h} \right)^3 \right] \quad (3)$$

where z is the vertical distance to the surface, h is the boundary layer top height, and K_h is the vertical eddy diffusivity. The second term of the RHS in the square bracket of Eq. (3) represents the contribution from CO₂ entrainment flux at the inversion layer. The term $[\partial q_{CO_2}/\partial t]_{bl}$ from Eq. (3) is coupled with dry-air density $\tilde{\rho}$ to form the term F_{bl} of Eq. (1).

Convective transport of CO₂ is implemented based on the Kain-Fristch convection scheme (Kain, 2004) and it can be expressed as Eq. (4)

$$\left[\frac{\partial q_{CO_2}}{\partial t} \right]_{cu} = \frac{(M_u + M_d)}{\rho A} \frac{\partial q_{CO_2}}{\partial z} + \frac{M_{ud}}{M} (q_{CO_2}^u - q_{CO_2}) + \frac{M_{dd}}{M} (q_{CO_2}^d - q_{CO_2}) \quad (4)$$

where q_{CO_2} , $q_{CO_2}^u$, and $q_{CO_2}^d$ are the CO₂ mixing ratio in the environment, updraft, and downdraft, respectively, M_u and M_d are the updraft and downdraft mass, respectively, ρ is the environment air density, A is the horizontal area of a cell, $M = \rho A \delta z$ is the mass of environmental air in a grid box, and M_{ud} and M_{dd} are the detrainment from the updraft and downdraft, respectively. The term $[\partial q_{CO_2}/\partial t]_{cu}$ of Eq. (4) is coupled with dry-air density $\tilde{\rho}$ to form the term F_{cu} of Eq. (1).

95 3 Development of the MPAS-CO₂ TL model

3.1 TL model development

The CO₂ advective transport process described in Eq. (2) is implemented by two different numerical schemes in the forward model: (1) a monotonic scheme with hyperviscosity (β) set to 0.25; and (2) a non-monotonic scheme with $\beta = 1.0$ (Skamarock et al., 2012). The monotonicity in the first scheme is achieved by applying a flux limiter in the last step of the third-order Runge-Kutta solver (Wang et al., 2009; Skamarock and Gassmann, 2011). While the second scheme is linear in CO₂, the first scheme is nonlinear due to the application of the flux limiter. Because both the YSU PBL and Kain-Fristch convection schemes are linear in CO₂, using the linear advective scheme makes the forward model a linear model in CO₂. In this paper, we develop the TL and adjoint models based on the linear version of the MPAS-CO₂ forward model, which can be symbolically expressed as:

$$105 \quad \mathbf{x}_t = \mathcal{M}(\mathbf{x}_0, \mathbf{e}), \quad (5)$$

where \mathbf{x}_0 and \mathbf{x}_t are the CO₂ dry air mixing ratio at the initial and forecast time (t), respectively. $\mathcal{M}(\cdot)$ represents the MPAS-CO₂ forward model and \mathbf{e} represents a timeseries of CO₂ fluxes between times 0 and t . While both \mathbf{x}_0 and \mathbf{x}_t are 3-dimensional in space, \mathbf{e} is 2-dimensional in space, indicating that CO₂ flux is applied only to the model's surface cells. Eq.(5) indicates that CO₂ mixing ratio at a forecast time (\mathbf{x}_t) is determined by the CO₂ mixing ratio at an initial time (\mathbf{x}_0) and the CO₂ flux (\mathbf{e}) through the forward model.

The TL and adjoint models are designed to calculate the sensitivity of \mathbf{x}_t with respect to \mathbf{x}_0 and \mathbf{e} . This is achieved by introducing the TL and adjoint variables of their counterparts in the forward model (Giles and Pierce, 2000). While the introduction of the TL and adjoint variables for the initial CO₂ mixing ratio (\mathbf{x}_0) is straightforward, it is a bit more complex for the CO₂ fluxes (\mathbf{e}). This complexity arises from the fact that CO₂ flux, at each surface cell of the model, varies with time throughout the model's entire simulation period. Depending on the underlying biosphere model and emission inventory used, CO₂ flux varies at a certain temporal frequency, ranging from hourly to monthly. Although it is possible to introduce TL and adjoint variables for CO₂ flux at the flux's temporal frequency, it is neither practical nor necessary to do so. Instead, a common approach is to introduce flux scaling factors (Henze et al., 2007; Zheng et al., 2018) as follows:

$$120 \quad \mathbf{e} = \mathbf{S}(\mathbf{k})\tilde{\mathbf{e}}, \tag{6}$$

where $\tilde{\mathbf{e}}$ are time-variant CO₂ fluxes, typically from a process model or inventory, and $\mathbf{S}(\mathbf{k})$ is a generic scaling function. Eq. (6) means that at each surface cell, the magnitude of the CO₂ flux ($\tilde{\mathbf{e}}$) is adjusted using a flux scaling factor before it is used to modify the cell's CO₂ mixing ratio. We implemented Eq. (6) in the forward model in a way that allows the flexibility of choosing the temporal frequency of the flux scaling factor. For instance, for a 24-hour forward model simulation forced by 3-hourly CO₂ flux, one can choose to have eight scaling factors at each surface cell (one for each of the eight 3-hour segments), or just one scaling factor for the entire time period. All the MPAS-CO₂ model runs used in the remainder of this paper are conducted using a single scaling factor for each surface cell that is repeated for each flux timestep in the entire simulation period. In this case, the scaling function $\mathbf{S}(\mathbf{k})$ in Eq. (6) is a function of a scaling vector \mathbf{k} that has the same dimension as the model's surface mesh. The introduction of the flux scaling factors turns CO₂ flux from active variables to parameters, and the impacts of their variation on CO₂ mixing ratio are calculated through their corresponding scaling factors \mathbf{k} . Accordingly, the MPAS-CO₂ forward model can be symbolically expressed as

$$\mathbf{x}_t = \mathcal{M}(\mathbf{x}_0, \mathbf{k}) \tag{7}$$

Eq. (7) shows that for a given set of CO₂ flux ($\tilde{\mathbf{e}}$), the forecast time CO₂ mixing ratio (\mathbf{x}_t) is a function of the initial time CO₂ mixing ratio (\mathbf{x}_0) and the flux scaling factor (\mathbf{k}).

135

The TL counterpart of the MPAS-CO₂ forward model represented by Eq. (7) can be symbolically expressed as the first derivative of the forward model:

$$\Delta \mathbf{x}_t = \mathbf{M}(\Delta \mathbf{x}_0, \Delta \mathbf{k}) \tag{8}$$

where $\mathbf{M}(\)$ represents the MPAS-CO₂ TL model, $\Delta \mathbf{x}_0$ and $\Delta \mathbf{x}_t$ are the TL variable of CO₂ mixing ratio at the initial and forecast time, respectively, and $\Delta \mathbf{k}$ is the TL variable of the flux scaling factor \mathbf{k} . In essence, Eq. (8) shows that the TL model computes the perturbation in the forecast time CO₂ mixing ratio ($\Delta \mathbf{x}_t$), given the perturbation in the flux scaling factor ($\Delta \mathbf{k}$)

and/or perturbation in the initial time CO₂ mixing ratio ($\Delta\mathbf{x}_0$).

Based on the source code of the forward model, we developed the TL code by differentiating each process relevant to CO₂ flux and transport, including advection, vertical mixing by the YSU PBL scheme, convective transport by the Kain-Fritsch scheme, and the CO₂ emission driver that implements Eq. (6). Automatic differentiation tools, such as Tapenade (Hascoet and Pascual, 2013) and Tangent and Adjoint Model Compiler (Giering and Kaminski, 1998), can be used to assist TL and adjoint code generation. However, the code these tools generate typically contains redundancies and is difficult to read, particularly for the adjoint code. To optimize the computation efficiency and facilitate future code upgrading, we manually developed the TL and adjoint code for MPAS-CO₂ with some minor assistance from Tapenade.

3.2 TL model validation

After the TL model is completed, a thorough examination of its correctness was undertaken. As indicated in Eq. (8), the TL model can calculate the sensitivity of \mathbf{x}_t with respect to both \mathbf{x}_0 and \mathbf{k} . The calculation of the sensitivity of \mathbf{x}_t with respect to \mathbf{x}_0 involves the TL code of all the CO₂ transport processes, including advection, PBL, and convective transport. In comparison, the calculation of the sensitivity of \mathbf{x}_t with respect to the flux scaling factor \mathbf{k} involves the TL code of the CO₂ emission driver in addition to the TL code of all the CO₂ transport processes. Because the calculation of sensitivity to \mathbf{k} includes the TL code of all the processes in the TL model, and because both the transport processes and emission driver are linear, the correctness of the entire MPAS-CO₂ TL model can be verified by checking whether the following equation is satisfied (Errico, 1997; Tian and Zou, 2020):

$$\Phi(\alpha) = \frac{\|\mathcal{M}(\mathbf{x}_0, (1 + \alpha)\mathbf{k}) - \mathcal{M}(\mathbf{x}_0, \mathbf{k})\|}{\|\mathbf{M}(0, \alpha\mathbf{k})\|} = 1, \quad (9)$$

where $\mathbf{M}()$ is the TL model, $\mathcal{M}()$ is the forward model and α is a scalar. The second item in the numerator of Eq. (9), $\mathcal{M}(\mathbf{x}_0, \mathbf{k})$, is a forward model run. The first item in the numerator, $\mathcal{M}(\mathbf{x}_0, (1 + \alpha)\mathbf{k})$ is an identical forward model run except that its flux scaling factor at each surface cell is adjusted by multiplying $1 + \alpha$. In the denominator, $\mathbf{M}(0, \alpha\mathbf{k})$ is a TL model run with its perturbation in initial time CO₂ mixing ratio set to zero ($\Delta\mathbf{x}_0 = 0$) and perturbation in flux scaling factor $\Delta\mathbf{k} = \alpha\mathbf{k}$, which is the difference in the flux scaling factors between the two forward model runs.

