Abstract.

The cycling of carbon in the oceans is affected by feedbacks driven by changes in climate and atmospheric CO₂. Understanding these feedbacks is therefore an important prerequisite for projecting future climate. Marine biogeochemical models are a useful tool there, but as any model is a simplification, need to be continually improved. In this study, we coupled the Finite-volumE Sea ice-Ocean Model (FESOM2.1) to the Regulated Ecosystem Model version 3 (REcoM3). FESOM2.1 is an update of the Finite Element Sea ice-Ocean Model (FESOM1.4) and operates on variable mesh resolution. Unlike standard structured-mesh ocean models, the mesh flexibility allows for a realistic representation of small-scale dynamics in key regions at affordable computational cost. Compared to the previous coupled model version FESOM1.4-REcoM2, the model FESOM2.1-REcoM3 utilizes a new dynamical core based on a finite volume discretization instead of finite elements, but retains central parts of the biogeochemistry model. As a new feature, carbonate chemistry including water vapor correction is computed by mocsy-2.0. Moreover, REcoM3 has an extended food web that includes macrozooplankton and fast-sinking detritus. Dissolved oxygen is added as a new tracer. In this study we assess the ocean and biogeochemical state simulated with FESOM2.1-REcoM3 in a global setup at relatively low spatial resolution forced with JRA55-do atmospheric reanalysis. The focus is on the recent period 1958-2021, to assess how well the model can be used for present-day and future climate change scenarios on decadal to centennial timescales. A bias in global ocean-atmosphere preindustrial CO₂ flux present in the previous model version FESOM1.4-REcoM2 could be significantly reduced. In addition, the computational efficiency is 2–3 times higher than that of FESOM1.4-REcoM. Overall, it is found that FESOM2.1-REcoM3 is a skillful tool for ocean biogeochemical modelling applications.

1 Introduction

There is an unequivocal consensus and concern about the effects of increasing greenhouse gases in the atmosphere due to human activities. Since the beginning of the preindustrial era, 1750, the concentration of carbon dioxide (CO₂) in the air has substantially risen from 277 ppm to 417.2 ppm in 2022 (Friedlingstein et al., 2022b). The ocean took up anthropogenic carbon at a rate of 2.9 PgC yr⁻¹ (26% of total CO₂ emissions) in 2021 (Friedlingstein et al., 2022b). Simultaneously, the terrestrial CO₂ sink is estimated to be 3.5 PgC yr⁻¹. The total air-to-land CO₂ flux is, however, lower by 1.1 PgC yr⁻¹ because of

25 emissions from land-use change, mainly deforestation. The ocean carbon sink has grown over the past decades in response
to the near-exponential rise in CO₂ emissions (Friedlingstein et al., 2022b). While the global ocean carbon sink estimate
is assigned an uncertainty of 0.4 PgC yr⁻¹ and medium confidence, regional patterns of the sink differ more strongly. This
points to the balance between physical and biological processes, which are more difficult to model as also illustrated in model
deficiencies of the seasonal cycle of pCO₂ and CO₂ fluxes (Mongwe et al., 2018). Both climate change and rising atmospheric
30 CO₂ feed back on the fraction of CO₂ emissions that will end up in the ocean over the next century (Friedlingstein et al., 2003;
Canadell et al., 2021). Models are important tools in estimating how large these feedbacks are.

The flux of CO₂ between atmosphere and ocean is controlled by two main mechanisms: the solubility pump and the bio-
logical pump. The solubility pump describes the air-sea CO₂ exchange that occurs to satisfy a thermodynamic equilibrium,
and the subsequent transport of carbon from the surface to the deep ocean with the overturning circulation. This leads to CO₂
35 uptake at mid- to high latitudes through high solubility in cold waters and large vertical motion in deep water formation re-
gions. In contrast, warm ocean regions in the tropics and subtropics as well as upwelling regions lose carbon to the atmosphere
(Takahashi et al., 2009; Wanninkhof et al., 2013). The solubility pump is responsible for anthropogenic carbon uptake. The
biological carbon pump comprises the fixation of CO₂ into biomass by phytoplankton and the subsequent downward transfer
of dead organic material (Boyd et al., 2019). The biological carbon pump is responsible for 75% of the natural vertical carbon
40 gradient (Sarmiento and Gruber, 2006), and for the large-interbasin gradient between the deep Pacific and Atlantic. Without
the biological carbon pump, atmospheric CO₂ would be higher by 200 ppm (Maier-Reimer et al., 1996), and perturbations
thereof can have large effects on atmospheric CO₂ (Kwon et al., 2009; Lauderdale and Cael, 2021) as also known from paleo
evidence (Galbraith and Skinner, 2020).

Global ocean biogeochemistry models (GOBMs, Fennel et al., 2022) are used to assess the global ocean carbon sink (Hauck
45 et al., 2020), its regional patterns (Fay and McKinley, 2021), and effects of climate change and variability on the ocean carbon
sink (Le Quéré et al., 2010; Hauck et al., 2013; DeVries et al., 2019; Bunsen, 2022). By their representation of pH, the marine
oxygen cycle and phytoplankton primary production as the base of the marine food web, they also offer information about
the environmental conditions for marine life and how these will develop under climate change (Bopp et al., 2013; Laufkötter
et al., 2015; Kwiatkowski et al., 2020). One such ocean biogeochemistry model is the Regulated Ecosystem Model (REcoM)
50 that describes the lower trophic levels of the marine ecosystem using the plankton functional type approach, and that bases
its description of primary production on a physiological model for phytoplankton growth that takes into account nutrient
availability effects on photoacclimation (Geider et al., 1998) and, for diatoms, on the relative frustule weight (Hohn, 2009).
One specificity of REcoM is the representation of flexible stoichiometry, which leads to a description of elemental fluxes that
can deviate from the fixed Redfield ratios often used in models (Redfield et al., 1963).

55 Modeling the marine biogeochemistry of the ocean is subject to several sources of uncertainties: First, GOBMs are expensive
with respect to the computational cost due to the advection of a large number of tracers and therefore, often demand low spatial
resolution. This leads to deficiencies in the representation of significant physical processes such as (sub)mesoscale currents
(McWilliams, 2016) which can have large impacts on transport and mixing processes that strongly affect biological productivity
(Lévy et al., 2018; Keerthi et al., 2022). Second, the descriptions of ecological interactions and of the physiology of primary

60 and secondary producers in GOBMs are still mostly based on empirical or semi-empirical mathematical descriptions, such as
e.g., the dependency of zooplankton grazing rates on prey abundance (Doney et al., 2001; Rohr et al., 2022). These contain a
large number of parameters that are only partly constrained from observations, making it necessary to tune these parameters in
GOBMs to some extent. Choices in these parameters can have strong effects on the biological carbon pump (e.g. Lauderdale
and Cael, 2021). It has been demonstrated that the largest source of uncertainty for projections of net primary production (NPP,
65 Tagliabue et al., 2021) comes from model uncertainty, not scenario uncertainty (Frölicher et al., 2016).

Ocean circulation models formulated on unstructured meshes have become an alternative to existing structured global ocean
models (Danilov, 2013). The Finite-Element Sea ice–Ocean Model (from now on FESOM1.4, Wang et al., 2014) is one of
the first global models with multiple resolutions designed to simulate the large-scale ocean circulation. While it has already
been used in numerous applications (Sidorenko et al., 2015; Wekerle et al., 2017), another dynamical core, the Finite-volume
70 Sea ice–Ocean Model version 2.1 (FESOM2.1), has been developed (Danilov et al., 2017). The advantages of a finite volume
formulation are (a) better throughput and scalability as a result of a more efficient data structure (Koldunov et al., 2019), (b) the
availability of clearly defined fluxes, and (c) the possibility to choose from a selection of transport algorithms, which was very
limited before (Danilov et al., 2017). Furthermore, the arbitrary Lagrangian Eulerian (ALE) vertical coordinate is introduced
which provides different types of vertical coordinates (Scholz et al., 2019).

75 Here we document the ocean biogeochemistry in the Regulated Ecosystem Model version 3 (REcoM3) coupled to the ocean
and sea ice model FESOM2.1, and assess its performance in reproducing carbon and nutrient biogeochemical fluxes as well as
the distribution of phytoplankton and zooplankton. Our aim is to analyze the new setup regarding the coupled model state under
historical atmospheric CO₂ forcing and the associated model bias and drift from the experiment with constant preindustrial
(PI) CO₂ level. We thus focus on evaluating model aspects with regard to the effects of climate change and CO₂ increase on
80 carbon fluxes on century-scale time-scales. We exclude in our analysis the deep-sea distribution of carbon and nutrients, which
would require model runs over at least 500 to two thousand years (Séférian et al., 2020), which will be done in follow-up work.

2 Methods

2.1 Model Description

We present the coupled ocean-sea ice-biogeochemistry model FESOM2.1-REcoM3. The previous model version FESOM1.4-
85 REcoM2 has been described by Schourup-Kristensen et al. (2014). Unlike its predecessor FESOM1.4 which uses a finite
element formulation, the ocean model is now based on a finite volume discretization, which makes tracer conservation much
easier to achieve. FESOM2.1 was described by Danilov et al. (2017) and evaluated in Scholz et al. (2019, 2021). The ocean
biogeochemistry is simulated by the Regulated Ecosystem Model version 3 (REcoM3), which builds upon the previous version
REcoM2 (Hauck et al., 2013; Schourup-Kristensen et al., 2014). The advection and diffusion of 28 passive biogeochemical
90 tracers is handled by FESOM2.1, whereas REcoM3 calculates sources and sinks, driven by biological interactions or biogeo-
chemical exchange processes.

2.1.1 Ocean Model FESOM2.1

FESOM2.1 solves the hydrostatic primitive equations under the Boussinesq approximation (Danilov et al., 2017). This equation set in differential form is discretized on a finite set of points (nodes). As a first step of mesh generation, a 2-dimensional grid is created by combining these nodes in triangular shapes (elements). At this stage, mesh resolution (i.e., the size of triangles) can be adjusted in areas of interest without requiring a nesting approach. A 3-dimensional mesh is produced by projecting triangles in vertical direction forming prisms. The scalar quantities (tracers, pressure) are located at nodes while the horizontal velocities are defined at centroids of elements (See Figs. 1 and 2 in Danilov et al., 2017). A pair of control volumes are defined. The vector control volumes are the prisms based on elements. The scalar control volumes are formed by connecting cell centroids with edge midpoints (Fig. 1). Integration is carried out on a staggered Arakawa B type of mesh (Scholz et al., 2019).

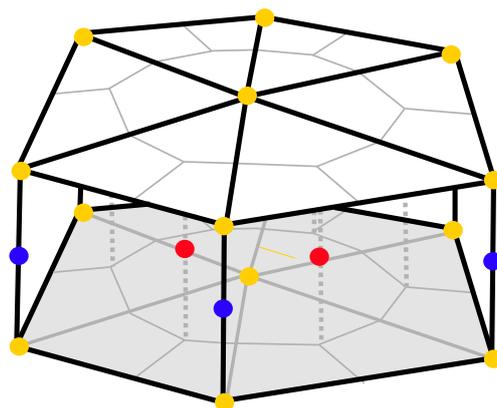

Figure 1. Scheme of the cell-vertex discretization in 3-dimensional space. Blue dots correspond to scalar quantities including REcoM2 state variables, located at the mid-layer vertices of triangles. Red dots represent horizontal velocities located at mid-layer cell centers of the triangles. Yellow dots depict vertical transfer velocities, placed at the layer boundaries aligned with scalar quantities in vertical.

We use FESOM2.1, an updated version of FESOM2.0. The updated model features include several developments, such as parallel and asynchronous output writing. An important new feature that we applied is the kinematic backscatter parameterisation. This method takes into account the scales at which energy is scattered back to the resolved flow by introducing a negative viscosity term (Juricke et al., 2020). This greatly improves the simulation of eddy effects in coarse resolution mesh setups (Juricke et al., 2020). The model code also includes representation of ice-shelf cavities (Timmermann et al., 2012), which has been used in regional studies with FESOM1.4-REcoM2 (Nissen et al., 2022). Ice-shelf cavities are, however, not used in this study. Isonutral tracer diffusion (Redi, 1982) and the Gent-McWilliams (GM, Gent and McWilliams, 1990; Griffies, 1998) eddy stirring parameterization are applied. Both GM and Redi are scaled with horizontal resolution with a maximum value of $2000 \text{ m}^2 \text{ s}^{-1}$ at 100 km horizontal resolution, and decrease linearly below a resolution of 40 km to reach zero at 30 km resolution effectively switching the parameterization. As vertical mixing parameterization, the K-profile scheme is used (KPP, Large et al., 1994) with a background vertical diffusivity of $1 \times 10^{-4} \text{ m}^2 \text{ s}^{-1}$ for momentum and $1 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$ for tracers.

Furthermore, the Monin-Obukhov length dependent vertical mixing parameterization is applied in the surface boundary layer south of 50°S (Timmermann and Beckmann, 2004).

115 Regarding the vertical discretization, FESOM2.1 is formulated with an arbitrary Lagrangian-Eulerian (ALE) scheme, a synthesis of different types of vertical coordinates. In the model configuration used here, we apply a full free-surface formulation and thus permit the vertical movement of the surface and of all other layers (referred to as *zstar*, Scholz et al. (2019)). This drastically improves tracer conservation properties (Campin et al., 2004). Partially filled cells are used at the ocean floor resulting in a smoother representation of the bathymetry.

120 The sea ice component (Finite-Element Sea Ice Model, FESIM version 2) solves for sea ice concentration, ice and snow thickness, as well as ice drift velocity (Danilov et al., 2015). It is discretized on the same unstructured horizontal mesh as the ocean model. The elastic-viscous-plastic solver and flux corrected transport scheme are used for sea ice advection (Danilov et al., 2015). The formulation of sea ice thermodynamics follows the work of Timmermann et al. (2009).

2.1.2 Biogeochemistry Model REcoM3

125 REcoM3 is a water column biogeochemistry and ecosystem model which incorporates cycles of carbon and nutrients (nitrogen, iron, and silicon) with varying intracellular stoichiometry in phytoplankton, zooplankton and detritus (see Appendix for detailed description and equations). Starting from the work by Schartau et al. (2007), REcoM was first used to describe carbon overconsumption in mesocosm experiments. After coupled to the ocean and sea ice model MITgcm (Marshall et al., 1997), the previous version (REcoM2) with two phytoplankton classes, one zooplankton and one detritus class was applied to study the cycling of marine carbon on present (Hauck et al., 2013, 2018) and glacial time-scales (Du et al., 2022; Völker and Köhler, 2013), as well as the marine iron cycle (e.g., Völker and Tagliabue, 2015; Tagliabue et al., 2016; Ye and Völker, 2017; Pagnone et al., 2019). Moreover, REcoM2 was employed in assessments on the efficiency of ocean alkalinity enhancement (Köhler et al., 2013; Hauck et al., 2016), in data assimilation studies (Pradhan et al., 2019) and as a test bed for model development, e.g., for development of a parameterization of iron-ligand binding based on pH (Ye et al., 2020) among others. Simultaneously, REcoM2 was coupled to FESOM1.4 (Schourup-Kristensen et al., 2014). These coupled model set-ups were used either in a global configuration (e.g., Schourup-Kristensen et al., 2014; Hauck et al., 2020) with a regional focus on the Arctic or the Antarctic (Hauck et al., 2015; Schourup-Kristensen et al., 2018; Oziel et al., 2022; Nissen et al., 2022) or in regional configurations (Taylor et al., 2013; Losch et al., 2014). Recently, the model has matured to include two groups of each classes of phytoplankton, zooplankton and detritus (REcoM3, Fig. 2).