If the TL model is correctly coded with regard to the forward model, Eq. (9) should be satisfied to the extent of machine accuracy until α is too small that the result is affected by round-off errors and drifts away from unity. To verify using Eq. (9), we ran a series of simulations using the forward model and newly developed tangent linear model with the scale factor α ranging from 1.0×10^3 to 1.0×10^{-4} (Table 1). All the simulations start at 2018-10-01 00:00 UTC, run for 1 month, and end at 2018-11-01 00:00 UTC. The meteorological initial condition is from the ERA5 reanalysis (Hoffmann et al., 2019) and the CO₂ initial condition (\mathbf{x}_0) is from the Carbon Tracker (Jacobson et al., 2020) v2022 (CT2022) posterior CO₂ mole fraction

at this time. Three-hourly CO₂ fluxes for the biogenic, fire, fossil fuel, and oceanic components from the CT2022 posterior
 175 are applied throughout the 1-month simulation period for each model run. Flux scaling factors of $\mathbf{k} = \mathbf{1}$ were used in all our
 simulations here, with $\mathbf{1}$ being a vector the same length as \mathbf{k} with ones in every element. The model simulations are conducted
 using the global variable-resolution (VR) mesh shown in Fig. 1. This VR mesh has a total of 15,898 cells, which range from
 120 km over most of the land regions to 480 km over oceans. Table 1 shows that the magnitudes of both the numerator and
 the denominator in Eq. (9) decrease as α decreases. Moreover, the table also shows that the ratio remains close to unity until α
 180 decreases to 1.0×10^{-1} , beyond which round-off errors lead to a deviation from unity. These results confirm that the MPAS-
 CO₂ TL model has been correctly developed with regard to the forward model. In the next section, we proceed to develop the
 MPAS-CO₂ adjoint model.

4 Development of the MPAS-CO₂ adjoint model

185 4.1 Adjoint model development

An adjoint model is an essential component of a variational data assimilation system and is very useful for adjoint sensitivity
 analysis (Tian and Zou, 2021; Zheng et al., 2018; Bosman and Krol, 2023). Symbolically, the MPAS-CO₂ adjoint model can
 be expressed as:

$$(\Delta \hat{\mathbf{x}}_0, \Delta \hat{\mathbf{k}}) = \mathbf{M}^T(\Delta \hat{\mathbf{x}}_t), \quad (10)$$

190 where $\mathbf{M}^T(\cdot)$ is the MPAS-CO₂ adjoint model, $\Delta \hat{\mathbf{k}}$ is the adjoint variable of the flux scaling factor, and $\Delta \hat{\mathbf{x}}_0$ and $\Delta \hat{\mathbf{x}}_t$ are the
 adjoint variables of CO₂ mixing ratio at the initial and forecast time, respectively. Eq. (10) shows that starting with $\Delta \hat{\mathbf{x}}_t$
 at the forecast time, the MPAS-CO₂ adjoint model runs backward in time to the initial time while ingesting CO₂ observations
 along the way, resulting in the adjoint variable of CO₂ mixing ratio at the initial time ($\Delta \hat{\mathbf{x}}_0$), and the adjoint variable of the
 flux scaling factor ($\Delta \hat{\mathbf{k}}$).

195

Similar to its TL model counterpart, the development of the MPAS-CO₂ adjoint model was carried out through manual
 implementation to avoid redundancy and optimize computational efficiency. The calculation of the CO₂ transport needs ac-
 cess to the meteorological fields at each time step. Since the forward and TL model both run forward in time, this access is
 straightforward. However, because the adjoint model runs backward in time, accessing the meteorological fields is more chal-
 200 lenging. One approach to this problem is saving meteorological fields in memory during the adjoint model's forward sweep,
 enabling accessing during the subsequent backward sweep (Guerrette and Henze, 2015; Zheng et al., 2018). However, since the
 MPAS-CO₂ adjoint model is intended for long simulations, this approach becomes impractical due to the excessive memory it
 demands. As an alternative strategy, we adopt an approach that combines both recalculation and storage of the meteorological
 fields. This strategy effectively divides a long simulation into segments, and the forward and backward sweeps are carried out

205 sequentially for each segment, requiring internal memory only large enough to accommodate one segment’s worth of meteorological fields. This internal manipulation is handled seamlessly by the adjoint model, enabling it to run as long as needed without overburdening memory resources. Another strategy we adopted for developing the adjoint code is to have the forward sweep save some immediate variables that are needed by the subsequent backward sweep so that they do not need to be recalculated. For instance, the values of some variables related to mass fluxes in the Kain-Fritsch convection scheme Kain (2004) 210 are saved by the forward sweep in the memory to speed up the subsequent backward sweep execution. This strategy not only increases the adjoint model efficiency but also simplifies some of its code development.

4.2 Adjoint model validation

The correctness of the newly developed MPAS-CO₂ adjoint model can be verified using the following equation (Tian and Zou, 215 2020):

$$\langle \Delta \mathbf{x}, \mathbf{M}(0, \Delta \mathbf{k}) \rangle = \langle \mathbf{M}^T(\Delta \mathbf{x}), \Delta \mathbf{k} \rangle, \quad (11)$$

where $\langle \rangle$ represents the inner product operator, $\Delta \mathbf{x}$ is a perturbation of CO₂ mixing ratio and $\Delta \mathbf{k}$ is a perturbation of CO₂ flux scaling factor. If the adjoint model is correctly coded with respect to the TL model, Eq. (11) should be satisfied for any choice of $\Delta \mathbf{x}$ and $\Delta \mathbf{k}$. $\mathbf{M}(0, \Delta \mathbf{k})$ on the LHS of the equation is the perturbation in forecast CO₂ mixing ratio resulting from a 220 TL model run whose perturbation in initial CO₂ mixing ratio is set to zero and perturbation to flux scaling factor is set to $\Delta \mathbf{k}$. The first item of the RHS, $\mathbf{M}^T(\Delta \mathbf{x})$, represents the adjoint variable of flux scaling factor, which is an output from the adjoint model integration from the forecast time backward to the initial time. The TL and adjoint model runs on the two sides of Eq. (11) have the same simulation time period, but the latter runs backward in time.

225 We conducted two sets of experiments using the TL and adjoint models following Eq. (11) to verify the correctness of the newly developed adjoint model. In the first set of experiments, we set $\Delta \mathbf{k} = 10^{-1} \mathbf{1}$, and $\Delta \mathbf{x} = \mathbf{M}(0, \Delta \mathbf{k})$. The experiments were carried out in two steps: First, the TL model was integrated 7 days from the initial time (2018-10-01 00:00 UTC) to the end time (2018-10-08 00:00 UTC), with $\Delta \mathbf{k} = 10^{-1} \mathbf{1}$, resulting in $\mathbf{M}(0, \Delta \mathbf{k})$ which is the perturbation in forecast time CO₂ mixing ratio; Second, the adjoint model is initialized at 2018-10-08 00:00 UTC with its adjoint variable for CO₂ mixing 230 ratio set to $\mathbf{M}(0, \Delta \mathbf{k})$. The adjoint model is then integrated backward in time for 7 days to 2018-10-01 00:00 UTC, resulting in $\mathbf{M}^T(\Delta \mathbf{x})$. The LHS and RHS of Eq. (11) are then calculated using the above results (Table 2). The table shows that the agreement between the LHS and RHS of Eq. (11) is about -5.16×10^{-15} . We note that this value is not exactly zero due to the machine rounding errors. This experiment is repeated with the same configuration but the simulation length is increased to 31 days, ending at 2018-11-01 00:00 UTC. As expected, the magnitude of both the LHS and RHS increased, and 235 they agreed to about -2.55×10^{-16} . In the second set of the experiment, $\Delta \mathbf{k} = 10^{-1} \mathbf{1}$ (same as the first set of experiments), but $\Delta \mathbf{x} = \mathcal{M}_{14d}(\mathbf{x}_0, \mathbf{k})$, which is the CO₂ mixing ratio at the end of 14-day forward model run (2018-10-01 00:00 UTC to

2018-10-15 00:00 UTC). We note that this forward model run uses \mathbf{x}_0 from CT2022 posterior CO₂ mole fraction, and $\mathbf{k} = \mathbf{1}$, however, Eq. (11) should satisfy for any configuration and simulation period of the forward model. The resulting LHS and RHS of Eq. (11) from the second set of experiments are about 2 orders of magnitude larger than their counterpart of the first experiments. This is caused by the much larger $\Delta\mathbf{x}$ of the second set of experiments. The LHS and RHS agree to about -3.42×10^{-15} for the 7-day simulation and about 2.66×10^{-15} for the 31-day simulation (Table 2).

The results shown in Table 2 obtained from the experiments based on Eq. (11) confirm that the MPAS-CO₂ adjoint model has been correctly developed with regard to the TL model. As the TL model has already been confirmed correct with respect to the forward model, it follows that both TL and adjoint models are correct with respect to the forward model of MPAS-CO₂. This validation ensures the reliability and integrity of the entire MPAS-CO₂ model system since the forward model has already been validated in Zheng et al. (2021). It allows MPAS-CO₂ to be used as the basis of a variational assimilation system for carbon flux estimation and as a platform for conducting sensitivity analyses in atmospheric carbon research.

Table 3 presents the computational cost of model simulations using the MPAS-CO₂ system. Using the global 120-480 km VR mesh (Fig. 1; 15898 cells), the 1-month forward model simulation completes in 20 minutes when using 128 processors. Both the TL and adjoint model simulations using the same configuration take approximately 10% longer than the forward model. This extra computation time for the TL/adjoint model is incurred by the execution of the TL/adjoint code of the CO₂ transport processes. Furthermore, we conducted another set of 1-month simulations using the models on a global quasi-uniform resolution (UR) mesh of about 120 km, consisting of a total of 40,962 cells. Table 3 demonstrates that the simulations with the VR mesh reduce the computational cost by over 50% for all three models, primarily due to its substantially smaller number of cells. This reduction in computation cost, while preserving the high resolution over areas of interest, should prove advantageous when the models are applied in variational assimilation problems, which typically require many iterations of forward and adjoint model runs.

260

5 Adjoint sensitivity analysis

5.1 Comparison with CT-L footprints

In addition to forming a key component of variational assimilation systems (Baker et al., 2006; Zheng et al., 2018; Tian and Zou, 2021), adjoint models are powerful tools for sensitivity analysis (Errico and Vukicevic, 1992; Errico, 1997; Zou et al., 1997; Tian and Zou, 2020). Studies focused on carbon flux estimation are often interested in exploring the sensitivity of atmospheric CO₂ measurements to surface CO₂ fluxes. This sensitivity is commonly referred to as observation influence functions or footprints (Cui et al., 2022). The computation of observation footprints using forward models requires a large number of model runs, making it impractical, except for optimizing state vector elements at coarse horizontal resolutions. In contrast, adjoint models can calculate observation footprints much more efficiently. For point measurements, such as those from tower

270 data, Lagrangian dispersion models offer an efficient alternative for obtaining footprints (Lin et al., 2003; Stohl et al., 2005). For an example of this, see the publicly available CO₂ observation footprints from Carbon Tracker- Lagrange (CT-L) (Hu et al., 2019), which are generated using the Lagrangian particle dispersion model STILT (Lin et al., 2003), driven by meteorology generated by the Weather Research and Forecast (WRF) model (Skamarock et al., 2008). This approach involves releasing a certain number of particles from the observation location/height and tracing their backward transport in time. Note that CT-L
275 is a regional modeling system that only provides observation footprints within the latitude range 10°-80° N and longitude 0°-180° W for up to 10 days backward in time.