140 Marine primary production is computed through representation of two phytoplankton functional types (PFTs), namely diatoms and small phytoplankton. The diverse group of small phytoplankton comprises a wide range of taxa, including, for instance, non-silicifying and calcifying and non-calcifying haptophytes and green algae. The model allows PFTs to adapt their internal stoichiometry (C:N:Chl:CaCO₃ ratios for small phytoplankton and C:N:Chl:Si for diatoms) to nutrient levels, ambient light and temperature, based on the photoacclimation model by Geider et al. (1998). Si uptake by diatoms is regulated as well, based on the internal Si:N quota, following Hohn (2009). This parameterization takes into account the strong decoupling between Si and N metabolism (e.g., Claquin et al., 2002), and prescribes the observed change in Si:N ratios under Fe and

145

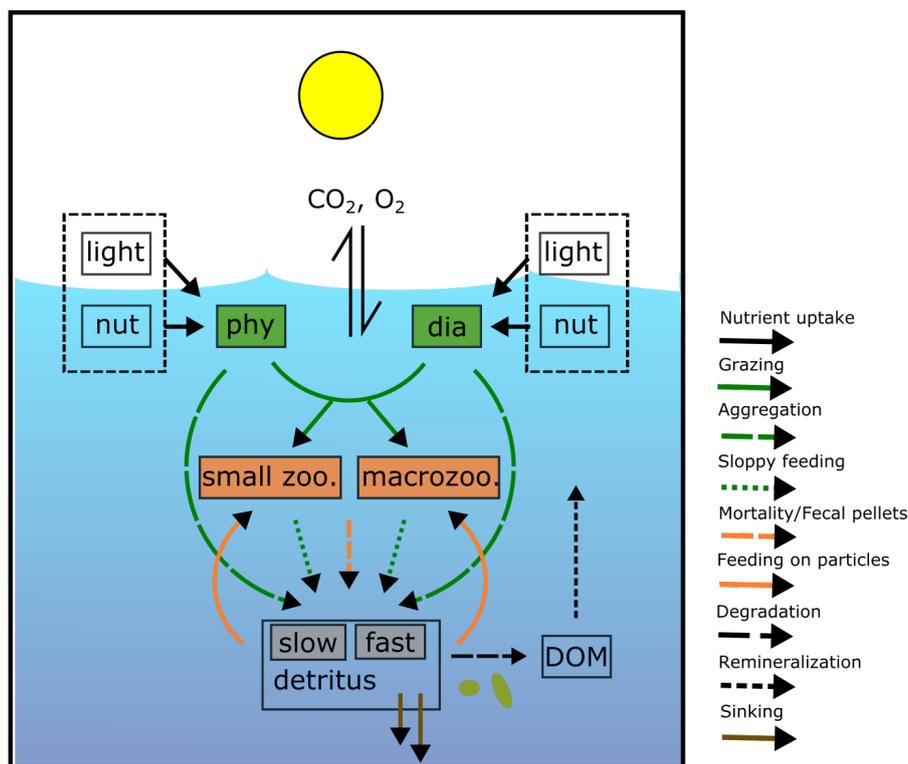

Figure 2. Schematic diagram of the components and interactions in the RECoM3 model. Small phytoplankton (phy) and diatoms (dia) take up inorganic nutrients (nut). Small zooplankton (small zoo.) and macrozooplankton (macrozoo.) consume phytoplankton and particles. Macrozooplankton feeds on small zooplankton. Phytoplankton aggregation, zooplankton sloppy feeding, mortality and fecal pellets generate sinking detritus (slow and fast). Sinking detritus degrades to dissolved organic carbon and nitrogen. Dissolved organic material (DOM) then remineralizes to dissolved inorganic carbon and nitrogen. The number of tracers and the other processes are shown in the appendix (Fig. A2).

N limitation. The intracellular iron pool is derived from intracellular nitrogen with a fixed Fe:N ratio, based on the fact that intracellular iron is mostly associated with the photosynthetic electron transport chain and nitrogen metabolism (Geider and La Roche, 1994; Raven, 1988). RECoM3 also includes the photo-damage parameterization by Álvarez et al. (2018). Calcium carbonate production is assumed to be linearly dependent on the gross small phytoplankton production. CaCO₃ dissolution is described by a depth-dependent dissolution rate.

Zooplankton is represented by two groups, small zooplankton and polar macrozooplankton (Karakuş et al., 2021) and each group has a carbon and a nitrogen tracer. The small zooplankton group in the model is associated with relatively higher grazing rates compared to macrozooplankton and is widely spread in the global ocean. The polar macrozooplankton is mainly present in the Southern Ocean and northern high latitudes. The respiration rate is described mechanistically for macrozooplankton taking into account reduced metabolism in winter and increased metabolism at high grazing rates (Karakuş et al., 2021). For small zooplankton, respiration is calculated with a fixed respiration rate constant and biomass in contrast to the previous version

REcoM2 where respiration was used to drive zooplankton C:N back towards Redfield ratio (Hauck et al., 2013; Schourup-Kristensen et al., 2014). Grazing is computed by applying a sigmoidal function with variable preferences on both phytoplankton and detritus (Fasham et al., 1990).

160 Particulate organic matter (detritus) is split into two groups. The sinking speed of the first detritus group increases linearly with depth (from 20 m day⁻¹ from the surface to 192 m day⁻¹ at 6000 m depth; Kriest and Oschlies, 2008). The sinking speed of the second group (fast-sinking detritus) is constant throughout the water column (200 m day⁻¹, Karakuş et al., 2021). Remineralisation of carbon and nitrogen occurs in two steps. Detrital material is first degraded to dissolved organic matter and then remineralised to the inorganic forms (dissolved inorganic carbon and nitrogen, DIC, DIN). For iron, it is assumed that the
165 organic form is directly bioavailable, so it enters the dissolved iron pool in one step.

REcoM3 comprises a single-layer sediment pool for nitrogen, silicon, dissolved inorganic carbon and calcium carbonate. The sinking detritus and associated minerals are accumulated in this layer when they reach the ocean floor. This material is subsequently returned back to the water column to the pools of dissolved inorganic nitrogen, carbon and silicon, as well as alkalinity with a fixed remineralisation rate. The release of iron to the bottom layer of the ocean is assumed to be proportional
170 to the release of inorganic nitrogen (Elrod et al., 2004).

2.1.3 Updates to previous REcoM version coupled to FESOM1.4

There are numerous improvements relative to the previously documented version FESOM1.4-REcoM2 (Schourup-Kristensen et al., 2014), and the main changes are listed below:

REcoM

- 175 1. The routines for calculating carbonate chemistry and air-sea CO₂-exchange used in FESOM1.4-REcoM2 which followed the guidelines provided by the Ocean Carbon Model Intercomparison Project (Orr, 1999) were replaced by the mocsy-2.0 scheme of Orr and Epitalon (2015). While both use the same thermodynamic equilibrium to calculate surface pCO₂ and CO₂ flux, mocsy-2.0 uses the faster and more accurate algorithm SolveSAPHE (Munhoven, 2013). Among other differences, it follows best practice guides and uses recommended equilibrium constants. The gas exchange formula-
180 tion is updated to Wanninkhof (2014), which is largely equivalent to Ho et al. (2006). The computed fluxes are scaled with the ice-free area.
2. Dissolved oxygen was added as a new tracer in REcoM3. The air-sea O₂ flux is calculated using the mocsy-2.0 routines (Orr and Epitalon, 2015). Photosynthesis, respiration and remineralisation change oxygen with a fixed O₂:C ratio, and remineralisation does not depend on O₂ levels in the current model version.
- 185 3. A second zooplankton group and a fast-sinking detritus class were added. The second zooplankton group represents a slow-growing polar macrozooplankton with a feeding preference on diatoms which produces fast-sinking and carbon-rich fecal pellets (Karakuş et al., 2021).

4. Intracellular iron concentration is connected to intracellular nitrogen via a constant ratio Fe:N leading to some variation in the Fe:C ratio, as briefly presented in Tagliabue et al. (2016) and Pagnone et al. (2019).
- 190 5. Sedimentary release of iron was added to the model (Tagliabue et al., 2016), in addition to the previously considered Fe input with dust deposition.

FESOM

Biogeochemical fluxes returned back to the ocean from the benthos are treated with a specific bottom boundary condition. Variable bottom topography leads to a smaller scalar control volume located at the lowermost level. This is because scalar control volumes are obtained by connecting the areas from the elements they are attached a constant level (see Fig. 1 in Danilov et al., 2017). Therefore, the number of elements around a single surface node may vary with depths when it meets non-flat topography. We thus computed the control volume and associated fluxes for each node by considering all surrounding elements at different depth levels.

Forcing

200 Our simulation was forced by the atmospheric reanalysis JRA55-do data set (Tsujino et al., 2018) instead of the CORE-II data set (Large and Yeager, 2009) that was used in previous assessments (Schourup-Kristensen et al., 2014). JRA55-do is a blend of reanalysis data and satellite observations and has the advantage to provide regularly updated near real time data up to present day with higher temporal (3-hourly) resolution.

2.2 Experimental setup and data

205 In this study, we used a mesh with a nominal resolution of 1 degree as a background. The horizontal resolution is enhanced on the equatorial belt and in the region north of 50°N to match 1/3 degree and 25 km, respectively. The mesh has 48 unevenly spaced vertical layers where the layer thickness ranges from 5 m in the surface to 250 m in the deep ocean (Scholz et al., 2019).

Initial fields for temperature and salinity were taken from the Polar Science Center Hydrographic Climatology (PHC3, updated from Steele et al., 2001). Total alkalinity (Alk) and preindustrial dissolved inorganic carbon (DIC) were initialized from version 2 of the Global Ocean Data Analysis Project (GLODAPv2) data set (Lauvset et al., 2016). Dissolved inorganic nitrogen (DIN) and dissolved silicic acid (DSi) were started with values from the Levitus World Ocean Atlas climatology of 2013 (Garcia et al., 2014). We used the Levitus World Ocean Atlas climatology of 2018 for dissolved oxygen (Garcia et al., 2019a) (See Table 2).

Due to scarcity of observations, the iron field (DFe) was initialized with output from the Pelagic Interaction Scheme for Carbon and Ecosystem Studies (PISCES) model (Aumont et al., 2003) which was corrected using observed profiles for the Southern Ocean (de Baar et al., 1999; Boye et al., 2001). Sensitivity tests indicated that high values stemming from a hydrothermal vent in the Eastern Equatorial Pacific lead to unreasonably large values in the interior Pacific Ocean due to advective fluxes. Therefore, the region spanning the latitudes of 12.5°S - 9.5°N, longitudes 72°W - 106°W was masked to a maximum value of 0.3 $\mu\text{mol m}^{-3}$ (below 2000 m). All other tracers were initialized with small values.

220 Iron was supplied to the ocean by dust deposition and from sediments. The sedimentary flux was assumed to scale with organic nitrogen flux into the sediment, as found in Elrod et al. (2004). REcoM3 used monthly averages of dust deposition (Albani et al., 2014). We assumed that 3.5% of the dust field consists of iron of which 1.5% dissolves into a bio-available form when deposited in the surface ocean. We did not include aeolian nitrogen deposition in our simulations.

Table 1. List of simulations performed in this study.

Experiment	Period	Atmospheric CO ₂	Atmospheric Forcing
pre-spinup	1611 – 1799	constant (278 ppm)	RYP61
<i>A_{spinup}</i>	1800 – 1957	increasing	RYP61
<i>B_{spinup}</i>	1800 – 1957	constant (278 ppm)	RYP61
A	1958 – 2021	increasing	JRA55-do
B	1958 – 2021	constant (278 ppm)	RYP61

225 The atmospheric reanalysis data sets of JRA55-do v.1.5.0 (Tsujino et al., 2018) were used to force the model for the period 1958–2021 (hereafter, JRA55-do). A single repeating annual cycle of all forcing fields (year 1961) was used to perform the spinup simulations and a control experiment. This is referred to as Repeat Year Forcing (hereafter called RYP61). We have deliberately chosen the year 1961 as it had rather neutral El Niño conditions and further contained a low amount of anthropogenic perturbation as compared to the years 1990 and 1991 recommended by Stewart et al. (2020).

230 A series of experiments was carried out in a global setup to investigate the performance of the coupled FESOM2.1-REcoM3 model. The experiments follow the definitions used in the Global Carbon Budget (Friedlingstein et al., 2022a) and in the RECCAP (Regional Carbon Cycle Assessment and Processes, <https://reccap2-ocean.github.io/>) projects and are summarized in Table 1. Our first experiment was forced with varying climate from the JRA55-do data set, and varying atmospheric CO₂ levels (hereafter referred as A). Atmospheric CO₂ mixing ratio ($x\text{CO}_2$) values are taken from the Global Carbon Budget (Joos and Spahni, 2008; Ballantyne et al., 2012; Friedlingstein et al., 2022a). A second simulation was forced by RYP61
235 atmospheric reanalysis fields and a preindustrial atmospheric CO₂ mixing ratio of 278 ppm. This configuration, here termed as B, is considered as the control run. Using these two simulations, the global ocean anthropogenic CO₂ sink was estimated by taking the model biases and drift from the control run into account. We used a coupled system spinup (i.e., a direct strategy, Séférian et al., 2016). Before starting simulations A and B, we performed spinup experiments in two stages. In the first stage, a 189-year long (equivalent to three cycles of JRA55-do forcing) preindustrial spinup simulation (named as pre-spinup) was
240 conducted using RYP61 atmospheric forcing and a preindustrial atmospheric CO₂ mixing ratio of 278 ppm until the air-sea CO₂ reaches a quasi-equilibrium state. The *A_{spinup}* and *B_{spinup}* simulations are a continuation of the pre-spinup simulation with either increasing (*A_{spinup}*) or constant (*B_{spinup}*) atmospheric CO₂ and run from 1800–1957. From the spinup simulations, A and B were branched off in 1958 and run until the end of 2020. FESOM1.4-REcoM2 and FESOM2.1-RECOM3 reach a throughput of 6 simulated years per day (SYPD) and 16 SYPD using the same mesh configuration and the same experimental
245 setup (See Table 1) on 288 cores with time steps of 15 min and 45 min, respectively. All modelled mean fields shown in this work are averaged over the period 2012–2021 unless stated otherwise.

Table 2. List of the observational data sets used to initialize the model and assess its performance.

Data set	Variable name	Unit	Reference
Dissolved inorganic carbon	DIC	mmol m ⁻³	Global Ocean Data Analysis Project version 2 (Lauvset et al., 2016)
Total Alkalinity	Alk	mmol m ⁻³	Global Ocean Data Analysis Project version 2 (Lauvset et al., 2016)
Dissolved inorganic nitrogen	DIN	mmol m ⁻³	World Ocean Atlas (Garcia et al., 2019a)
Dissolved inorganic silicon	DSi	mmol m ⁻³	World Ocean Atlas (Garcia et al., 2019a)
Oxygen	O ₂	mmol m ⁻³	World Ocean Atlas (Garcia et al., 2019b)
Chlorophyll <i>a</i> concentration	Chl	mg m ⁻³	OC-CCI (Sathyendranath et al., 2019) and Southern Ocean (Johnson et al., 2013)
Net primary production	NPP	mmol m ⁻³	CPBM (Westberry et al., 2008) and VGPM (Behrenfeld and Falkowski, 1997)

3 Results and discussion

In this section we assess the performance of FESOM2.1-REcoM3 in simulating the observed mean state of nutrients, chlorophyll *a*, net primary production, and export production in the near-surface ocean as well as air-sea CO₂ flux primarily under elevating CO₂. Before assessing the biogeochemical variables, we analyze key features of the ocean model.

3.1 Modelled hydrography, mixed layer and Atlantic meridional overturning

An extended analysis of analogous FESOM runs is presented in Scholz et al. (2019, 2021). Here we analyze only a few relevant diagnostics to prove the validity of the presented research. We start the analysis by inspecting the spatial distribution of the model bias in surface hydrography, presented in Fig. 3 as the difference between modeled mean 2012-2021 and the PHC3 Climatology (Steele et al., 2001). In the northern North Atlantic the bias is expressed by the cold (~4°C colder) and fresh (~1 psu fresher) anomalies around Newfoundland which is the typical bias for standalone and climate models at coarse resolutions (see e.g., Scaife et al., 2011). Further south, the bias depicts a dipole anomaly associated with the Gulf Stream going too far north, which is a commonly addressed shortcoming for non-eddy-permitting models (see e.g., Zhang and Vallis, 2007; Storkey et al., 2018). Similar issues are found in comparable current systems, such as the Kuroshio and Malvina systems. It is, however, surprising that in general FESOM is far too saline at the surface being on average 0.3 psu saltier than the climatology.

The differences in surface hydrography between runs A and B is shown in the lower panels of Fig. 3. These are on average smaller than the bias to climatology but depict large scale patterns. In most of the ocean the SST and SSS differences act in an opposite manner at buoyancy. Hence increase or decrease in SST is accompanied with an increase or decrease in SSS. The only exception is the Indian Ocean, where East and West in run A become less and more buoyant, respectively.

In Fig. 4, we augment the diagnostic by inspecting the Atlantic meridional overturning circulation (AMOC) which provides the most general characteristic of water mass transformation and production. The mean AMOC in both runs is expressed with the basinwide mid depth cell showing a maximum of ~ 15 Sv at ca 40°N. The bottom cell, induced by the circulation of the

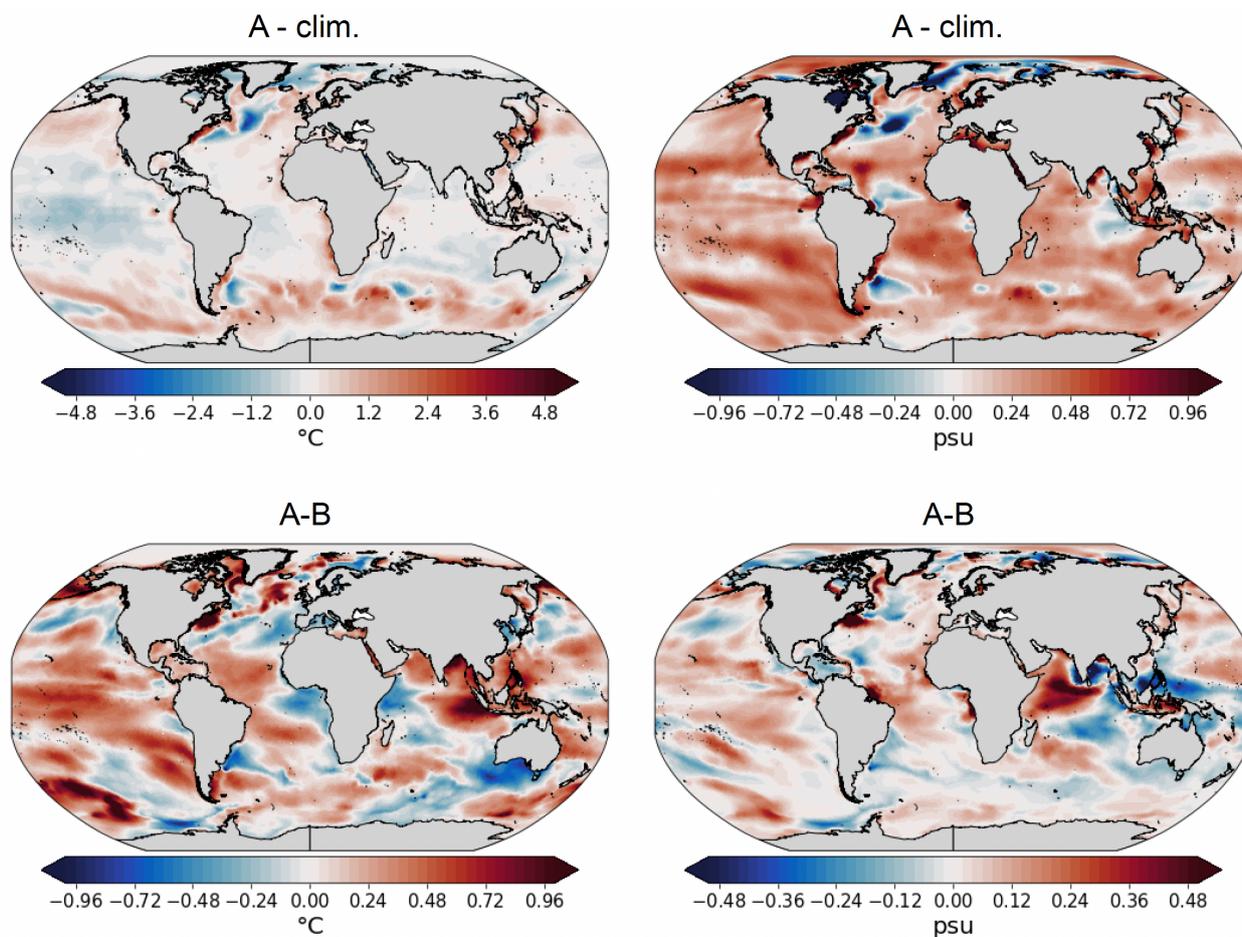

Figure 3. Maps showing differences in surface temperature [°C] (left column) and practical salinity (right column) between FESOM2.1 and the PHC climatology (top row) and between simulations A and B (bottom row) averaged over the time period 2012-2021.

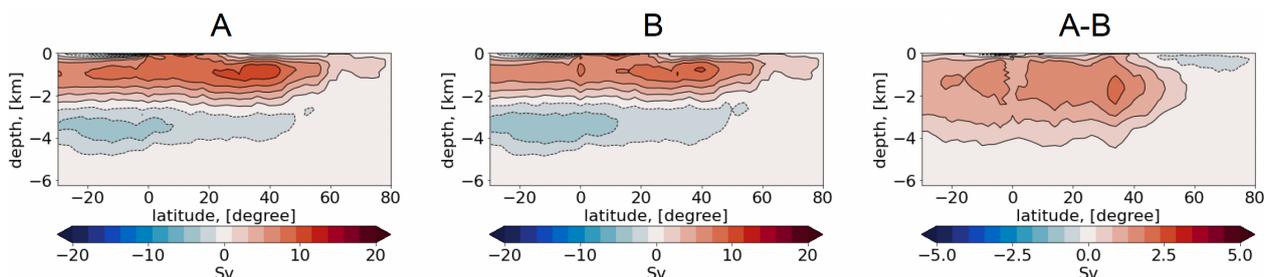

Figure 4. Vertical representation of the Atlantic Meridional Overturning Circulation (AMOC) in simulations A, B and their difference [Sv].

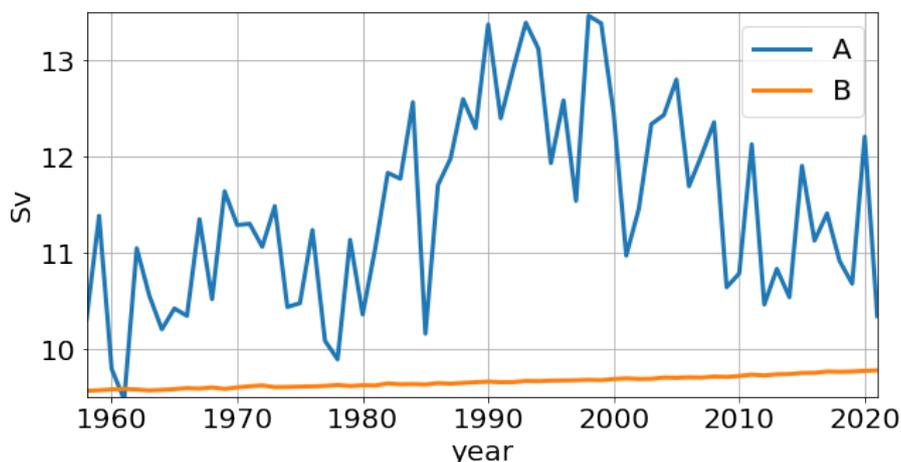

Figure 5. Time-series of annual mean Atlantic Meridional Overturning Circulation (AMOC) maxima in simulations A and B.

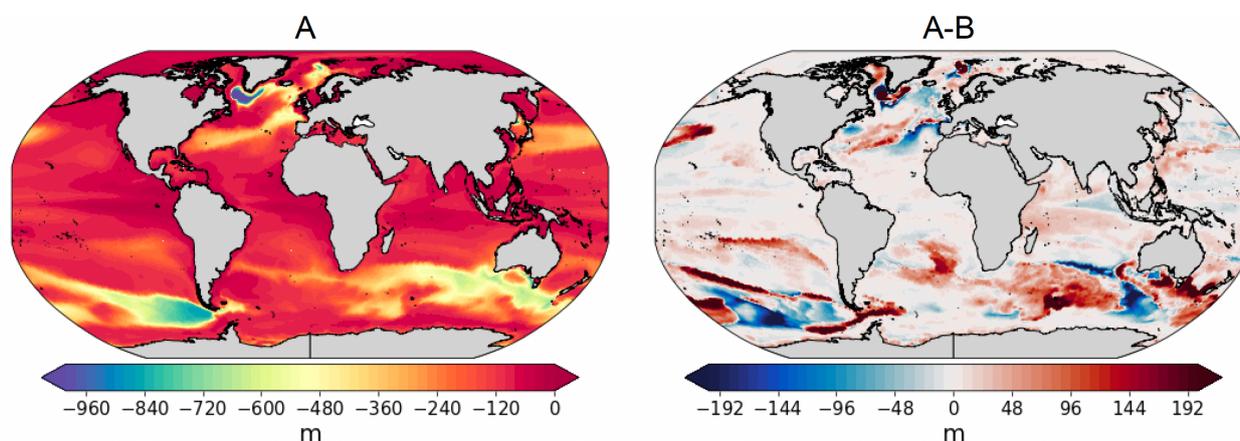

Figure 6. Mean of 2012-2021 annual maximum Mixed Layer Depth (MLD) in simulation A and difference between simulations A and B.

Antarctic Bottom water, is also well reproduced with a minimum of ~ -5 Sv. Even though the runs depict large differences in temperature and salinity from the observed climatology, the simulated AMOC shows the canonical picture as known from other works. This indicates that although biases in the representation of water mass properties and ventilation mechanisms are present, they still result in a reasonable density distribution which maintains realistic transports.

The difference between runs A and B shows that the mid depth and bottom cells are stronger in simulation B. Consequently, the difference A-B is expressed by a basinwide positive anomaly with a maximum of ~ 3 Sv. We also show the time-series of both AMOC maxima for the years 1958-2021 (Fig. 5). In run A, the time-series depicts a multidecadal variability with a minimum of ~ 9.5 Sv and a maximum of ~ 13.5 Sv. Concurrently the reference run B depicts a nearly constant value between 9.5 Sv and 10 Sv, a result of repeated year forcing.

Finally in Fig. 6 we present the annual maximum mixed layer depth (MLD) pattern. It matches those known from literature with the deepest MLD (>1000 m) found in the Labrador Sea (LS). The (annual maximum) MLD difference between the two simulations is within the depth range of ~ 200 m. In run B the MLD is deeper in the central LS but shallower in the surrounding area of it. Interestingly, the MLD difference there pursues the differences we found for SST and SSS patterns shown in Fig. 1. From inspecting the model runs and their differences we conclude that FESOM2.1 simulated a reasonable ocean state which can be used for further analysis.

3.2 Nutrients, ocean productivity and ecosystem

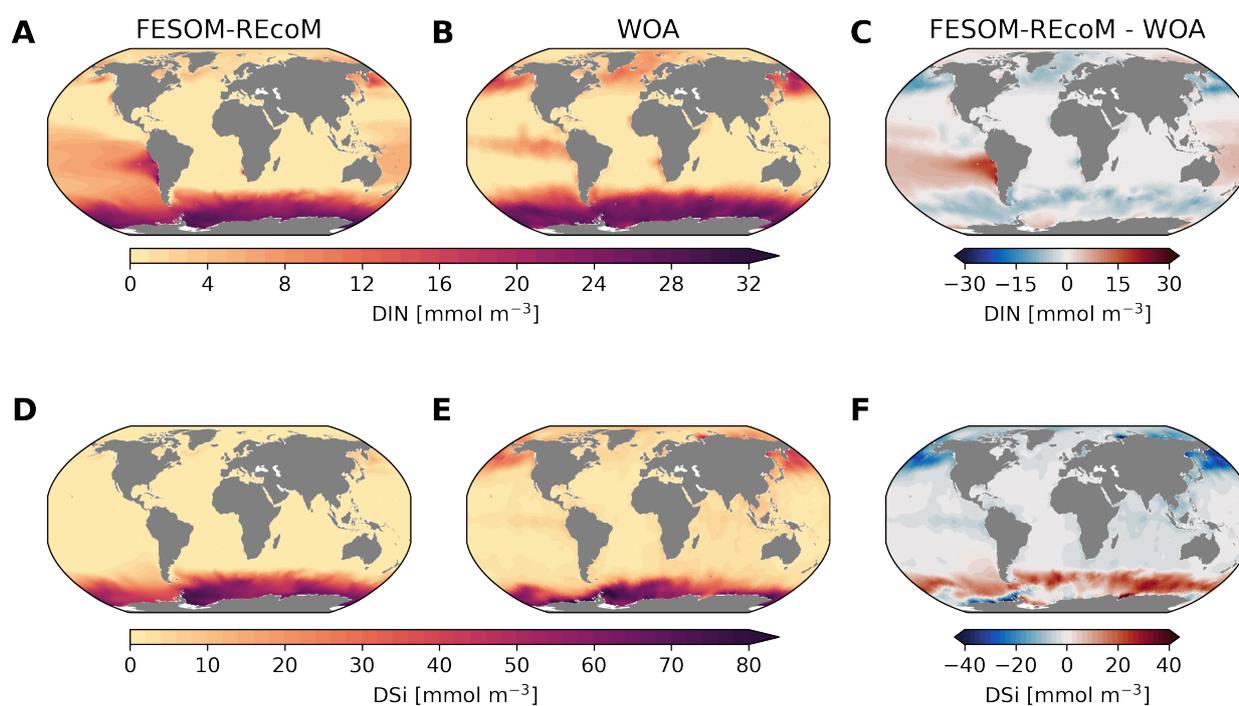

Figure 7. Maps of simulated FESOM2.1-REcoM3 surface [0-100m] concentration of dissolved inorganic nitrogen [mmol m^{-3}] (A), dissolved inorganic silicon [mmol m^{-3}] (D) with observations from the World Ocean Atlas 2018 climatology (B and E, Garcia et al., 2019b) and corresponding differences (C, F) averaged over the time period 2012-2021.

3.2.1 Modeled versus in situ nutrients

We first compared the spatial distribution of surface (averaged over the top 100m depth layer) ocean dissolved inorganic nitrogen (DIN) and dissolved silicate (DSi) from REcoM3 with the World Ocean Atlas 2018 (Garcia et al., 2019b) climatologies (Fig. 7). While simulated surface DIN concentrations were lower than observations in the subpolar regions, a large positive DIN bias of up to 20 mmol m^{-3} was found in the subtropical South Pacific Ocean. The simulated DSi was overestimated in

the Southern Ocean and underestimated in the northern Pacific. Exceptions are the Pacific and Atlantic sectors of the coastal
290 Southern Ocean where the modeled DSi concentrations are lower than the observations. These patterns were already present
in FESOM1.4-REcoM2 (Schourup-Kristensen et al., 2014), however, two recent improvements should be noted. First, the
large and positive DIN bias in the northern subtropical Pacific (Schourup-Kristensen et al., 2014) disappeared. This is caused
by replacing the dust deposition input forcing field from Mahowald et al. (2003) with Albani et al. (2014), which results in
more realistic (i.e., less strong) iron limitation. Second, the silicate bias in the Southern Ocean is reduced in magnitude and
295 extent compared to Schourup-Kristensen et al. (2014). This is related to tuning experiments (not shown), which resulted in
a larger share of diatoms in the Southern Ocean (Figure 12) compared to Schourup-Kristensen et al. (2014), thus drawing
down more silicic acid. Along with the increased share of diatoms, the Southern Ocean opal export has also increased from
74.5 Tmol Si yr⁻¹ in Schourup-Kristensen et al. (2014) to 115 Tmol Si yr⁻¹ in the present study and is thus more centrally
positioned in the range of 69-185 Tmol Si yr⁻¹ (Dunne et al., 2007) and close to the best estimate of Tréguer et al. (2021)
300 (Table 3). The silicic acid bias is rather insensitive to formulation and parameter choice of opal dissolution, but very sensitive
to the share of diatoms in the Southern Ocean. The correlation coefficient and root mean squared error (RMSE) between
simulated and observed annual mean DIN were 0.88 and 0.86 mmol m⁻³ respectively, and 0.47 and 0.54 mmol m⁻³ for
DSi. The correlation with observed DIN is higher than in Schourup-Kristensen et al. (2014, 0.75), which we relate to the
disappearance of the DIN bias in the northern subtropical Pacific. The correlation with observed DSi is lower than in FESOM-
305 1.4-REcoM2, despite the reduction in magnitude and extent in the Southern Ocean DSi bias. Moderately high silicic acid
values in the northern high latitudes are not reproduced.