In this section, we perform sensitivity analyses using the MPAS-CO₂ adjoint model, which employs backward-in-time integration to calculate two quantities: (1) the sensitivity of atmospheric CO₂ to the model's initial CO₂ mixing ratio, and (2)
280 the sensitivity to the surface flux scaling factor. When a spatially uniform time-invariant surface flux of unity value is used and $S(\mathbf{k}) = \mathbf{k}$ in Eq. (6), the sensitivity to the surface flux scaling factor calculated by the MPAS-CO₂ adjoint model is the observation footprint. To compare with CT-L footprints, all MPAS-CO₂ adjoint model simulations conducted in this section use a time-invariant CO₂ surface fluxes of 1.0 $\mu\text{mol}/(\text{m}^2 \text{ s})$ for all surface cells, including both land and ocean cells. Because $S(\mathbf{k}) = \mathbf{k}$ is used, Eq. (6) takes the form of $\mathbf{e} = \mathbf{k}\tilde{\mathbf{e}}$. The units of the CO₂ flux ($\mu\text{mol m}^{-2} \text{ s}^{-1}$) and the multiplicative nature
285 of the flux scaling factor \mathbf{k} determine the units of the adjoint variable $\Delta\hat{\mathbf{k}}$ (which represents observation footprints) to be $\text{ppm}/(\mu\text{mol m}^{-2} \text{ s}^{-1})$. Meteorological initial conditions for MPAS-CO₂ model simulations conducted in this section are from the ERA5 reanalysis (Hoffmann et al., 2019). Footprints calculated by the MPAS-CO₂ adjoint model are of the 120-480km variable resolution grid while the CT-L footprints are of $1^\circ \times 1^\circ$.

290 First, we conduct MPAS-CO₂ adjoint model simulations for *in situ* CO₂ observations at two towers in the United States: WKT, located at Moody, Texas (31.31° N, 97.33° W), and WGC, located at Walnut Grove, California (38.26° N, 121.49° W). For each tower, the adjoint model is initialized at 00:00 UTC on March 31, 2018. We add an adjoint forcing of 1 ppm CO₂ at that time to the model grid cell closest to the tower location and the intake height (457m at WKT and 483m at WGC). The forcing is turned off for subsequent time steps and the adjoint model is run backward in time for 30 days, ending at 00:00 UTC
295 on March 1, 2018. The resulting sensitivity of CO₂ at the WKT tower to the model's CO₂ mixing ratio, which is 3-dimensional, is shown as a column average in the left panel of Fig. 2. The right panel of Fig. 2 shows the observation footprint (sensitivity to the surface flux scaling factor) at the corresponding times. The figure panels show that the sensitivity to the initial CO₂ is highest and concentrated closest to the tower site at the time closest to the measurement: 5-days. With the increasing length of the backward-in-time integration, the sensitivity spreads over a larger area and its magnitude decreases. After 30 days, the
300 sensitivity to the initial condition has propagated across most of the northern hemisphere. Figure 2 also indicates that the spatial variation in the sensitivity magnitude decreases with time. To examine this, we calculated the standard deviation (σ) of sensitivity for each day of the 30 days (Fig. 3). The triangles in Fig. 3 show that the magnitude of the standard deviation of the sensitivity to the initial CO₂ mixing ratio decreases rapidly with the increasing length of the adjoint model simulation for both towers. On the other hand, the sensitivity to the surface flux scaling factor (footprint) exhibits a different pattern from the sensi-

305 tivity to the initial CO_2 mixing ratio. As shown in Fig. 2, the footprint spreads spatially but the near field to the tower maintains a much higher magnitude than the far fields. By the end of 30 days, the footprint of the WKT tower covers almost the entire northern hemisphere, with the area north and northwest of the tower within the conterminous United States exhibiting a much higher magnitude than the more distant area. The circles in Fig. 3 indicate that the standard deviation of the footprint increases with time, but the rate of increase diminishes substantially after about 10 to 15 days. The finding suggests that extending the ad-
310 joint model integration further backward in time will still result in changes to the footprint but with a much-reduced change rate.

For comparison, in Fig. 4 we plot the MPAS- CO_2 adjoint model-calculated 10-day footprints in the CT-L geographic domain. The figure reveals that the MPAS- CO_2 adjoint model-calculated WKT tower footprint spans most of the western and northwestern United States, with the highest sensitivity in Texas, Missouri, Iowa, Kansas, and Nebraska. Additionally, the foot-
315 print extends to a substantial area over the northeastern Pacific Ocean. The spatial pattern of the CT-L calculated footprint (Fig. 4c) is similar to that from the MPAS- CO_2 adjoint model, but it is visibly less continuous. Fig. 4 also shows that the MPAS- CO_2 adjoint model-calculated footprint for the WGC tower covers northern California, Oregon, west Nevada, and a portion of the northeastern Pacific Ocean. The CT-L-calculated footprint exhibits a similar spatial pattern and magnitude. Overall, both the MPAS- CO_2 adjoint model and CT-L provide valuable information on the sensitivity of atmospheric CO_2 measurements to the
320 surface flux: similar spatial patterns although with some differences due to resolution and the Lagrangian/Eulerian framework difference.

In the second set of experiments, we compare CT-L and MPAS- CO_2 adjoint model footprints for a swath of OCO-2 X_{CO_2} measurements. The ground track of the OCO-2 orbit used in the experiments is indicated by the blue color line in Fig. 1.
325 This orbit crosses North America from the Caribbean Sea to Canada's Northwest Territories in a northward direction between 18:31 UTC and 18:48 UTC on June 30, 2016. Since OCO-2 X_{CO_2} represents the column average of atmospheric CO_2 , CT-L calculates X_{CO_2} footprints at 14 discrete height levels, ranging from 50 to 14,000 meters above the ground. For each height level, footprints are computed by placing a number of particles at that specific height. To ensure consistency with the CT-L approach, the MPAS- CO_2 adjoint model is configured to apply the adjoint forcing at the corresponding vertical levels within
330 the model. This is done by interpolating the CT-L's 14 height levels to MPAS- CO_2 model's 55 vertical levels. This configuration allows for a direct comparison between the footprints calculated by the MPAS- CO_2 adjoint model and the CT-L footprints.

Figure 5 shows the footprints of a point located south of Jamaica in the Caribbean Sea (17.82°N , 77.88°W) at four different height levels: 500m, 2,000m, 4,500m, and 10,000m. The top three rows of Fig. 5 shows that both the MPAS- CO_2 adjoint
335 model and CT-L footprints largely extend eastward over the Atlantic Ocean, indicating transport from the surface due to the influence of the easterly trade winds. Additionally, the MPAS- CO_2 adjoint model-calculated footprint includes a branch that crosses the equator and extends southeastward to the southern hemisphere between 30°W and 40°W longitude. This feature is not shown in the CT-L footprint due to its limited-area domain. The bottom panel of Fig. 5 shows the footprints of 10,000 m calculated by both the MPAS- CO_2 adjoint and CT-L feature a primarily counterclockwise extension, covering the Gulf of

340 Mexico and Texas. Moreover, there is a second segment extending westward from Texas toward the west coast. Upon closer examination, we observe that the CT-L-calculated footprint has a lower magnitude than the MPAS-CO₂ adjoint model at the 500m, 2,000m, and 4,500m height levels, but not at the 10,000m height level. The distinct patterns in both systems' footprints at different height levels indicate significant differences in horizontal and vertical transport patterns.

345 Figure 6 shows the corresponding footprints for an OCO-2 X_{CO₂} sounding location in eastern Kentucky (36.8°N,82.9°W) for the same four height levels as shown in Fig. 5. The figure shows that the footprints of 500m and 2,000m extend predominantly northward, covering the Great Lakes region and part of the Canadian Shield. In comparison, the footprint for 4,500m is mostly directed to the west. Another notable difference is that the highest magnitude portion of the 500m and 2,000m footprints are in close proximity to the sounding location, while the 4,500m footprint is not in proximity at all. These differences among the height levels are evident in both the MPAS-CO₂ adjoint model and CT-L calculated footprints. Figure 7 shows the
350 footprints of an OCO-2 sounding location on the southwest coast of Hudson Bay, Canada (56.96°N, 91.89°W) for the four height levels. Both the MPAS-CO₂ adjoint and CT-L footprints for 500m and 2,000m are largely either close to or north of the sounding location, indicating that surface fluxes from these regions have a significant influence on the atmospheric CO₂ at the two height levels. In comparison, the footprint of 4,500m is located more than 2,000km northwestward, mostly covering
355 Alaska; the particles move that far horizontally in the time it takes them to advect and mix 4,500m in the vertical. These findings emphasize the significant impact of vertical mixing on the spatial distribution of footprint at different altitudes, highlighting the unique patterns of horizontal and vertical transport in each case.

In additional MPAS-CO₂ adjoint model runs, we quantitatively compare the footprints of the entire OCO-2 track at each of
360 the 14 height levels with the CT-L footprints. This comparison is conducted by performing a single MPAS-CO₂ adjoint model run for each height level to calculate the footprint at the end of the 10-day backward-in-time integration. We then compare these resulting footprints with their CT-L counterparts. Figure 8 shows the comparison at 4 height levels: 500m, 2,000m, 4,500m, and 10,000m above the surface. At each height level, the value in the figure represents the average of the footprints of all the cells that are part of the OCO-2 track. The figure reveals that the footprints calculated by the two systems have similar spatial
365 patterns within the limited-area domain of CT-L. However, it is important to note that a substantial portion of the footprints extends beyond the CT-L domain. For instance, the footprints of 2,000m and 4,500m levels have significant coverage over Russian Siberia, while the footprint of the 10,000m level extends from the eastern Pacific Ocean to northeastern and western China, both of which are outside the CT-L model domain.

370 In order to compare the footprints from the two systems quantitatively, we aggregated the footprints onto a 2° × 3° (lat×lon) grid within the area covered by the CT-L model domain for each of the 14 height levels. Figure 9 shows the comparison for each of the 14. In the figure, the CT-L calculated footprints are on the X-axis, and MPAS-CO₂ adjoint model calculated footprints are on the Y-axis. The solid line in each subfigure of Fig. 9 is the 1:1 line and the dashed line is a linear fit without intercept. The correlation coefficient R^2 is labeled in each subfigure. The figure demonstrates that the agreement between the

375 two systems is better for footprints at lower heights, particularly between 250m and 1,500m, with R^2 all greater than 0.7. Footprints from the two systems agree to a much lesser degree at between 3,500m and 14,000m, where R^2 is less than 0.5 in all cases. The linear fit lines (dashed lines) show that the MPAS-CO₂ adjoint model calculated footprints are of greater magnitude in general than their CT-L counterparts at heights ranging from 50m to 1,000m; Between 1,500m and 2,500m, the two sets of footprints are of similar magnitude on average; At 3,500m and above, the CT-L footprints are of larger magnitude in general.