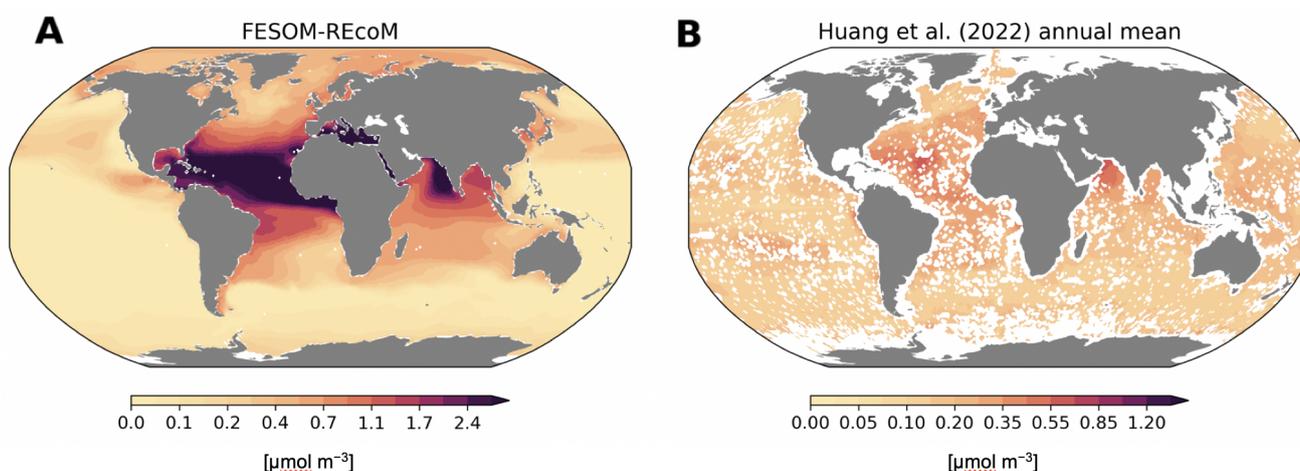

Figure 8. Maps of simulated FESOM2.1-REcoM3 surface [0-50m] concentration of dissolved iron [$\mu\text{mol m}^{-3}$] (A), and of the AI-based global reconstruction by Huang et al. (2022) (B). Note the different colorscale for the two plots.

Despite the enormous increase in the number of observations of dissolved iron with the GEOTRACES project, observations have not reached a global coverage that makes it possible to construct a global climatology. Therefore the modeled dissolved

iron is compared here to the global surface pattern of dissolved iron by Huang et al. (2022), which uses an artificial intelligence
310 method (random forest) to construct a near global iron field, based on the observations in the second intermediate GEOTRACES
data product (Schlitzer et al., 2018), plus some older in-situ iron observations compiled in Tagliabue et al. (2012), and on co-
located hydrographic observations. The pattern of modeled dissolved iron (Figure 8, averaged over the top 50 m) shows the
expected pattern of high concentrations in regions with high dust deposition, mainly in the tropical Atlantic Ocean and the
eastern part of the Arabian Sea, but also to some extent in the southern subtropical Atlantic and Indian Oceans. Concentrations
315 are extremely low in the subpolar Southern Ocean, and almost the whole Equatorial and South Pacific. Iron concentrations are
also low in the subpolar North Pacific, and — less so, but still noticeable — in the subpolar North Atlantic. Oceanic regions
adjacent to extended shelves, especially in the Arctic, show somewhat elevated iron concentrations. If we compare this to the
AI-generated global pattern of dissolved iron from Huang et al. (2022) we find qualitatively similar patterns, like the elevated
iron concentration in the equatorial and subtropical Atlantic and the Arabian Sea, or the low concentrations in the subpolar
320 Southern Ocean, the equatorial Pacific, and the subpolar North Pacific, but the amplitude of the patterns is quite a bit smaller.
An important difference is that the distribution by Huang et al. (2022) shows slightly elevated iron concentrations in the center
of the subtropical South Pacific, where the model in contrast has extremely low values. This discrepancy causes a too strong
iron limitation in this region in the model, probably explaining the overly high DIN concentrations in the model South Pacific.
The too strong amplitude of the patterns in modeled dissolved iron, which is also found in other models, likely has a number of
325 causes. The most important one is probably the assumption of a constant solubility in dust-deposited iron. Dust deposition close
to the main source regions is on average coarser and has experienced less chemical processing during its transport, which both
would lead to a lower solubility, while the opposite is true for regions far from the source regions, such as in the South Pacific.
A second contribution might be the missing source from pyrogenic aerosols, which are far more soluble. Also, the effect of
dust particles as iron scavengers, which has not been included in this simulation, has been shown to reduce the overly high
330 dissolved iron concentrations often found in models under the main dust deposition regions (Ye and Völker, 2017; Pagnone
et al., 2019). Despite the overall too strong amplitude of the patterns in dissolved iron, especially in the regions of high dust
deposition, the model is able to reproduce the main regions where iron availability limits phytoplankton productivity (Moore
et al., 2013), namely the subpolar Southern Ocean, the equatorial and North Pacific, and to some extent also the seasonal iron
limitation in the subpolar North Atlantic (Nielsdóttir et al., 2009), but overestimates iron limitation in the subtropical South
335 Pacific.

3.2.2 Modeled versus satellite-based Chlorophyll *a*

The modeled spatial distribution of (log10 transformed) chlorophyll *a* concentration averaged from 2012 to 2021 was compared
with the Ocean Colour Climate Change Initiative (OC-CCI) merged data set (Sathyendranath et al., 2019). Over large parts
of the global ocean, the mean surface chlorophyll *a* concentrations are in agreement with observations (Fig. 9 panels C and
340 D). Yet, there are regional differences. The model underestimates chlorophyll concentration in most of the coastal regions,
such as in the coastal Arctic regions with biases reaching about 3 mg chlorophyll *a* m⁻³. In temperate latitudes, the modeled
chlorophyll *a* concentrations are somewhat higher than observed while the subtropical gyres show concentrations slightly

345 lower than observations. The comparison of modeled and observational-based satellite estimates of chlorophyll *a* yielded a correlation of 0.66. Note, however, that remote sensing global semi-analytical algorithms, such as the one use in OC-CCI (the Garver–Siegel–Maritorena model version 1; GSM01, Maritorena et al., 2002) are mostly adapted for global studies, but still require regional tuning in coastal regions, where the presence of non-biotic optically active material makes chlorophyll *a* retrieval challenging (Blondeau-Patissier et al., 2014).

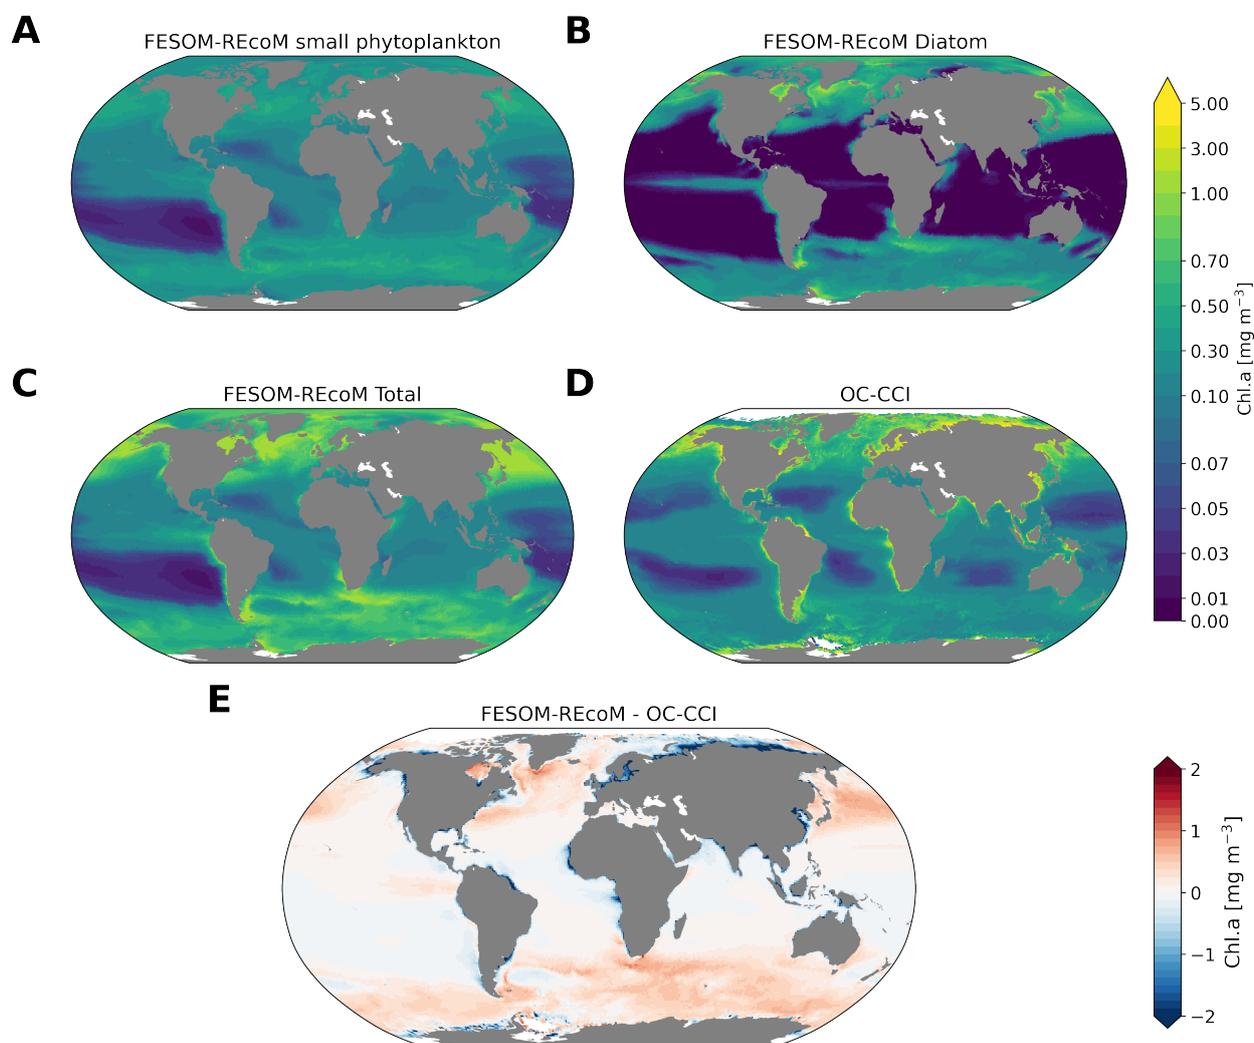

Figure 9. Maps of simulated FESOM2.1-REcoM3 (simA) surface chlorophyll *a* concentration [mg Chl m^{-3}] of small phytoplankton (A), diatoms (B) and the sum of both phytoplankton groups (C). The satellite-based merged dataset OC-CCI is shown in (D, Sathyendranath et al., 2019) with corresponding differences between FESOM2.1-REcoM3 and OC-CCI (E). Note the different time periods of the simulation (2012-2021) and OC-CCI (1998-2019).

3.2.3 Modeled versus satellite-based NPP

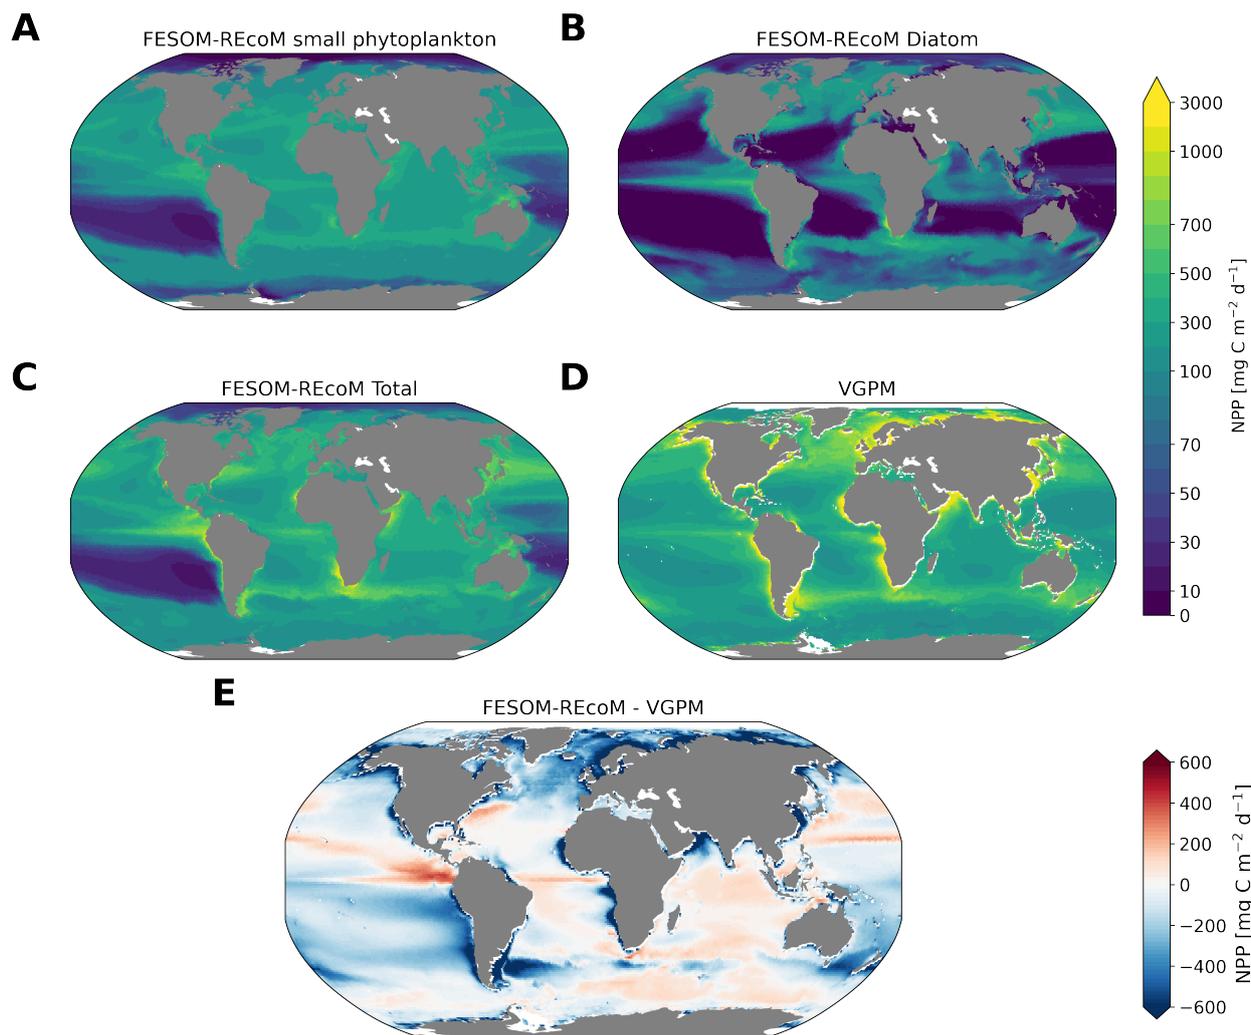

Figure 10. Maps of simulated FESOM2.1-REcoM3 (simA) vertically integrated net primary production [$\text{mg C m}^{-2} \text{d}^{-1}$] of small phytoplankton (A), diatoms (B), and the sum of both phytoplankton groups (C). The satellite-based Vertically Generalized Production Model (VGPM) is shown in (D; Behrenfeld and Falkowski, 1997) with corresponding differences between FESOM2.1-REcoM3 and VGPM (E). All fields are averaged over the time period 2012 to 2021.