380

These differences in magnitude between the two systems could be attributed to various factors, including differences in model configurations, spatial resolution, and treatment of vertical mixing processes. Previous studies have shown that Lagrangian models, such as CT-L, can sometimes have different vertical mixing behavior compared to Eulerian models, especially at high altitudes (Karion et al., 2019).

385

5.2 Influence of vertical distribution of OCO-2 soundings on footprints

In a final experiment, we use the MPAS-CO₂ adjoint model to examine the impact of different vertical distributions on footprint calculation. Two adjoint model simulations were conducted for the OCO-2 orbit that crosses South America and North America between 17:36 UTC and 18:13 UTC on August 23, 2016 (the red color track in Fig. 1). Both simulations have the same adjoint forcing of 1 ppm X_{CO_2} added to each MPAS-CO₂ model cell along the orbital track at 18:00 UTC on August 23, 2016, and running backward in time for 30 days. The difference between the two simulations lies in the vertical distributions of the adjoint forcing. For the first simulation, we adopt profile 1, which is obtained by combining the X_{CO_2} averaging kernel and pressure weight function (O'Dell et al., 2018). In contrast, profile 2 prioritizes X_{CO_2} information in the lower part of the troposphere (Fig. 10). The 20 pressure levels in the figure are interpolated to the MPAS-CO₂ model's 55 vertical levels for the adjoint forcing placement. This experiment aims to highlight how these differences in vertical distribution impact the footprint calculation, leading to variations in flux estimation using variational assimilation. The results of this experiment will provide valuable insights to the importance of selecting appropriate vertical distribution when using the adjoint model for CO₂ flux estimation.

400 The top two panels of Fig. 11 show the footprints resulting from MPAS-CO₂ adjoint model simulations using the two distinct vertical distribution profiles for the adjoint forcing (Fig. 10). Although the two footprints may initially appear very similar, substantial differences become evident as shown in the bottom panel in Fig. 11. Specifically, the footprint calculated using Profile 1 exhibits lower magnitudes compared to that obtained using Profile 2 in most extratropical regions in both the Northern Hemisphere and Southern Hemisphere. Conversely, over some of the tropical regions, particularly the tropical Pacific Ocean, the footprint calculated using Profile 1 shows slightly higher magnitudes than for Profile 2. Since the two adjoint model simulations have the same meteorology, these differences in the resulting footprints might be explained by how the convective transport of CO₂ impacts the two distinctive vertical distribution profiles of the adjoint forcing. The prevalence of deep convection over the tropical Pacific Ocean can more effectively transport surface CO₂ flux to the upper atmosphere than

405

over the extratropics, where surface CO₂ flux is more likely to be confined in the lower atmosphere. Thus Profile 1's higher
410 amount of adjoint forcing in the upper atmosphere results in its higher magnitude footprint over the tropical Pacific Ocean,
but not over the extratropics, where its lower amount of adjoint forcing in the lower atmosphere leads to its lower magnitude
footprint. These findings underscore the critical importance of selecting an appropriate vertical distribution for the model-data
difference when using an adjoint model during variational assimilation.

6 Conclusions

415 The MPAS-CO₂ system consists of forward, TL, and adjoint models that are built upon the variable-resolution capability of
the compressible non-hydrostatic MPAS-A model (Skamarock et al., 2012). It promises to be a useful tool for carbon flux
inverse modeling at the global and regional scales. The forward model of MPAS-CO₂ is documented by Zheng et al. (2021). In
this paper, we focus on the development of its tangent linear and adjoint models. Through rigorous testing, we have confirmed
the correctness and accuracy of the newly developed MPAS-CO₂ TL and adjoint models. A key challenge in developing the
420 adjoint model was efficiently accessing meteorological variables during the model's backward-in-time integration. We have
successfully implemented a strategy that combines recalculation and storage of meteorological variables. This approach sig-
nificantly reduces the memory requirement, making the adjoint model feasible for long simulations, which are often necessary
for CO₂ inverse modeling.

425 The results of the sensitivity analysis using the newly developed MPAS-CO₂ adjoint model provide valuable insights for
designing CO₂ data assimilation systems. The increasing homogeneity of the sensitivity to the initial atmosphere CO₂ mixing
ratio with longer integration length highlights the importance of selecting an appropriate assimilation window length. The com-
parison of the CO₂ observation footprints between the MPAS-CO₂ adjoint model and the NOAA CT-L system demonstrates
good agreement, validating the accuracy of the adjoint model's footprint calculations. The comparison of OCO-2 X_{CO₂} foot-
430 prints reveals differences in sensitivity between the two systems at different altitudes. MPAS-CO₂ adjoint model-calculated
footprints tend to have higher magnitudes at low altitudes and lower magnitudes at high altitudes compared to CT-L. These
differences in footprints could be caused by the differences in configuration, spatial resolution, and vertical mixing processes
between the two model systems. Lastly, the sensitivity analysis using two different vertical distribution profiles for adjoint
forcing highlights the importance of correctly mapping model-data difference in X_{CO₂} to the transport model's vertical levels.

435

In addition to being a powerful tool for sensitivity analysis, the adjoint model plays a critical role in CO₂ variational data
assimilation (Bosman and Krol, 2023; Tian and Zou, 2021; Zheng et al., 2018). Our future research efforts will focus on
integrating the forward and adjoint models of MPAS-CO₂ into such a system. This integration has the potential to bridge a
significant gap by establishing an online Eulerian transport model-based global variational assimilation system for CO₂ that
440 targets high resolution in critical regions while at the same time avoiding the pitfalls associated with the lateral boundaries
needed in regional-domain inversions.

Code and data availability

The MPAS-CO₂ forward, TL, and adjoint models v7.3 described in this paper can be downloaded from the CERN-based Zenodo archive at <https://doi.org/10.5281/zenodo.8226620>. This includes the model source code, instructions for compilation, and an example script for running models. Instructions for how to compile and run the models are provided in the package. The computation and plotting scripts used in producing the figures in this manuscript can be downloaded from the CERN-based Zenodo archive at <https://doi.org/10.5281/zenodo.10425739>. CarbonTracker CO₂ flux and posterior mixing ratio data can be obtained from the NOAA website: <https://www.esrl.noaa.gov/gmd/ccgg/carbontracker/download.php>. CT-L footprints can be obtained from the NOAA website: <https://gml.noaa.gov/ccgg/carbontracker-lagrange/>

450 Author contributions

TZ designed and developed the MPAS-CO₂ TL and adjoint models. XT generated the 120-480km VR mesh used in model simulations. TZ, SF, JS, and XT designed and carried out the model accuracy verification experiments. TZ, SF, DB, and MB designed the adjoint sensitivity analysis experiments. All authors contributed to writing the paper.

Competing interests

455 The authors declare that they have no conflict of interest.

Acknowledgment

We thank the MPAS development team for making their code available to the public; We thank Dr. Bill Skamarock for his advice regarding the MPAS-A advection scheme. The model developments and simulations were carried out using Michigan State University High-Performance Computing Center (HPCC). PNNL is operated by the US Department of Energy by the Battelle Memorial Institute under contract DE-A05-76RL01830.

7 Financial support

This research has been supported by the National Aeronautics and Space Administration Carbon Monitoring System (CMS) grant no. 80HQTR21T0069.

Figure 1. A MPAS-CO₂ global variable resolution mesh ranging from $\sim 120\text{km}$ over most of land regions to $\sim 480\text{km}$ over oceans. Also shown in the figures are the ground tracks of two OCO-2 orbits, which are used for the adjoint sensitivity studies described in Section 5. The blue-colored ground track crosses North America from the Caribbean Sea northward between 18:31 UTC and 18:48 UTC on June 30, 2016. The red-colored ground track crosses from South America to North America between 17:36 UTC and 18:13 UTC on August 23, 2016.

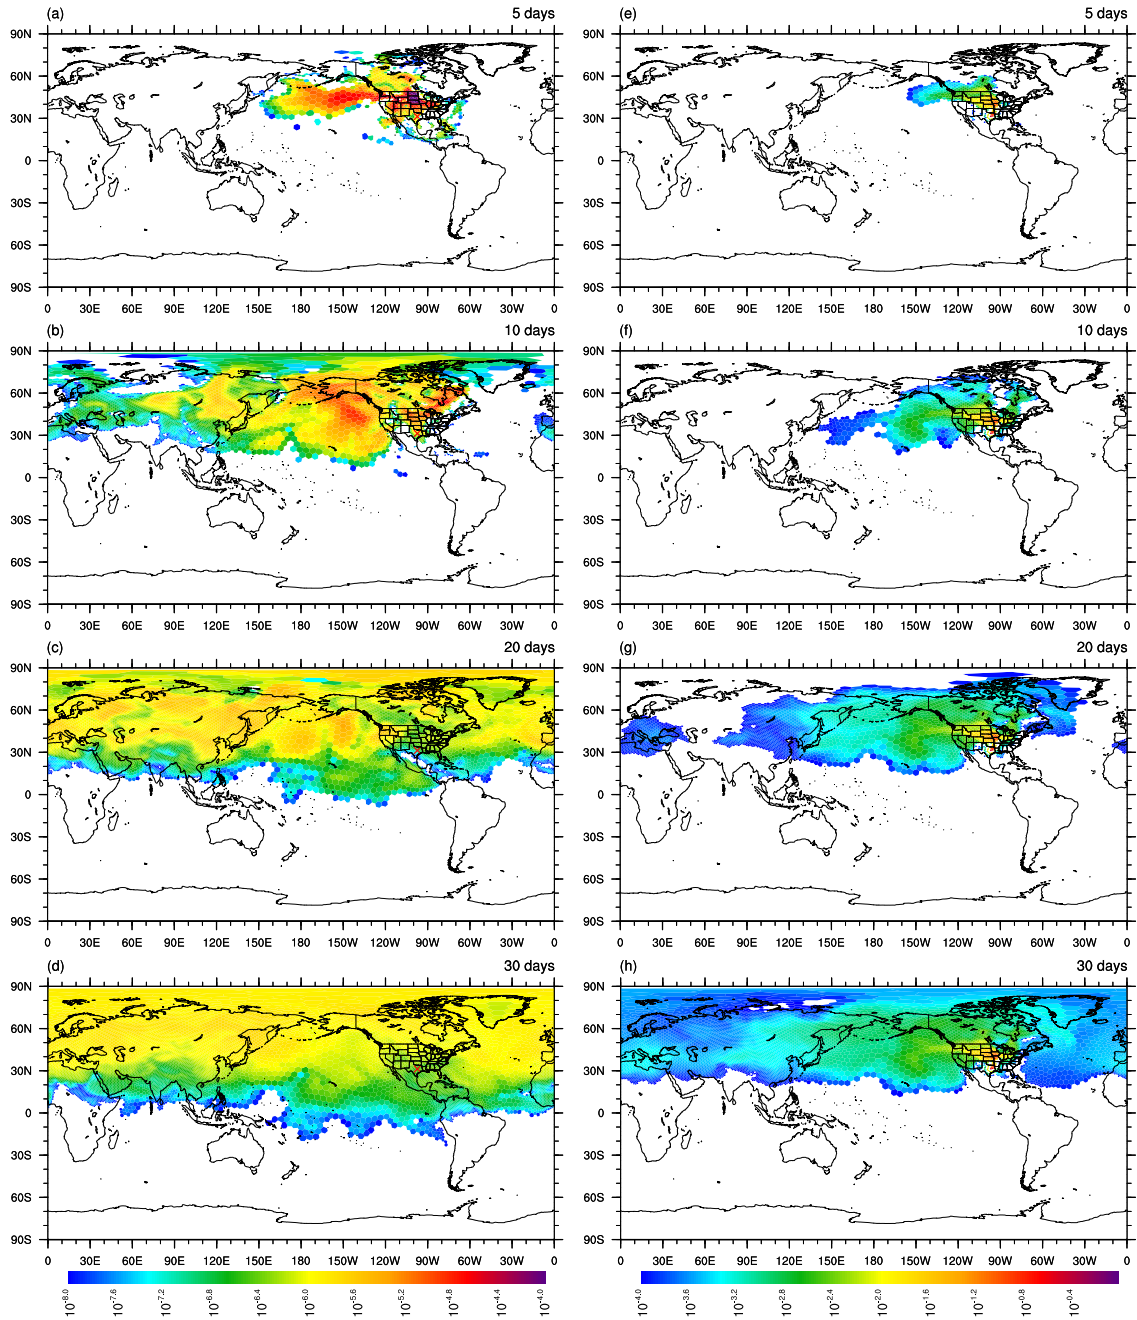

Figure 2. Sensitivity of CO₂ mixing ratio at the WKT tower at 00:00 UTC on March 31, 2018 to the initial CO₂ mixing ratio (left column, units: ppm/ppm) and the surface flux scaling factor (right column, units: ppm/($\mu\text{mol m}^{-2} \text{s}^{-1}$)). The four rows from top to bottom show the sensitivities at 5, 10, 20, and 30 days before the observation. The sensitivities to the initial CO₂ mixing ratio (left column) are plotted as the column average. The WKT tower (31.3149°N , 97.3269°W) measurements used here are taken at 457 meters above the ground level and labeled by the red color cross in the figures of the left column.

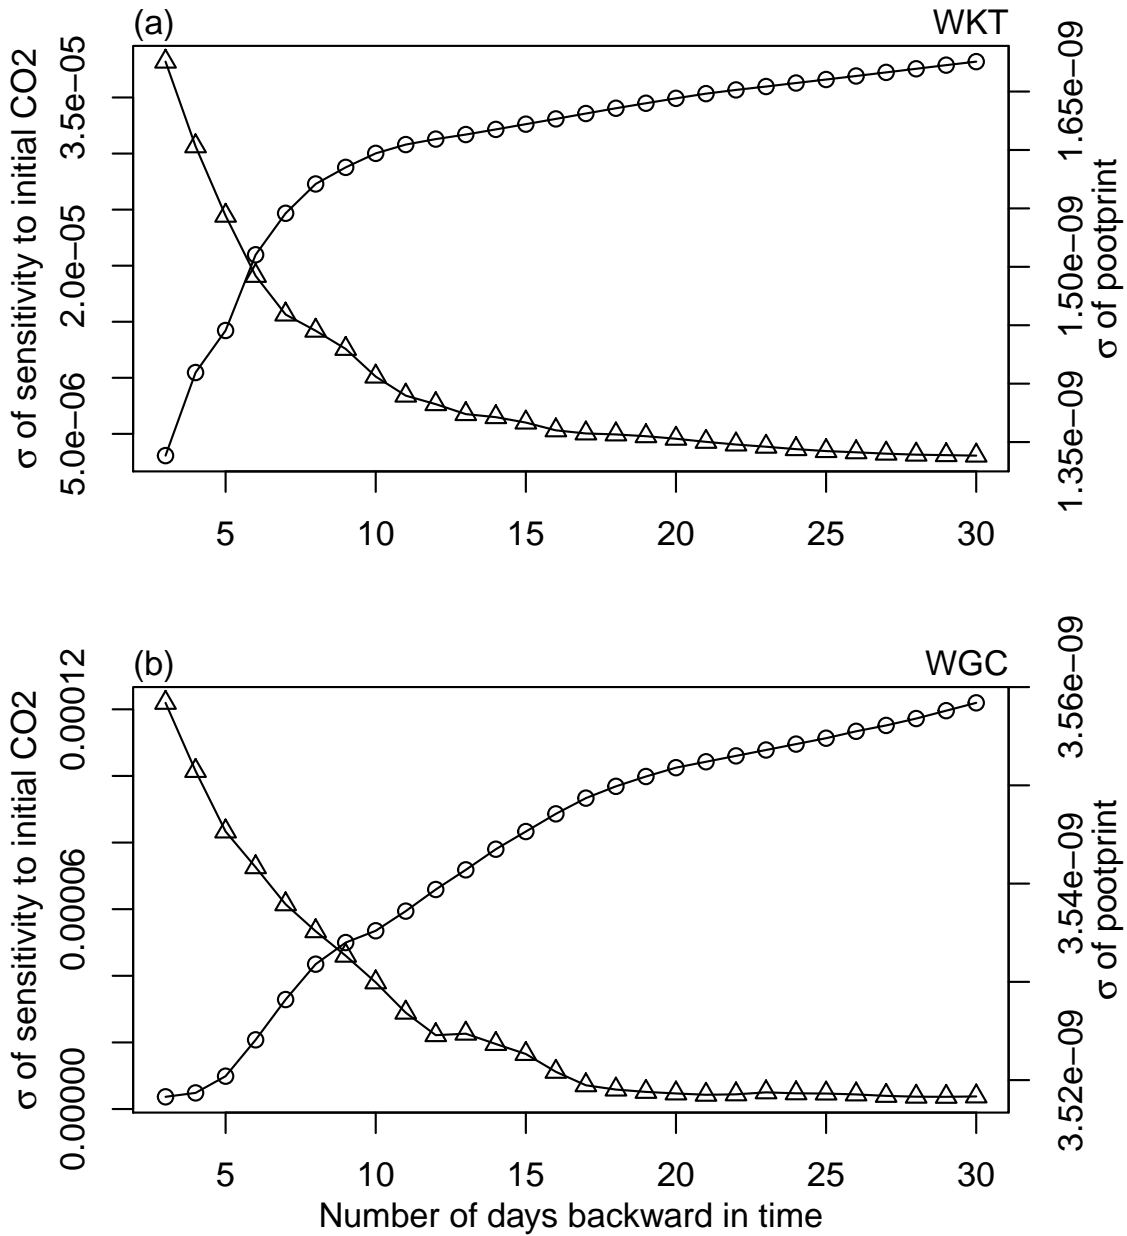

Figure 3. The variation over time of the standard deviation (σ) of two quantities: the sensitivity to the initial CO₂ mixing ratio and the sensitivity to the flux scaling factor (footprint). The standard deviations were calculated from MPAS-CO₂ adjoint model simulations starting on 2018 March 31 at 00:00 UTC, running 30 days backward in time, and ending on 2018 March 1 at 00:00 UTC. The top panel (a) is for the WKT tower (457 magl) while the bottom panel (b) is for the WGC tower (483 magl). In each figure, the triangles represent the standard deviation of sensitivity to the CO₂ mixing ratio field (units: ppm/ppm), and the circles represent the standard deviation of footprint (units: ppm/($\mu\text{mol m}^{-2} \text{s}^{-1}$)).

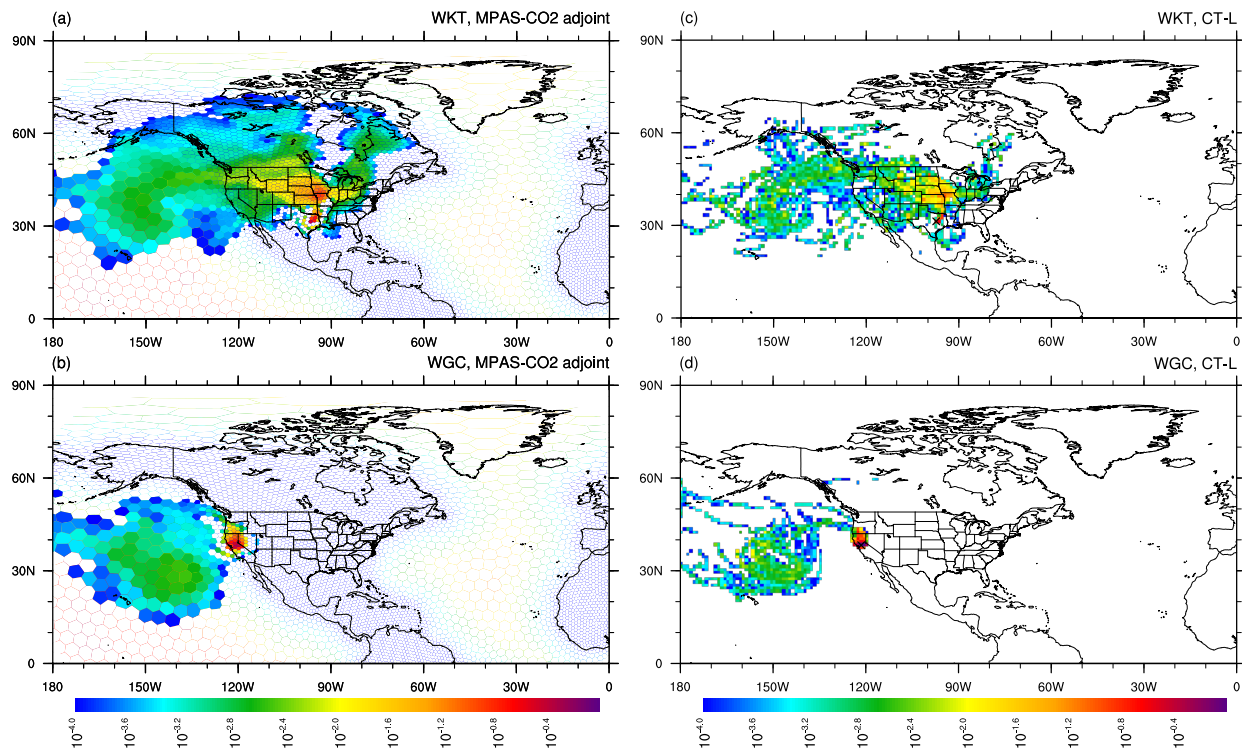

Figure 4. The 10-day backward in time CO₂ measurement footprint (units: ppm/($\mu\text{mol m}^{-2} \text{s}^{-1}$)) given by two tall towers: WKT and WGC. The figures on the top panel are the footprint of the WKT tower calculated using the MPAS-CO₂ adjoint model (a) and CT-L (c). The figures on the bottom panel are the footprint of the WGC tower calculated by the MPAS-CO₂ adjoint model (b) and CT-L (d). The location of the towers is marked by the black crosses in the figure on the right panel.