We also compared the modeled vertically integrated Net Primary Production (NPP, Fig. 10) with the Vertically Generalized Production Model (VGPM, Behrenfeld and Falkowski, 1997). VGPM is a chlorophyll-based algorithm that can be considered as a standard NPP estimation from ocean color for the last 20 years (Lee and Marra, 2022). VGPM therefore carries uncertainties related to the global Chlorophyll algorithm (OC4) adapted to CASE-I waters (low influence of dissolved organic matter

and non-algal particles) that is not adapted to coastal regions (CASE-II waters, high influence of dissolved organic matter and non-algal particles). For example, turbid waters contaminated by yellow substances or sediments over the Arctic shelves is a known issue that artificially increases both Chlorophyll a and NPP (Matsuoka et al., 2012; Mitchell, 1992; Mustapha et al., 2012). Some recent advances used local parametrizations with in situ data which resulted in much lower productivity levels in those coastal areas (Lewis et al., 2020; Lewis and Arrigo, 2020). Therefore, we additionally compared modelled NPP with the updated Carbon-based Productivity Model (CbPM, Westberry et al., 2008, see Appendix Fig. A1). CbPM uses spectrally resolved light attenuation and is based on a semi-analytical algorithm (Garver-Siegel-Maritorena, GSM, Maritorena et al., 2002) which tries to distinguish optical signatures from phytoplankton, particles and dissolved organic matter. Nevertheless, both algorithms are subject to large uncertainties (Lee and Marra, 2022). When compared with VGPM, the model simulation generally underestimated the remotely sensed NPP estimations (Table 3), especially in the subtropical Pacific. Yet, with a value of 35.9 PgC yr⁻¹ the modeled global total NPP is slightly above the range of earlier modeling studies (23.7 - 30.7 PgC yr⁻¹, Schneider et al., 2008), and within the range of recent Earth System Models (24.5 - 57.3 PgC yr⁻¹, Séférian et al., 2020). It is lower than other satellite-based estimates of 47.3 PgC yr⁻¹ (Behrenfeld and Falkowski, 1997), 52 PgC yr⁻¹ (Westberry et al., 2008) and 48.7 - 52.5 PgC yr⁻¹ reported by Kulk et al. (2020).

The low values of primary production could be caused by several top-down and/or bottom-up effects. The nutrient dynamics that partly control NPP, are the result of a delicate balance between physical (mixing, stratification and upwelling systems) and biogeochemical processes. To investigate bottom-up controls on regional NPP dynamics, we derived the most limiting factor (either light or nutrients) of growth of diatom and small phytoplankton. This factor ranges between 0 (most limiting) and 1 (no limitation) and is based on the nutrient uptake Michaelis–Menten kinetics of REcoM. The Michaelis–Menten coefficient (MM) is computed as $MM = [Nut]/([Nut] + KNut)$, with [Nut] being the nutrient concentration, and KNut a nutrient and phytoplankton dependent half-saturation constant. The light limitation is defined as the carbon-specific photosynthesis rate divided by the maximum photosynthetic rate. We derived maps showing the most limiting factor (factor closest to zero, either nutrients DIN, DSi, or DFe, or light) in the annual mean (Fig. 11).

Spatial distribution of the dominant growth-limiting factor for diatoms and small phytoplankton over the time period 2012-2021 is shown in Fig. 11. Over large areas of the Southern Pacific and almost the entire Southern Ocean diatoms were limited by iron availability. Elsewhere, except for the Arctic Ocean where light was the most limiting factor, diatom growth was controlled by the abundance of dissolved silicic acid. Nutrient uptake of small phytoplankton was limited by iron in the South Pacific, DIN within the band of 45°S-45°N in the Atlantic and Indian Oceans and insufficient light at high latitudes (south of 45°S and north of 45°N).

The large-scale patterns of limitation were in general agreement with observations (Moore et al., 2013) and other modelling studies (Long et al., 2021a), although the degree of silicic acid limitation for diatoms (outside the iron-limited Southern Ocean) varied across models (Laufkötter et al., 2015). The more severe than expected limitation in iron in most of the Pacific might contribute to the lower productivity levels than observed in the same regions (Fig. 10).

In addition to bottom-up explanations, one can also raise a too high grazing pressure from zooplankton due to the choice of grazing formulations and parameter values as a reason for low primary production (Anderson et al., 2010; Prowe et al.,

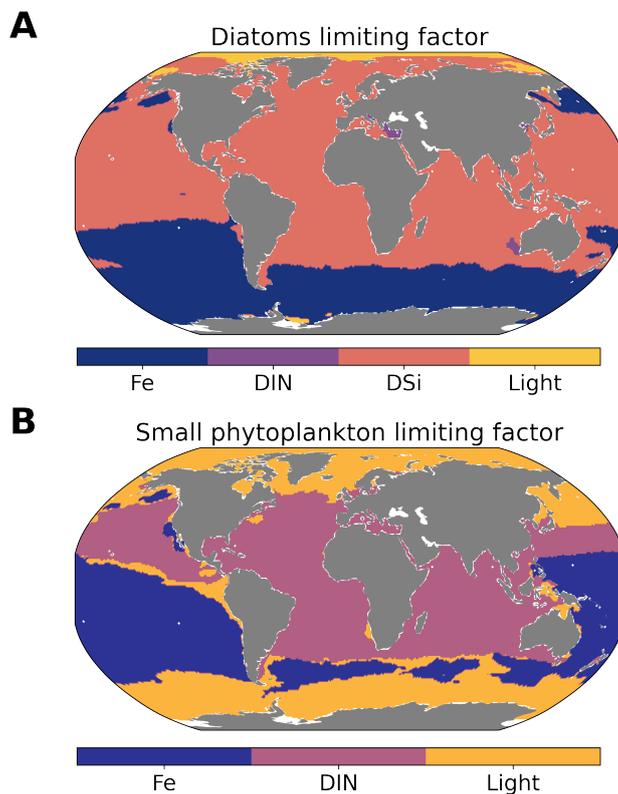

Figure 11. Maps showing the spatial distribution of the most limiting factor in the model's surface water for Diatoms (A) and small phytoplankton (B). Fe: iron, DIN: dissolved inorganic nitrogen, DSi: dissolved silicic acid.

2012; Karakuş et al., 2021). In fact, Karakuş et al. (2022) demonstrated that a separation of the small zooplankton group in REcoM into micro- and mesozooplankton leads not only to a 25% increase in NPP but also to a reduction of overly strong iron limitation in the South Pacific, due to nutrient recycling by zooplankton. Further, REcoM does not explicitly represent picophytoplankton (e.g., non N_2 -fixing cyanobacteria such as *Synechococcus* and *Prochlorococcus*) and nitrogen fixers, and this might contribute to an underestimation of NPP.

Too low primary production and chlorophyll *a* levels were particularly evident in coastal regions, which could be linked to deficiencies in either the chlorophyll data set (see above) or in the model. For the latter, reasons could be coarse model resolution and associated weak upwelling and missing phytoplankton classes in the model, but also insufficient nutrient input from terrigenous sources. The results for net primary productivity and chlorophyll obtained here are comparable to those presented by Schourup-Kristensen et al. (2014).

The latitudinal distribution of chlorophyll *a* and NPP were compared with estimations from remote sensing products (Fig. 12). In low latitudes, FESOM2.1-REcoM3 shows a reasonably simulated latitudinal variation of chlorophyll *a* and NPP compared to VGPM. In the southern high latitudes, FESOM2.1-REcoM3 follows the Southern Ocean adjusted chlorophyll data set

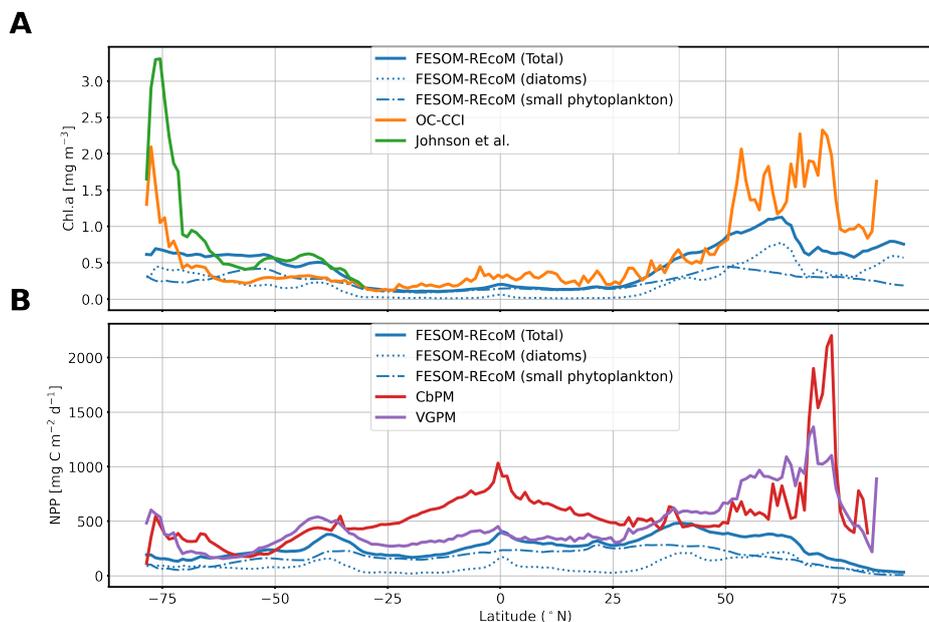

Figure 12. Latitudinal distribution of vertically integrated and zonally averaged (A) chlorophyll a [mg Chl m^{-3}] and (B) net primary production [$\text{mg C m}^{-2} \text{d}^{-1}$] simulated by FESOM2.1-REcoM3 (blue line). The satellite-based merged chlorophyll a datasets of OC-CCI (Sathyendranath et al., 2019, orange line) and the improved chlorophyll a algorithm of the Southern Ocean (Johnson et al., 2013, green line) are shown in (A). The satellite-based dataset of the Vertically Generalized Production Model (VGPM) (Behrenfeld and Falkowski, 1997, purple line) and the Carbon-based Productivity Model (CbPM) (Westberry et al., 2008, red line) are shown in (B).

well, except for the coastal regions close to Antarctica (approximately south of 70°S). Similarly, NPP corresponds reasonably well to the VGPM estimate in the open Southern Ocean, but may underestimate NPP in Antarctic coastal waters. In the northern high latitudes, however, the simulated chlorophyll a values are lower than the satellite estimations. Inspecting the spatial distribution (Fig. 9) reveals that this is also largely a coastal underestimation. In the open ocean in northern high-latitudes, chlorophyll is reasonably well reproduced and even partly higher than the satellite-based estimate. In terms of NPP, differences between simulated and satellite estimations are larger in productive areas north of 50°N , which are strongest at the coast, but also apparent in the open ocean of the North Atlantic. For regional applications, further analysis and possibly tuning may be needed.

3.2.4 Modeled versus MAREDAT zooplankton biomass

410 In REcoM3, the small zooplankton group is widely spread in the global ocean and the highest biomass occurs in high-productivity regions (Fig. 13A). The macrozooplankton is present in the high latitudes (Fig. 13B) since it is parametrized as a polar macrozooplankton group (Karakuş et al., 2021). We compared the latitudinal distribution of integrated modeled zooplankton biomass with gridded global zooplankton biomass data from MAREDAT (Buitenhuis et al., 2010; Moriarty et al.,

2013; Moriarty and O'Brien, 2013). The simulated biomass of small and total zooplankton reproduces MAREDAT-derived biomass reasonably well in low to mid latitudes, but underestimates biomass in the polar regions (Fig. 13C). The underestimation of zooplankton biomass in the northern high latitudes may be related to an underestimation of primary production in the same region. In agreement with the MAREDAT data set (Moriarty et al., 2013), macrozooplankton is not present in low latitudes.

3.2.5 Synthesis

The modeled biogeochemical fluxes were compared to the previous version FESOM1.4-REcoM2 and observational studies (Table 3). Modelled global NPP is higher in FESOM2.1-REcoM3 than in FESOM1.4-REcoM2, but still lower than in satellite-based estimates. The estimate is comparable to other modelling studies (Schneider et al., 2008; Séférian et al., 2020). Export production (EP) is slightly lower in FESOM2.1-REcoM3 than in the previous version, and falls within the observational range previously documented in the literature for both the global and the Southern Ocean. For the global ocean, FESOM2.1-REcoM3 NPP and EP estimations remained at the lower end of the range despite a slight increase in NPP. A more detailed description of zooplankton can increase NPP by 25% (Karakuş et al., 2022). In the Southern Ocean, estimations of NPP and EP remained very close to observations. Maybe the most noticeable change between the two model versions is the substantial increase in opal export which almost doubled in the Southern Ocean, passing from the lower to the middle of observational range in an earlier review (Dunne et al., 2007), and is in excellent agreement with an updated estimate (Tréguer et al., 2021). This is due to an increase in diatoms relative contribution to the total NPP in high latitudes (Fig. 12).

3.3 Carbon cycle

3.3.1 Dissolved inorganic carbon and alkalinity

Insight into the carbonate system can be obtained by inspecting surface maps of modeled dissolved inorganic carbon (DIC) and alkalinity and the corresponding observational GLODAPv2 climatologies (Fig. 14). Global patterns of simulated concentrations resemble the observed fields reasonably well ($R = 0.81$, $RMSE = 59.3 \text{ mmol m}^{-3}$, calculated from annual means) with highest DIC values in the subtropical gyres of the Atlantic and south Pacific, as well as the subpolar North Atlantic and the Southern Ocean. Similar to GLODAP, highest alkalinity values are found in the subtropical gyres of the Atlantic and south Pacific. Yet, simulated surface DIC and alkalinity concentrations were slightly overestimated throughout the surface ocean. Two exceptions are the Arctic Ocean and the North Atlantic where the concentrations were underestimated. The departure from observations differ in their patterns relative to FESOM-1.4-REcoM (too low DIC and ALK in the tropics and subtropics, too high in high latitudes, not shown), which indicates that different realisations in circulation or mixing may drive these bias patterns. This is in line with an overestimation of surface salinity in most of the global ocean with the exception of the North Atlantic and the Arctic Ocean (see Fig. 3). Also, surface alkalinity biases are generally attributed to a dominant physical (preformed) signal with a smaller contribution from the calcium carbonate cycle and a negligible contribution from organic matter remineralization (Koeve et al., 2014). However, tuning the model to result in a higher CaCO_3 production could possibly also counteract the