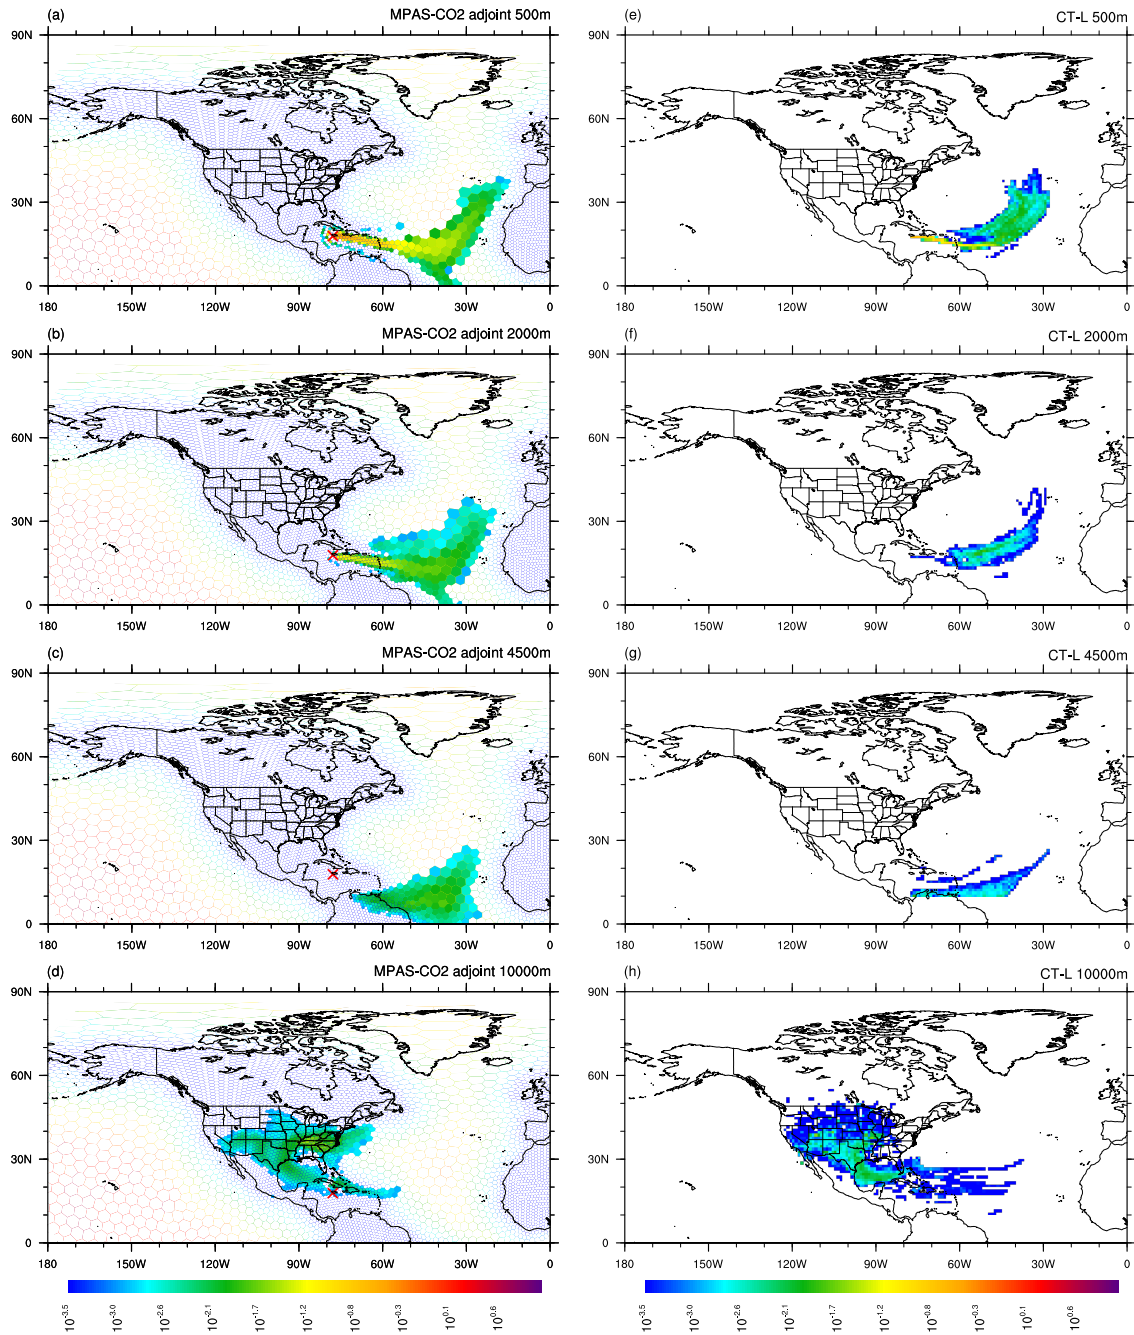

Figure 5. Comparison of footprints calculated by MPAS-CO₂ adjoint model and CT-L of an OCO-2 sounding (17.82°N, 77.88°W) (red crosses, left panel) along the ground track shown in Fig. 1 (blue color). The footprints are calculated at four different heights: 500m, 2,000m, 4,500m, and 10,000m (bottom panel), and 10 days backward in time.

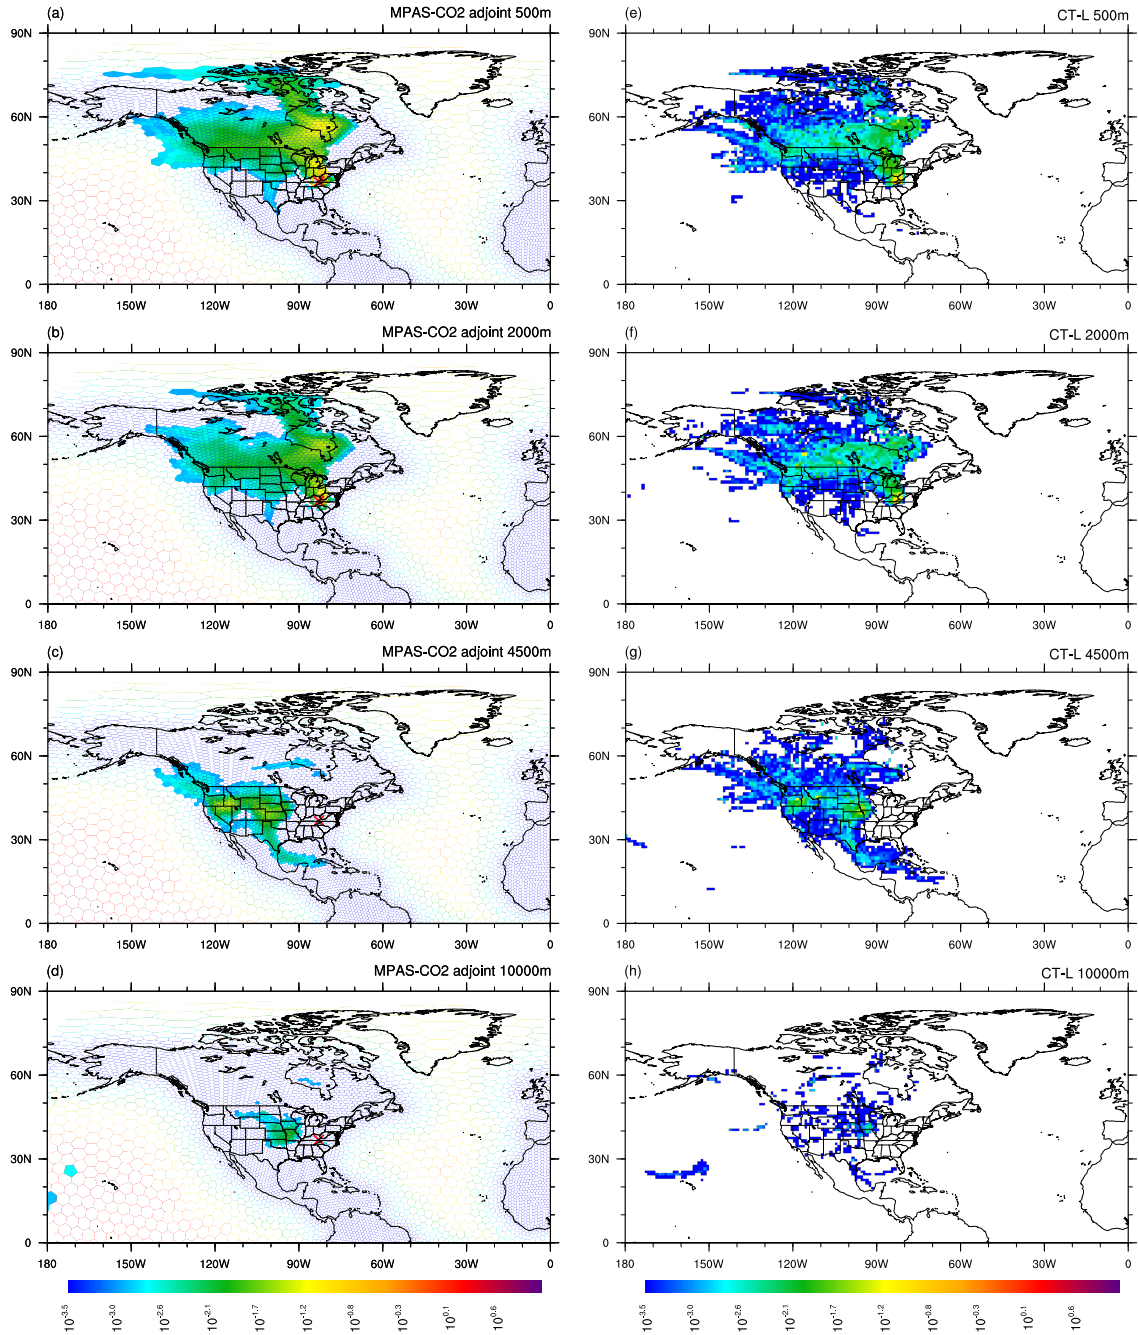

Figure 6. Same as Figure 5, except for a different OCO-2 sounding location ($36.8^{\circ}\text{N}, 82.9^{\circ}\text{W}$).

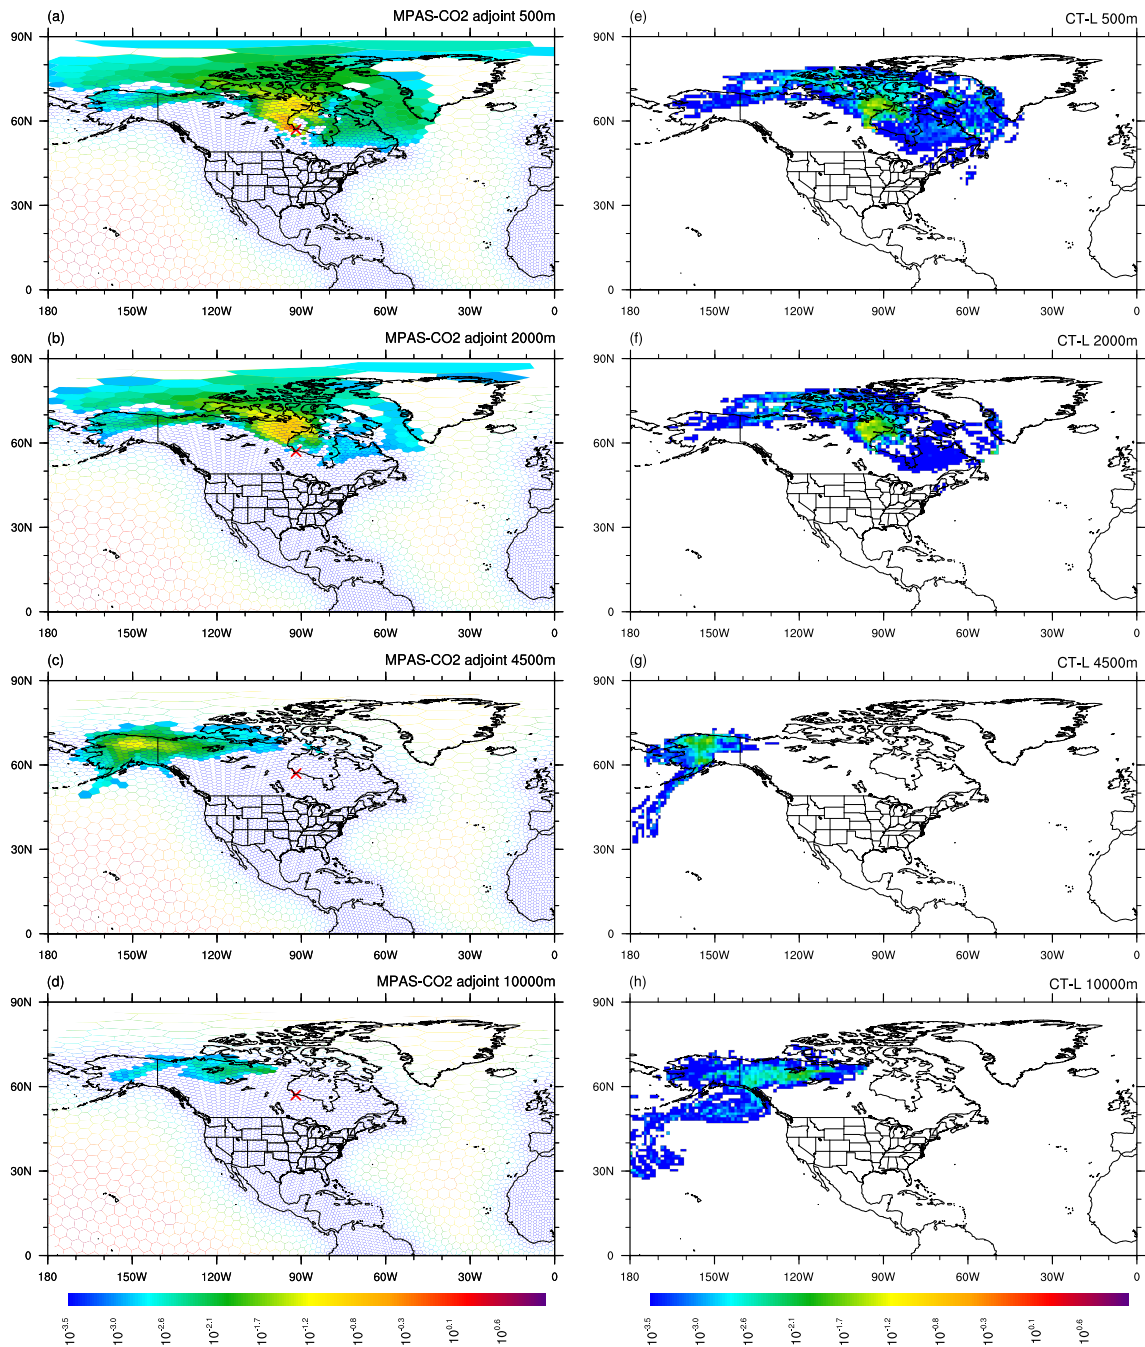

Figure 7. Same as Figure 5, except for a different OCO-2 sounding location (56.96°N, 91.89°W).

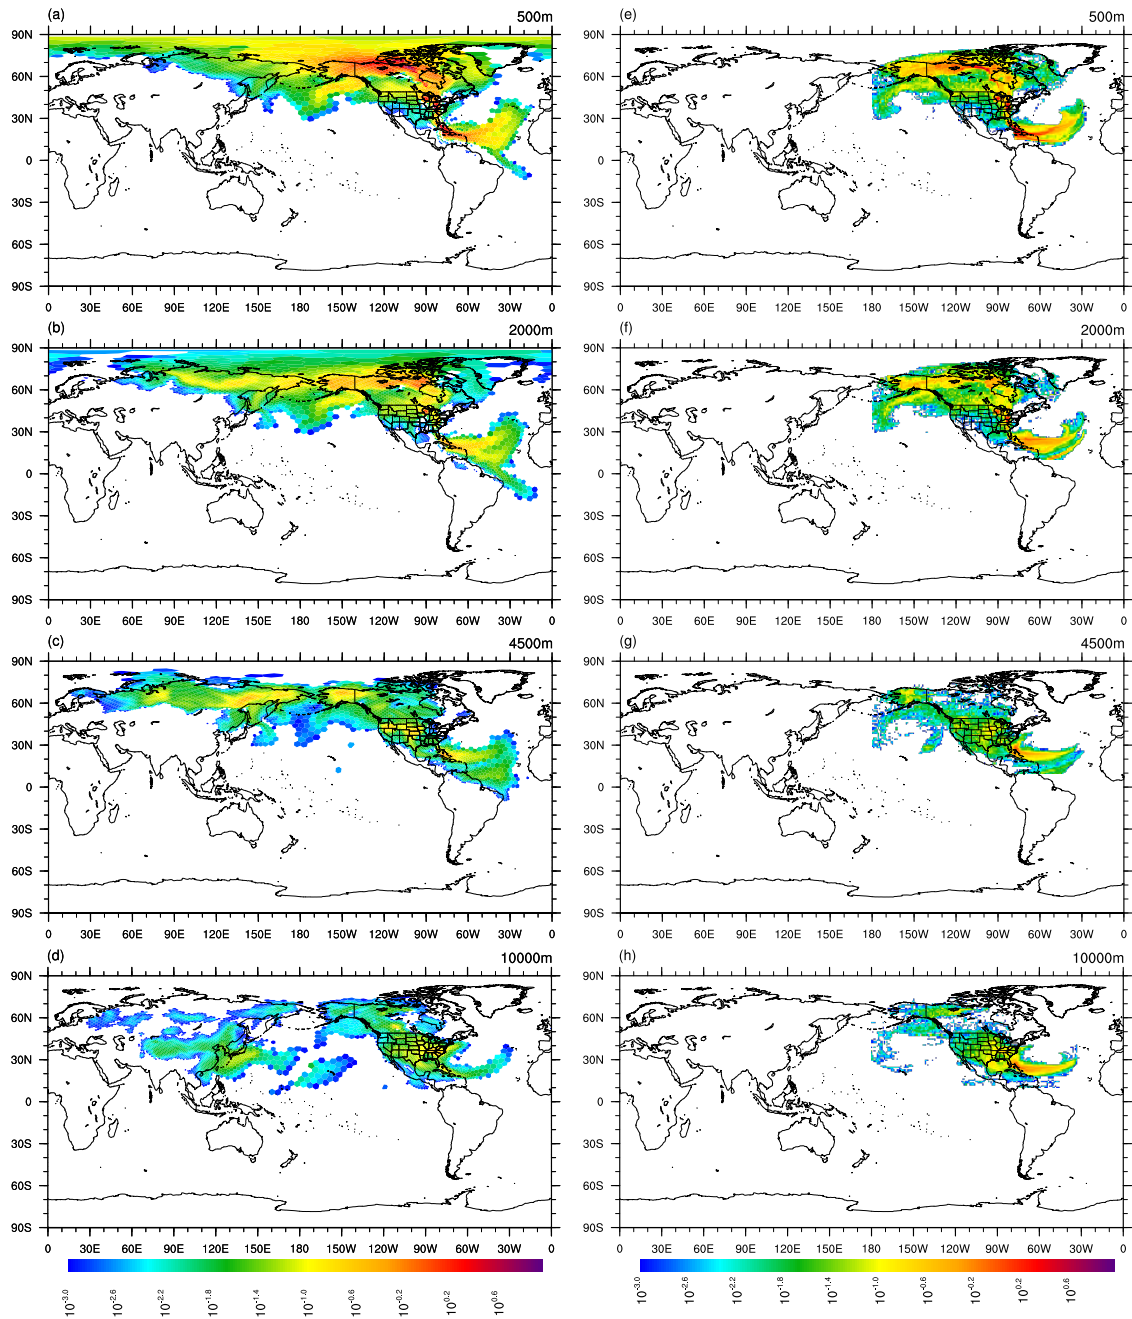

Figure 8. The footprint of the OCO-2 ground track shown in Fig. 1 (with blue color) calculated by the MPAS-CO₂ adjoint model (left panel) and by CT-L (right panel). The footprints are calculated by placing the adjoint forcing (for the MPAS-CO₂ adjoint model) or releasing particles (for CT-L) at four different height levels above the ground: 500m, 2000m, 4500m, and 10000m. The footprints are computed for 10 days backward in time.