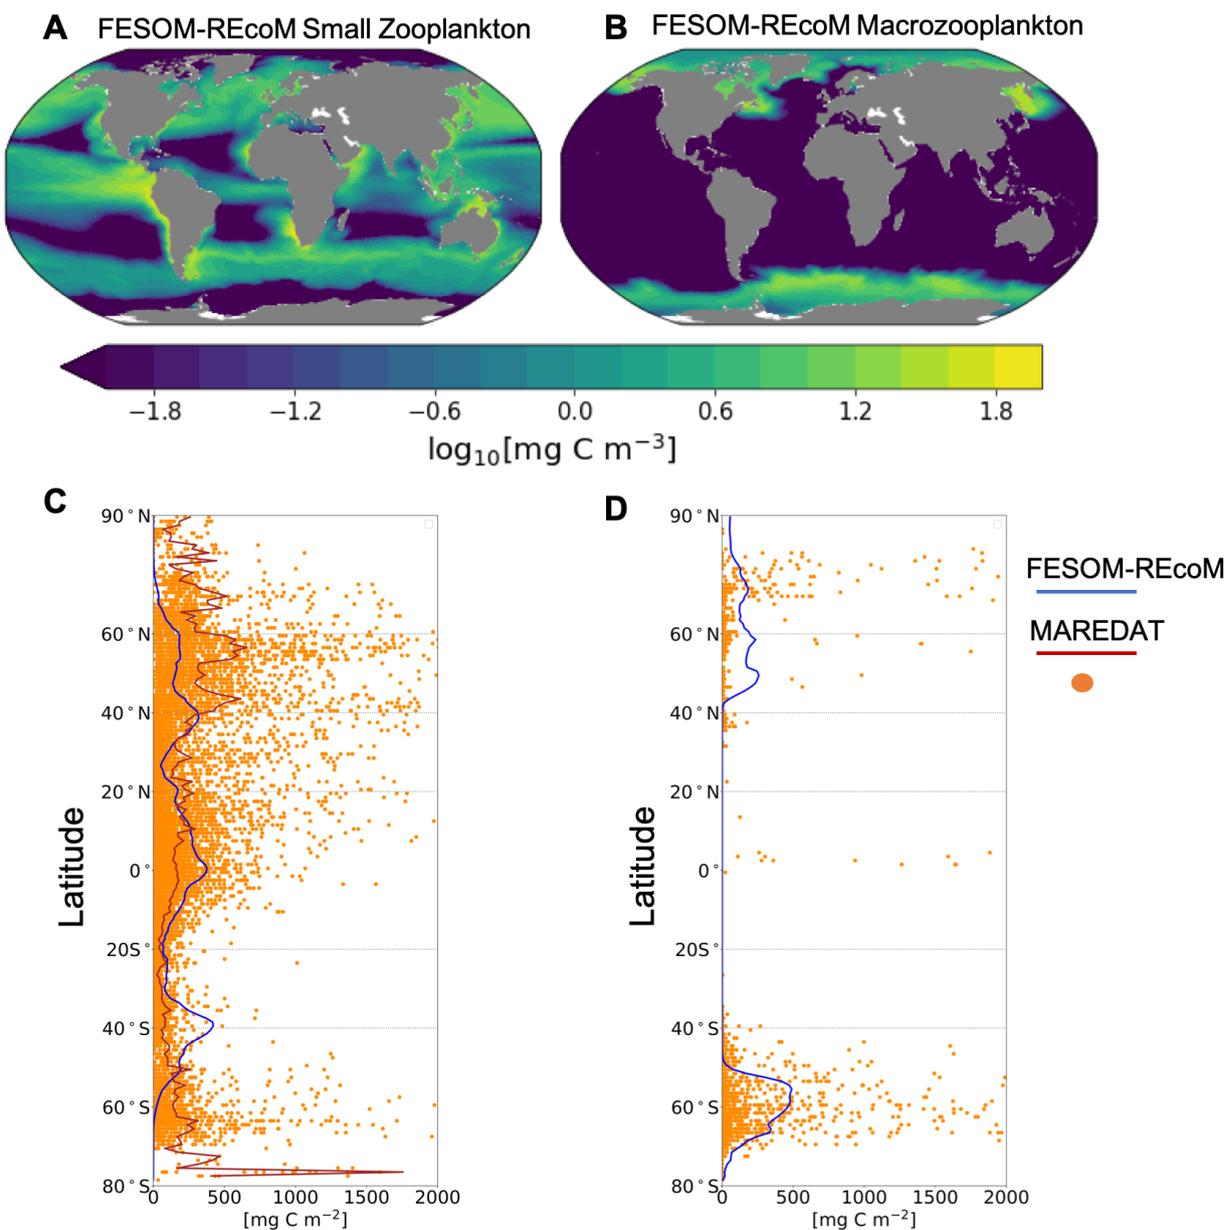

Figure 13. Maps of annual mean surface (A) small zooplankton and (A) macrozooplankton concentrations in FESOM2.1-REcoM3. Latitudinal distribution of vertically integrated $[\text{mg C m}^{-2}]$ of (C) modeled small zooplankton (solid blue line) and sum of microzooplankton and mesozooplankton from MAREDAT (orange dots and solid brown line, Buitenhuis et al., 2010; Moriarty and O'Brien, 2013) and (D) modeled macrozooplankton (solid blue line) and macrozooplankton from MAREDAT (orange dots, Moriarty et al., 2013). Modeled zooplankton biomass is averaged over the time period 2012 to 2021.

Table 3. Global and Southern Ocean net primary production (NPP) and export production (EP) in FESOM2.1-REcoM3 and estimates from the literature. The Southern Ocean is considered as the region south of 50°S. The numbers for VGPM and CbPM are recalculated after interpolation to the model mesh over the years 2012-2019

	Unit	FESOM1.4-REcoM2 (Sim. A)	FESOM2.1-REcoM3 (Sim. A)	Range from literature
NPP global	PgC yr ⁻¹	32.5	35.8	50.5 (VGPM, this study) 68.9 (CbPM, this study) 47.3 (Behrenfeld and Falkowski, 1997) 52 (Westberry et al., 2008) 23.7 – 30.7 (Schneider et al., 2008) 48.7 - 52.5 (Kulk et al., 2020) 24.5 - 57.3 (CMIP6) (Séférian et al., 2020)
EP global	PgC yr ⁻¹	6.1	5.9	9.6 (Schlitzer, 2004) 5.8-13 (Dunne et al., 2007) 5 (Henson et al., 2011) 5.9 (Siegel et al., 2014)
Opal export global	Tmol Si yr ⁻¹	74.5	115	69-185 (review in Dunne et al., 2007) 112 (Tréguer et al., 2021)
CaCO ₃ export global	PgC yr ⁻¹	1.2	0.59	0.1 - 4.7 (Seifert et al., 2022)
NPP Southern Ocean	PgC yr ⁻¹	3.1	3.2	3.48 (VGPM, this study) 3.92 (CbPM, this study) 1.1-4.9 (Carr et al., 2006) 5.7 (Behrenfeld and Falkowski, 1997)
EP Southern Ocean	PgC yr ⁻¹	1.1	1.1	1.0 (Schlitzer, 2002; Nevison et al., 2012)
Opal export Southern Ocean	Tmol Si yr ⁻¹	21.5	38	21-54 (Dunne et al., 2007)
CaCO ₃ export Southern Ocean	PgC yr ⁻¹		0.044	0.018 (Dunne et al., 2007)

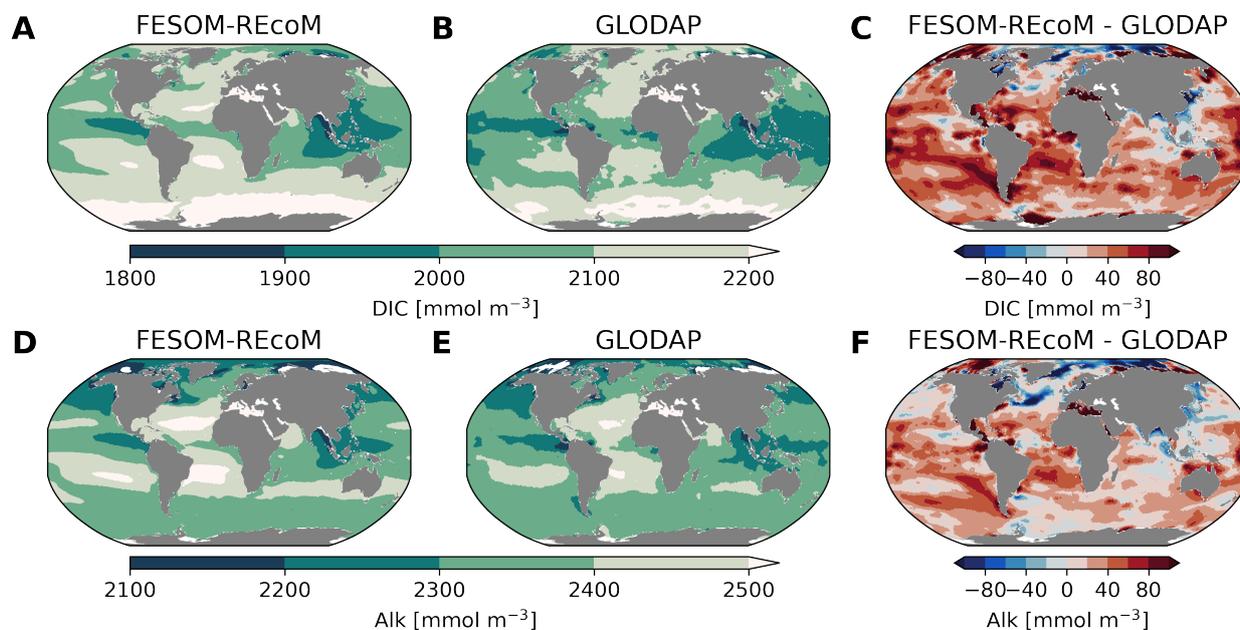

Figure 14. Maps of simulated FESOM2.1-REcoM3 surface [0-100m] concentration of dissolved inorganic carbon [mmol m^{-3}] (A) and alkalinity [mmol m^{-3}] (D); corresponding data from GLODAPv2 (B, E; Lauvset et al., 2016) and model-data differences (C, F). The comparison is for the period of 2012-2021.

positive alkalinity bias. Similarly, a higher NPP in the South Pacific could regionally ameliorate the high DIC bias. A positive bias in alkalinity at constant atmospheric CO_2 in the spin-up (not shown) and simulation A (Fig. 14) leads to a positive bias in DIC as surface water with a higher alkalinity can hold more CO_2 in equilibrium than a low-alkalinity surface ocean. The range of biases is similar as in other ocean biogeochemical models (e.g., Tjiputra et al., 2020; Long et al., 2021a).

450 3.3.2 Surface ocean pCO_2 and air-sea CO_2 flux

We compare the pattern of the temporal mean (2012-2021) surface ocean partial pressure of CO_2 (pCO_2 , Figure 15) and air-sea CO_2 flux (Figure 16) to the pCO_2 -based data-product of Chau et al. (2022) with a seamless coverage from open ocean to the coasts (Fig. 16). The spatial patterns of pCO_2 -products largely agree with each other although the magnitude differs (Fay et al., 2021; Fay and McKinley, 2021). Therefore we chose one of them (Chau et al., 2022) and focus on the comparison of
455 the spatial pattern with our model. We further evaluate the temporal evolution of pCO_2 in FESOM2.1-REcoM3 with a direct comparison to surface ocean pCO_2 observations from the Surface Ocean CO_2 Atlas (SOCAT, Bakker et al., 2016), where we subsampled the model output for spatio-temporal locations where observations exist, following Hauck et al. (2020) and Friedlingstein et al. (2022b) in Figure 17.

The large-scale spatial patterns of pCO_2 are well reproduced (Figure 15) with high values in the tropics that are typically
460 higher than atmospheric values (red colors), and lower values in the subpolar Southern and Pacific Ocean and the high-latitude

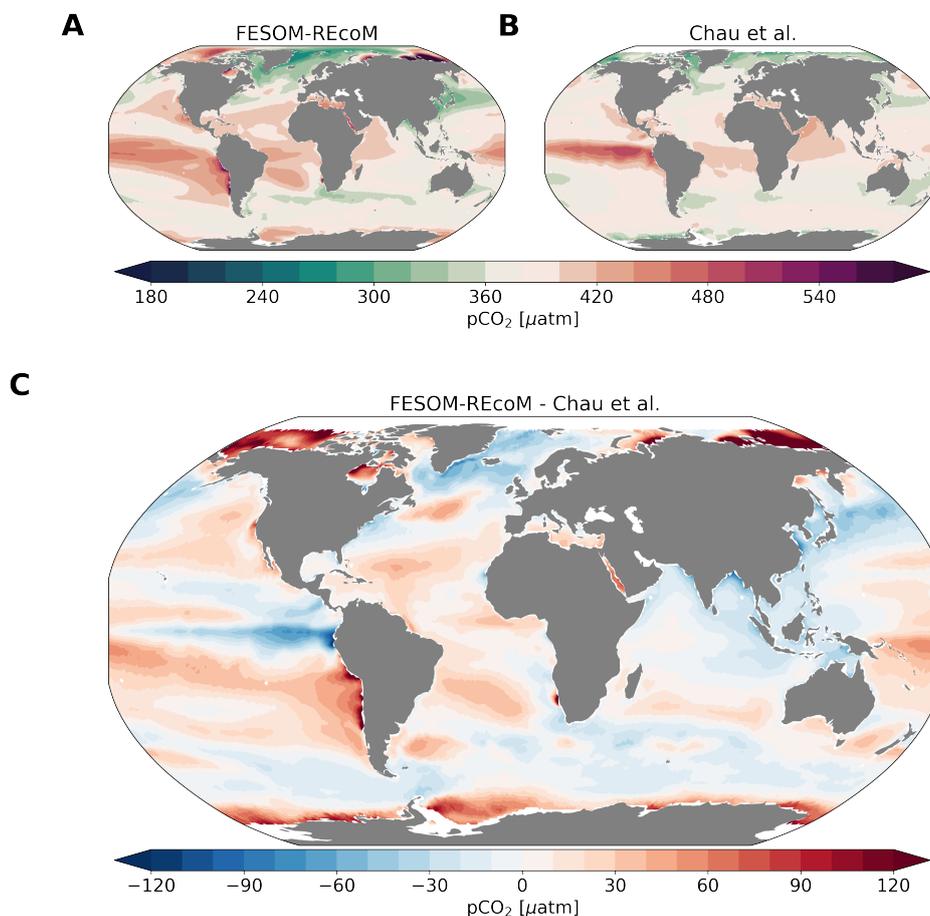

Figure 15. Maps of surface ocean pCO₂ [μatm]. The top row compares the (A) simulated FESOM2.1-REcoM3 surface partial pressure of CO₂ to the (B) pCO₂-based data-product (Chau et al., 2022), both averaged over 2012-2021. The bottom panel (C) shows model-data differences.

North Atlantic. However, compared to the pCO₂-product of Chau et al. (2022), model pCO₂ values are overestimated in the subtropical gyres (Figure 15C). Further, the North Atlantic pCO₂ is on average lower than the pCO₂-product, and the two data sets also differ on over- versus undersaturation of pCO₂ relative to the atmosphere in the polar Southern Ocean (higher values in FESOM2.1-REcoM3). The latter may well be explained by a known summer bias in Southern Ocean pCO₂ observations (e.g., Metzl et al., 2006; Gregor et al., 2019). FESOM2.1-REcoM3 also simulates very high pCO₂ values on the Russian shelves in the Arctic, where hardly any observations exist. Similarly high pCO₂ values were reported for this region by Anderson et al. (2009), but missing repeat observations prevent a conclusion on whether this is a robust signal and what its extent in time and space is.

FESOM-2.1-REcoM3 reproduced the temporal evolution of surface ocean pCO₂ reasonably well compared to SOCAT when accounting for where and when pCO₂ sampling took place (Figure 17). The annual correlation coefficient and root

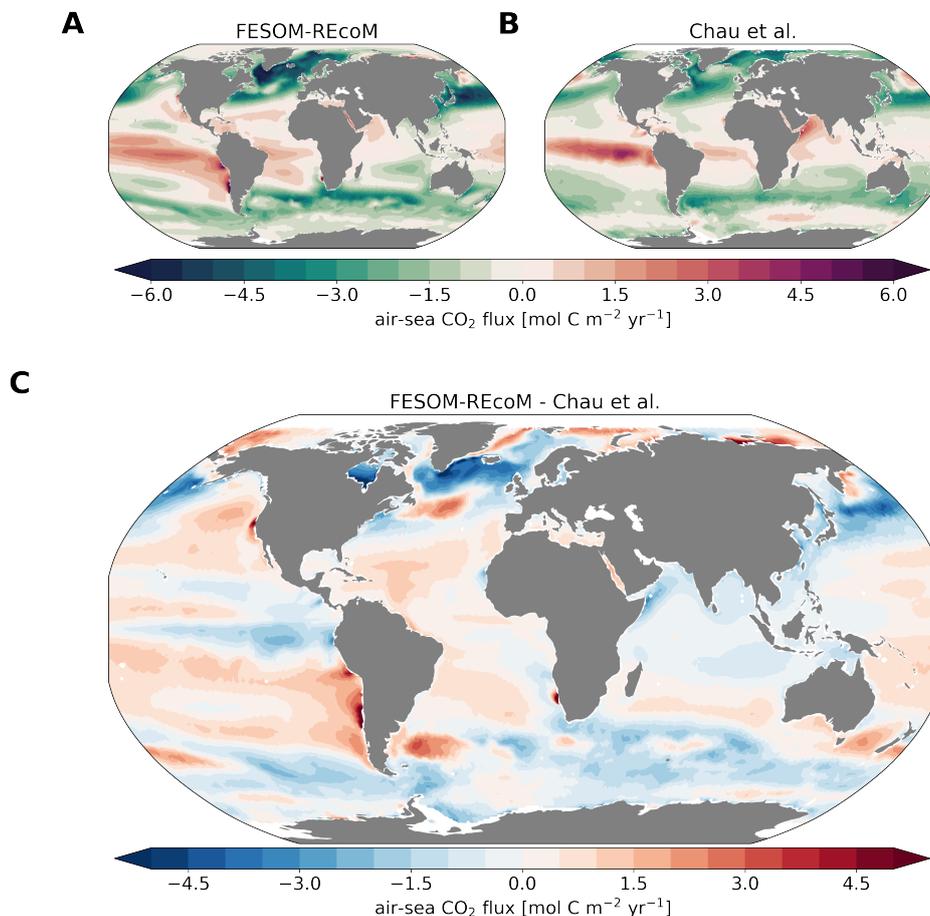

Figure 16. Maps of air-sea CO₂ fluxes. The top row compares the (A) simulated FESOM2.1-REcoM3 CO₂ flux to the (B) pCO₂-based data-product (Chau et al., 2022), both averaged over 2012-2021. The bottom panel (C) shows model-data differences.

mean squared error (RMSE) between simulated and observed global mean pCO₂ are 0.93 and 4.6 μatm, respectively. The subsampled model follows the SOCAT time-series closely, including its variability, which may to some extent be caused by sampling distribution. The global mismatch with SOCAT pCO₂ as measured by the RMSE is comparable or slightly below the value for FESOM-1.4-REcoM2 (see supplementary Figure S9, 1985-2018, in Hauck et al., 2020) and comparable, but at the high end of the range of other models in GCB2022 (1990-2021, Friedlingstein et al., 2022b). On a monthly scale, the RMSE is higher (38 μatm), as the models capture the large-scale patterns better than smaller-scale variability according to a previous assessment (Hauck et al., 2020). An analysis of large-scale regional patterns (North, Tropics, South, Figure 17) reveals that the model overestimates pCO₂ in the tropics and underestimates pCO₂ in the northern extra-tropics and to a lesser extent in the southern extra-tropics in recent decades, as also indicated in the maps (Figure 15).

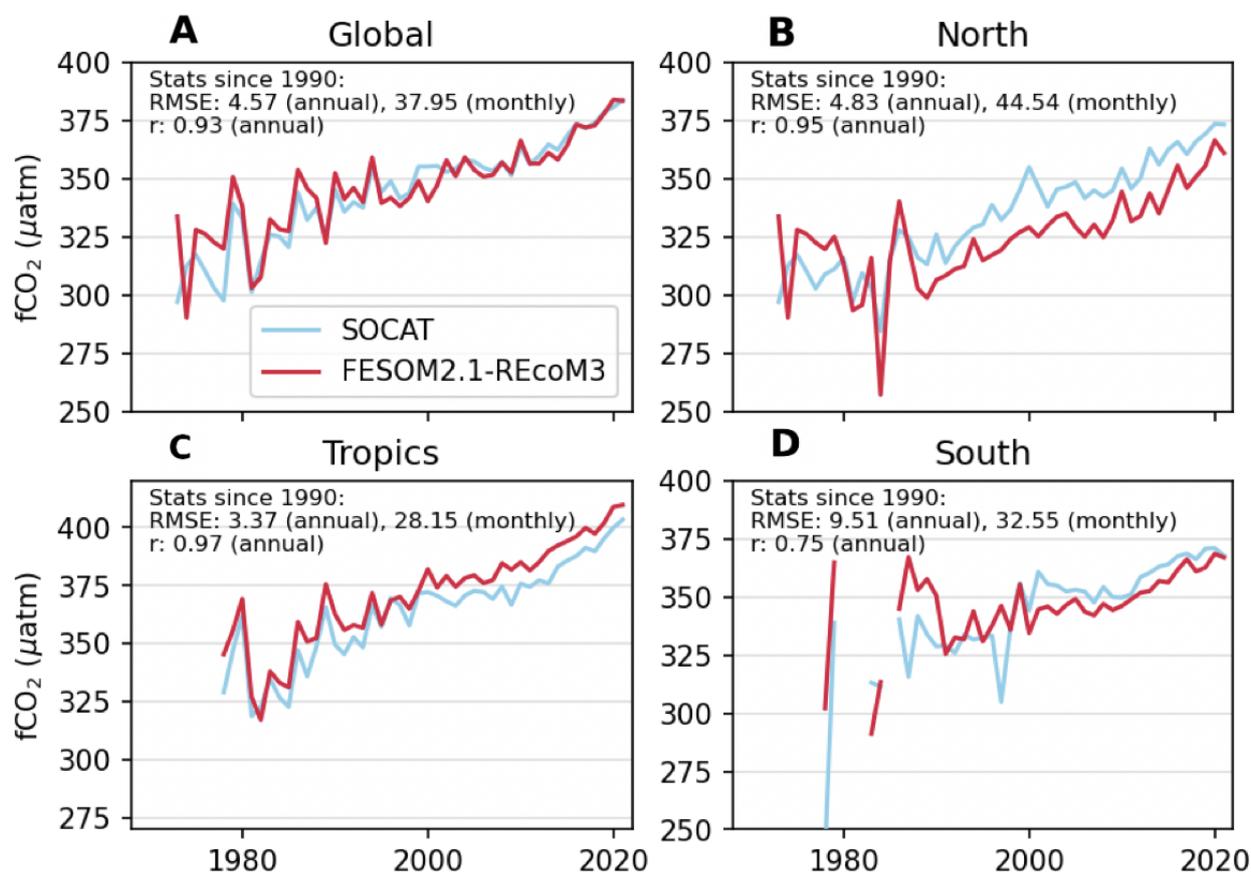

Figure 17. Comparing annual mean $p\text{CO}_2$ [μatm] from FESOM2.1-REcoM (subsamped for spatiotemporal locations of observations in SOCAT, red) with observations from SOCATv2022 (light blue, updated from Bakker et al., 2016). Results are shown spatially averaged for (A) the global ocean, (B) the northern hemisphere ($>30^\circ\text{N}$), (C) the Tropics (30°S - 30°N), and (D) the southern hemisphere ($<30^\circ\text{S}$). The time-series are shown for all observations in SOCAT (since 1970), but correlation coefficient r (unitless) and Root Mean Squared Error RMSE (μatm) are indicated in the panels for the time period 1990–2021.

480 The air-sea CO₂ flux spatial pattern was reasonably reproduced by FESOM2.1-REcoM3 with CO₂ uptake in the subpolar regions of both hemispheres, and outgassing in the tropics and north Pacific (Figure 16). Generally, the CO₂ flux patterns mirror the pCO₂ patterns (Figure 15), but with the additional imprint of spatial variability of wind speed. Hence, the CO₂ uptake in the subpolar Southern Ocean may appear large compared to pCO₂, which is not as strongly undersaturated in the South as in the North Atlantic. Regions of mean outgassing in the Southern Ocean are of smaller extent in the model than in the

485 pCO₂-product. While it is well established that outgassing of CO₂ in the polar Southern Ocean occurs in winter (e.g., Bakker et al., 1997), its magnitude and timing varies between estimates and is under debate (Gruber et al., 2009; Lenton et al., 2013; Gray et al., 2018; Bushinsky et al., 2019; Sutton et al., 2021; Long et al., 2021b). The misfit between the annual mean modelled CO₂ flux and the pCO₂-based data-product generally mimic pCO₂ misfits and thus shows small positive misfits (less uptake or more outgassing) in the subtropical gyres and small negative biases (stronger uptake or less outgassing) in the equatorial

490 Pacific, and the Southern Ocean (Fig. 16, bottom panel). The strongest misfits were found in the northern high latitudes and the upwelling zone of the eastern tropical Pacific. The large mismatch in pCO₂ on the Siberian shelves does not show up in CO₂ flux as sea ice prevents CO₂ outgassing throughout most of the year.

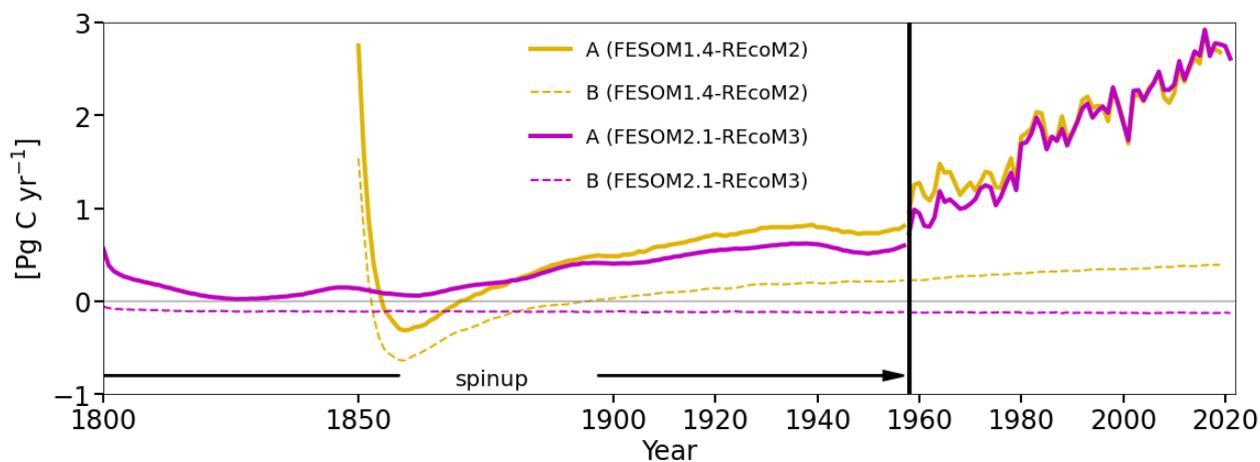

Figure 18. Time-series of simulated annual mean global ocean-atmosphere CO₂ flux in PgC yr⁻¹ in the experiments conducted in this study. FESOM-2.1-REcoM3 spinup was conducted for 347 years (including 189 years of pre-spinup, not shown) under repeat year forcing taken from the year 1961 (RYF61). Here we show the spin-up since 1800 that is continued as the control simulation B after 1958 for FESOM-1.4-REcoM2 (yellow) and FESOM-2.1-REcoM3 (magenta) with a constant CO₂ concentration of 278 ppm (dashed lines) and the spin-up under increasing CO₂ that is continued as simulation A after 1958 (solid lines). The control simulation B started in the year 1958 and was conducted for 64 years with RYF61 (dashed lines). Simulation A also started in 1958 and was forced with inter-annual varying forcing JRA55-do-1.4.0 (solid lines). Please note that spinup period for FESOM1.4-REcoM2 and FESOM2.1-REcoM3 differ from each other, the latter being longer than the former.

We continue our investigation with the analysis of the global ocean-atmosphere CO₂ flux time-series (Fig. 18). In 1800, the first year of spinup after the first 189 years of pre-spinup of simulation B (not shown), the global ocean-atmosphere CO₂ flux

495 was already in a stable state and converged towards a value close to zero. Under the assumption that the ocean and atmosphere
were in equilibrium at constant preindustrial CO_2 and without riverine carbon transported into the ocean (Aumont et al., 2001;
Resplandy et al., 2018; Regnier et al., 2022), an equilibrium flux of zero is expected for simulation B. Any deviation from
this can be considered a bias (Hauck et al., 2020). The global bias of the annual air-sea CO_2 flux in the FESOM-2.1-REcoM3
control simulation amounts to $-0.12 \text{ PgC yr}^{-1}$, and could be further reduced towards zero with a longer spin-up. The control
500 simulation conducted with the older model version FESOM1.4 had a larger bias with a positive flux of around 0.4 PgC yr^{-1}
at the end of the simulation. In addition to the bias, the drift is reduced from $0.00264 \text{ PgC yr}^{-2}$ in FESOM1.4-REcoM2 to
 $-0.00011 \text{ PgC yr}^{-2}$ in FESOM2.1-REcoM3 with longer spin-up. Despite different spinup procedures (FESOM1.4 has a shorter
spin-up period), simulation A with both FESOM2.1 and FESOM1.4 reveals similar CO_2 fluxes under interannually varying
forcing after 1980, which indicates a dominance of the forcing over the initial conditions. This also questions the common
505 assumption that the same bias occurs in the control and historical simulations.

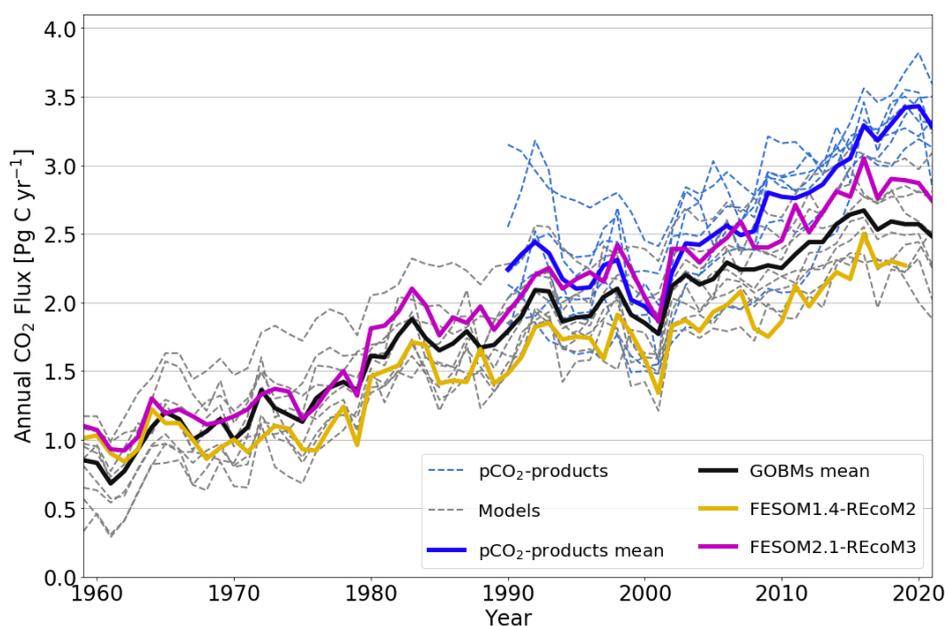

Figure 19. Globally integrated annual air-sea CO_2 flux from Global Ocean Biogeochemistry Models (GOBMs) and pCO_2 -based data-products used in the Global Carbon Budget 2022, after applying bias correction to the models and river flux adjustment of 0.65 PgC yr^{-1} (Regnier et al., 2022) to the pCO_2 -products. The thick black line indicates the model ensemble mean and the thick blue line shows the mean of the pCO_2 -product ensemble. Thin dashed lines are from individual models and pCO_2 -products. FESOM2.1-REcoM3 (magenta) shows the ocean carbon flux for the period of 1959-2021 whereas FESOM1.4-REcoM2 (yellow) covers the period of 1959-2019. Positive numbers indicate a flux into the ocean.