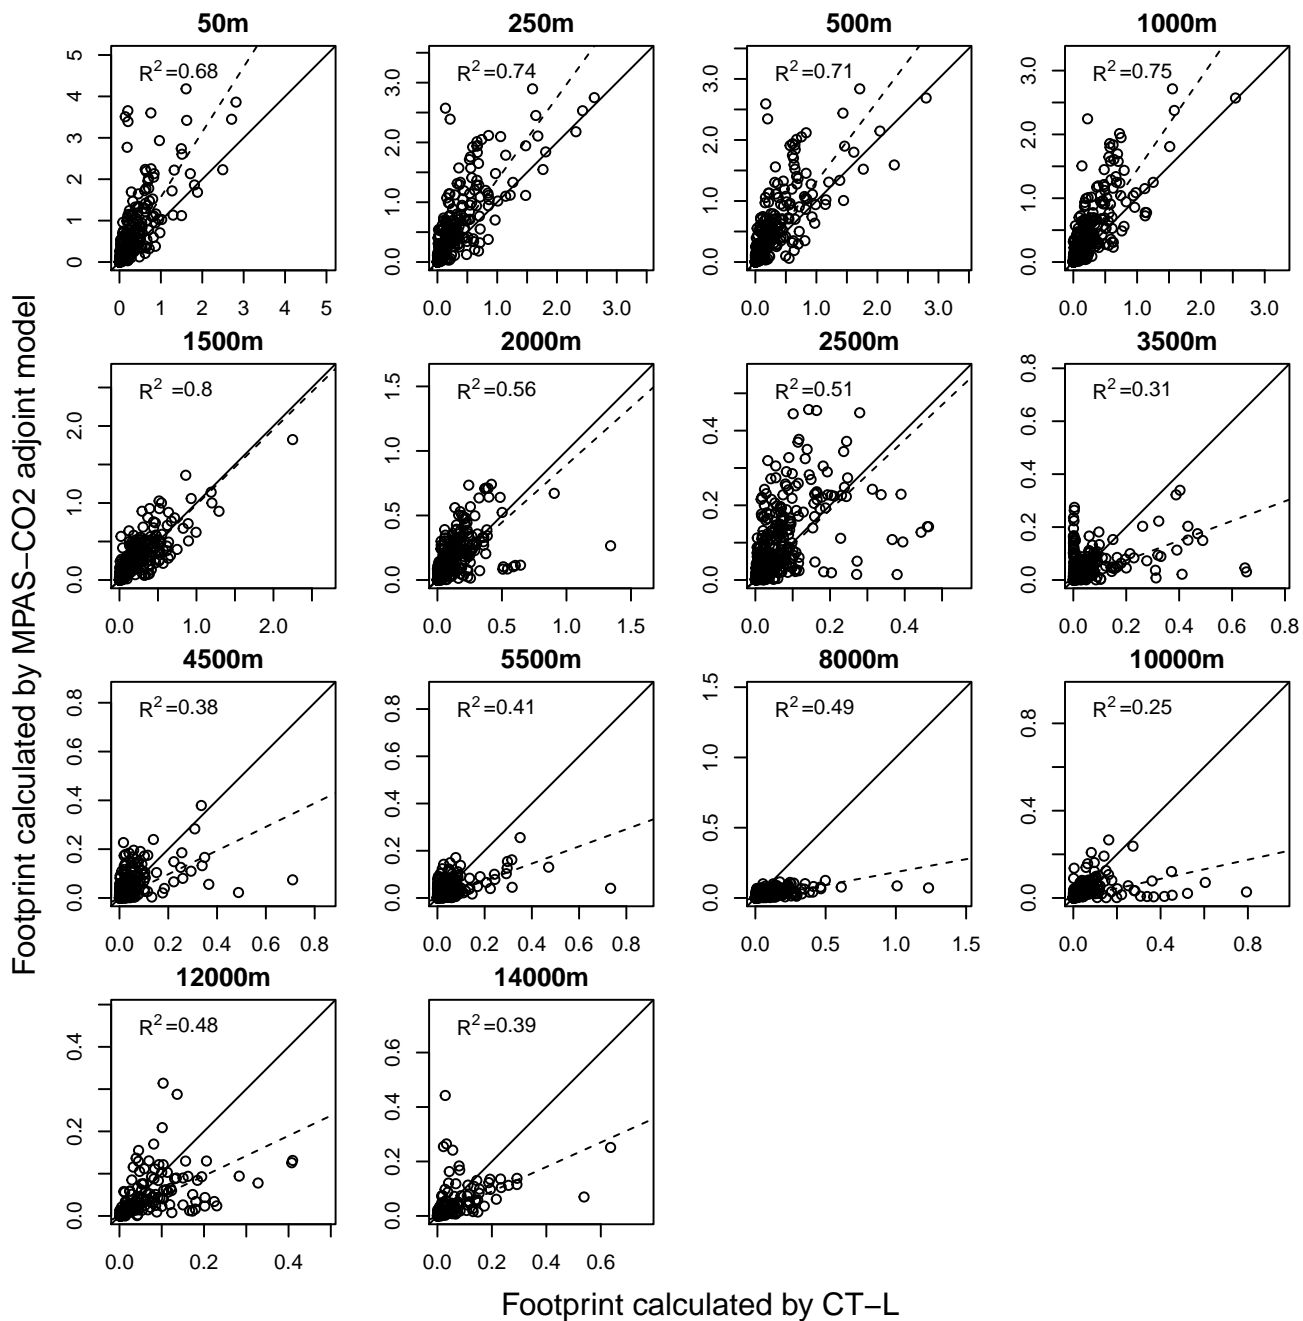

Figure 9. Comparison of the OCO-2 groundtrack footprints from the MPAS-CO₂ adjoint model and CT-L after 10 days integration backward-in-time. For each of the 14 height levels, the values of the footprints (units:ppm/($\mu\text{mol m}^{-2} \text{s}^{-1}$)) are extracted as the average value of $2^\circ \times 3^\circ$ boxes within the range of the CT-L spatial domain (10° - 80°N , 0° - 180°W). The solid line in each subfigure is the 1:1 line and the dashed line is a linear fit with zero intercept. The correlation coefficient R^2 of the linear fit is also labeled in each subfigure.

Figure 10. Two different profiles for vertically distributing a unit (ppm) of X_{CO_2} . Profile 1 is determined by OCO-2 X_{CO_2} averaging kernel and pressure weight functions. Profile 2 is based on a redistribution of Profile 1 that gives more weight towards CO_2 in the lower troposphere than in the upper part of the atmospheric column. The circles of profiles are on the twenty pressure levels of OCO-2 X_{CO_2} pressure weight function. Both profiles integrate to unity.

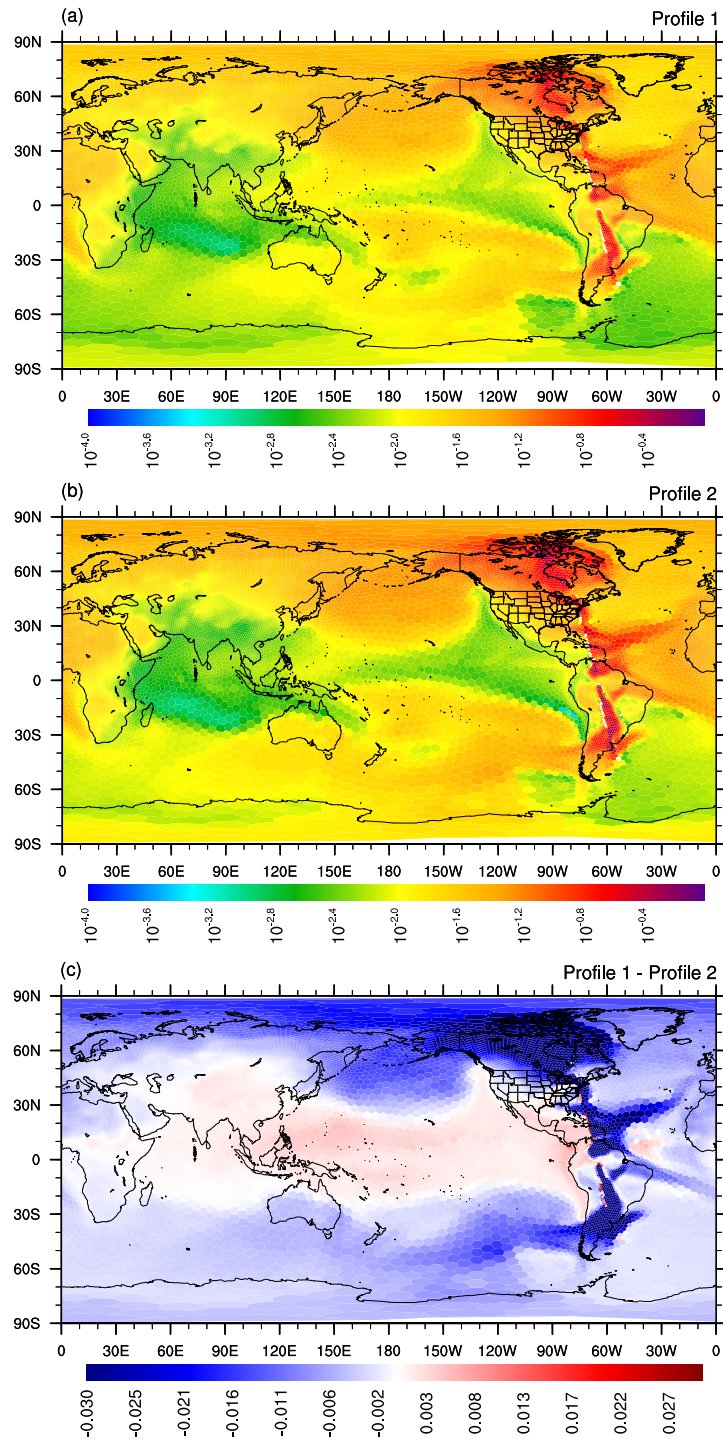

Figure 11. MPAS-CO₂ adjoint model-calculated footprints (units:ppm/($\mu\text{mol m}^{-2} \text{s}^{-1}$)) obtained after 30 days of backward-in-time integration starting on August 23, 2016 at 18:00 UTC (the time of the OCO-2 measurement). The top figure is obtained when using Profile 1 (Fig. 10) to vertically distribute 1 ppm of adjoint forcing. The middle figure is the footprint using Profile 2. The bottom figure is the difference in footprint between the two profiles.

Table 1. Results of the correctness check for the newly-developed MPAS-CO₂ tangent linear model. The results are from 1-month integration (from 2018-10-01 00:00 UTC to 2018-11-01 00:00 UTC) of the forward and tangent linear models using the 120-480 km global variable-resolution mesh (Fig. 1). The terms in the table refer to Eq. (9).

α	$\ \mathcal{M}(\mathbf{x}_0, (1 + \alpha)\mathbf{k}) - \mathcal{M}(\mathbf{x}_0, \mathbf{k}) \ $	$\ \mathbf{M}(0, \alpha\mathbf{k}) \ $	$\ \mathcal{M}(\mathbf{x}_0, (1 + \alpha)\mathbf{k}) - \mathcal{M}(\mathbf{x}_0, \mathbf{k}) \ / \ \mathbf{M}(0, \alpha\mathbf{k}) \ $