We next assess the model performance of the interannually varying simulation (A) by comparison with the Global Carbon Budget's ensemble of pCO_2 -based data-products and other ocean biogeochemistry models (Fig. 19). Note that all model time

series shown in Fig. 19 are referenced relative to their control simulations. Although being consistent with the interannual variability, air-sea CO₂ fluxes of FESOM1.4 are at the lower end of the range compared to other Global Ocean Biogeochemistry
510 Models and pCO₂-based estimates. In contrast, starting from the mid-1960s, FESOM2.1 shows a higher CO₂ flux in comparison to FESOM1.4. Considering the fact that both model versions do not depart much from each other in simulation A, the increase in net CO₂ flux is mostly attributed to the level of CO₂ fluxes in their control simulations with a constant atmospheric CO₂ concentration and without climate-change forcing (simulation B; Fig. 18).

After accounting for the bias in simulation B, the simulated ocean carbon sink is 1.74 ± 0.11 PgC yr⁻¹ and 2.17 ± 0.13 PgC yr⁻¹
515 for FESOM1.4-REcoM2 and FESOM2.1-REcoM3 versions between 1990 and 1999, respectively. Hence, FESOM2.1-REcoM3 is closer to the best estimate for the 1990s (2.2 ± 0.4 PgC yr⁻¹, IPCC, Denman et al., 2007; Ciais et al., 2014) than FESOM1.4-REcoM2. The cumulative uptake over the period of 1959-2019 amounts to 93.4 PgC (FESOM1.4-REcoM2) and 116.6 PgC (FESOM2.1-REcoM3) which is a 25% increase in CO₂ flux. Yet, the FESOM2.1-REcoM3 CO₂ fluxes are lower than the mean of the pCO₂-based data-products since about 2008 and thus affirm the growing discrepancy between global ocean bio-
520 geochemistry models and pCO₂-products (Friedlingstein et al., 2022a).

3.3.3 DIC Inventory Changes

Table 4. FESOM2.1-REcoM3 DIC inventory for simulation A (PgC) in 1994, and change in DIC inventory between 1800-1994 and 1994-2007. The FESOM-2.1-REcoM3 numbers are from simulation A and hence encompass anthropogenic and natural carbon cycle processes. Gruber et al. (2019) estimate the anthropogenic carbon inventory change. We have given the Gruber et al. (2019) anthropogenic plus back-of-the-envelope natural carbon inventory changes in parenthesis (only available for global).

	Year	Global	North	Tropics	South
FESOM-2.1-REcoM3	1994	38167.4	5259.8	21108.1	11799.5
FESOM-2.1-REcoM3	1800 to 1994	91.6	14.5	35.5	41.6
FESOM-2.1-REcoM3	1994 to 2007	27.7	5.2	11.6	11.0
Sabine et al. (2004), (Gruber et al., 2019)	1800 to 1994	118±19 (111±21)	25.1	46.6	48.0
Gruber et al. (2019)	1994 to 2007	34±4 (29±5)	5.9	17.5	10.4

The interior ocean DIC inventory in FESOM-2.1 amounts to about 38,200 PgC, which is in the reported range of 37,200 to 39,000 PgC (Sundquist, 1985; Keppler et al., 2020). The DIC inventory grew over time in accordance with observation-based estimates (Table 4, Sabine et al., 2004; Gruber et al., 2019). The increase from 1994-2007 is with 27.7 PgC slightly lower than
525 the best estimate by Gruber et al. (2019), which, however, only quantifies the anthropogenic CO₂ increase (34 ± 4 PgC). The model estimate falls within the uncertainty range of Gruber et al. (2019) when considering in addition the poorly constrained response of the natural carbon inventory to climate change (29 ± 5 PgC). Similarly, the simulated DIC inventory change 1800-1994 (91.6 PgC) is at the lower end but within the reported uncertainty of the observation-based total DIC inventory change (111 ± 21 PgC). FESOM-2.1-REcoM3 is thus one of the few ocean biogeochemistry models that falls within the range of

530 interior ocean anthropogenic carbon accumulation that is also supported by O_2/N_2 ratios (Tohjima et al., 2019) and atmospheric
inversions (see also discussion in Friedlingstein et al., 2022b). Notably, FESOM2.1-REcoM3 can reproduce the latitudinal
distribution of anthropogenic carbon accumulation 1994-2007 with the maximum in the tropics (30°S - 30°N), followed by the
Southern Ocean south of 30°S , and the North (north of 30°N), although it also underestimates the accumulation in the
tropics, as most other models do (Friedlingstein et al., 2022a). If the observation-based separation into North, Tropics and
535 South is correct, this may indicate a too weak transport of anthropogenic carbon from the Southern Ocean into the tropics, or
a generally too weak CO_2 uptake in the tropics.

3.4 Oxygen

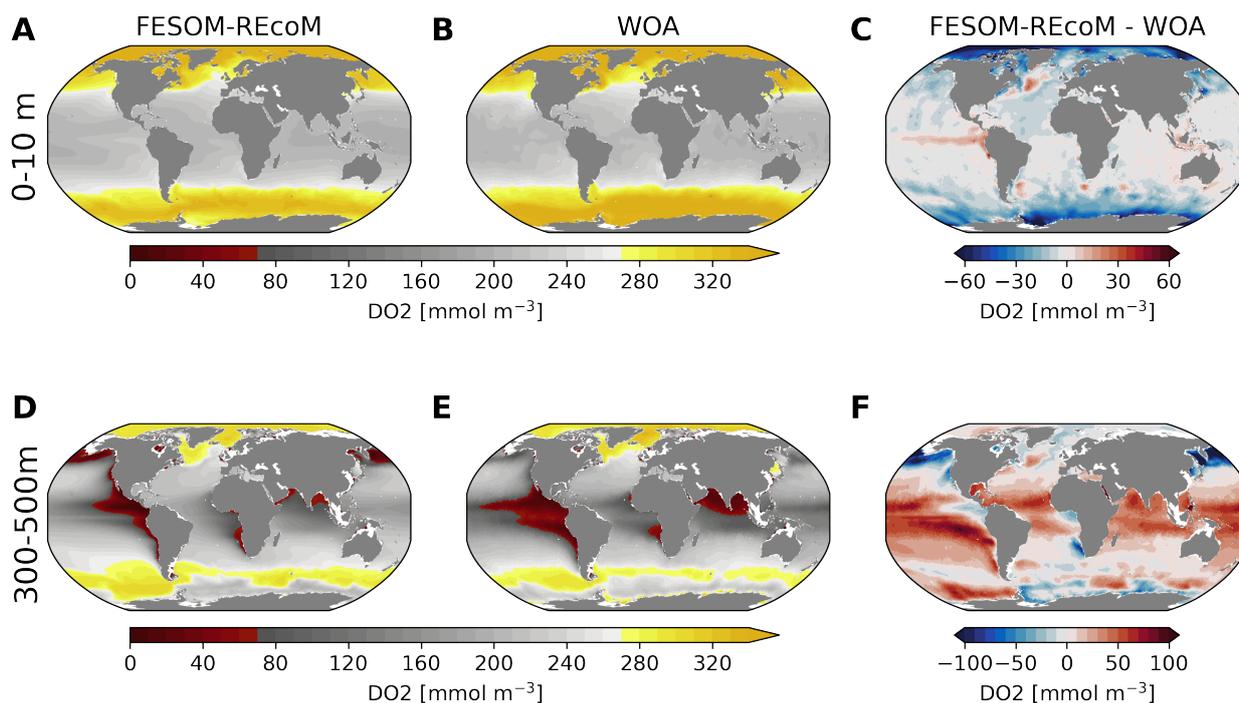

Figure 20. Maps of surface (0-10m, top row) and intermediate (300-500m, bottom row) concentration of simulated FESOM2.1-REcoM3 dissolved O_2 [mmol m^{-3}] (A, D), World Ocean Atlas 2018 climatology of dissolved O_2 (B, E; (Garcia et al., 2019b)) and corresponding differences (C, F) over the time period 2012-2021.

The simulated global O_2 concentration distribution at the surface ocean and intermediate depths was consistent with observed patterns in WOA2018 (Fig. 20). The model successfully reproduced the typical spatial patterns (Schmidtke et al.,
540 2017): (1) Oxygen Minimum Zones in the western boundary upwelling systems where old deoxygenated waters are brought to the surface, (2) high concentrations in the high latitude regions where cold temperature increases oxygen solubility (Arctic and Southern Oceans), and (3) moderate oxygen concentrations in the more stratified tropical gyres. Nevertheless, there

were regional discrepancies. At the surface, the model slightly underestimated O_2 concentrations in the high latitude surface ocean. At intermediate depth, the model generally overestimated oxygen levels, especially in the Pacific Ocean and the sub-polar Southern Ocean with biases exceeding 100 mmol m^{-3} . Compared to other models which compared oxygen concentrations within the 100–600 m layer (Cocco et al., 2013), REcoM3 performed remarkably well with simulated values of about $160 \pm 105 \text{ mmol m}^{-3}$, which is very close to the observations from the WOA ($158 \pm 103 \text{ mmol m}^{-3}$).

4 Conclusions and Outlook

We have presented a new coupled ocean biogeochemistry model FESOM2.1-REcoM3. Building upon finite volumes for the ocean component improves the numerical efficiency and leads to higher numerical throughput of the coupled model (Danilov et al., 2017). Furthermore, the biogeochemistry component was extended to incorporate state of the art carbonate chemistry routines, a second zooplankton and detritus group and simulates the cycling of oxygen in the ocean. In its present configuration, the overall realism of FESOM2.1-REcoM3 in simulating the observed mean biogeochemical state is comparable to that of most GOBMs, while being among the more realistic models for estimating global ocean anthropogenic carbon uptake. There are still a number of model shortcomings, such as a lower simulated NPP and regional misfit between the annual mean CO_2 flux of the model simulation and the pCO_2 -based data-product that will be addressed in the future.

This model set-up provides the basis for further model development, e.g., the inclusion of coccolithophores as an additional phytoplankton functional type and CO_2 sensitivities of phytoplankton growth (Seifert et al., 2022), as well as the separation of the generic small zooplankton group into micro- and mesozooplankton that reduces model biases in nutrient fields, increases net primary production and better captures the top-down control on phytoplankton bloom phenology (Karakuş et al., 2022). We further plan to incorporate more detailed iron biogeochemistry as developed in REcoM coupled to MITgcm (e.g., Ye et al., 2020), and the explicit representation of the effects of viscosity and ballasting on particle sinking speed, as well as oxygen-dependent remineralization, following Cram et al. (2018) to address knowledge gaps in carbon export and transfer to depth (Henson et al., 2022). Other on-going work addresses the role of rivers for carbon and nutrient transport into the ocean and the remineralization time-scale of this river-derived organic material (Aumont et al., 2001; Lacroix et al., 2020; Regnier et al., 2022), and thus tackles a major uncertainty in the ocean carbon cycle and comparison of ocean carbon sink estimates based on pCO_2 -products and ocean biogeochemistry models (e.g., Hauck et al., 2020).

Code availability. The FESOM2.1-REcoM3 source code is available at https://github.com/FESOM/fesom2/tree/fesom2.1_recom (last access: 31 December 2022); the version of FESOM2.1-REcoM3 used for this paper can be found at <https://doi.org/10.5281/zenodo.7502419>. A manual is available at: <https://recom.readthedocs.io/en/latest/>.

Author contributions. Conceptualization was done by OG, LO, CV and JH. Data were prepared by OG, JH, and OK. Analysis of simulations and visualization was done by all authors. All authors contributed to writing of the paper.

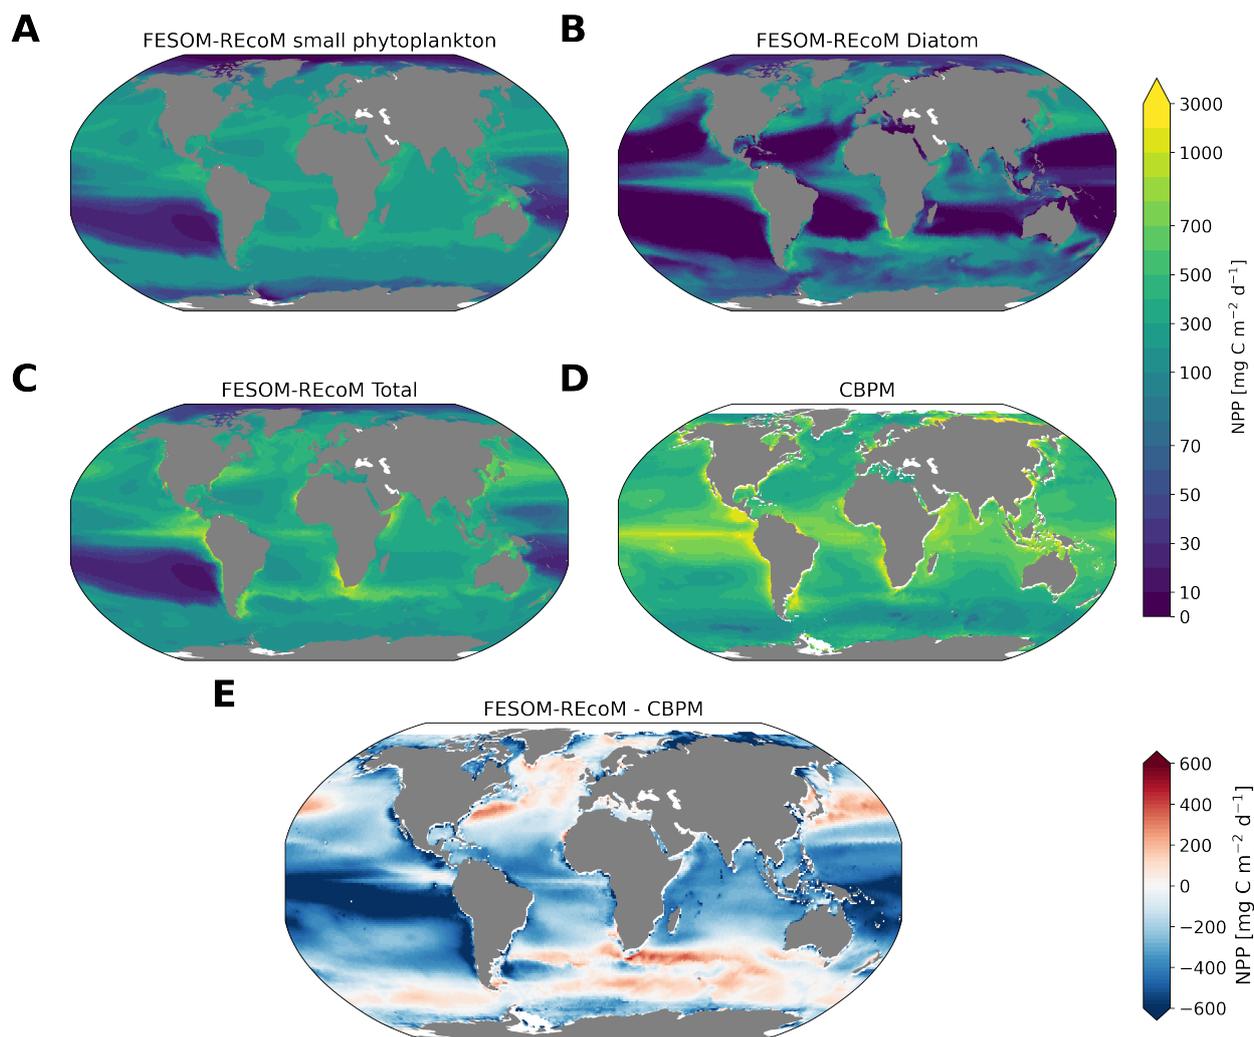

Figure A1. Maps of simulated FESOM2.1-REcoM3 (simA) vertically integrated net primary production [$\text{mgC m}^{-2} \text{d}^{-1}$] of small phytoplankton (A), diatoms (B), and the sum of both phytoplankton groups (C). The satellite-based Carbon-based Productivity Model (CbPM) is shown in (D; Westberry et al., 2008) with corresponding differences between FESOM2.1-REcoM3 and VGPM (E). All fields are averaged over the time period 2012 to 2021.

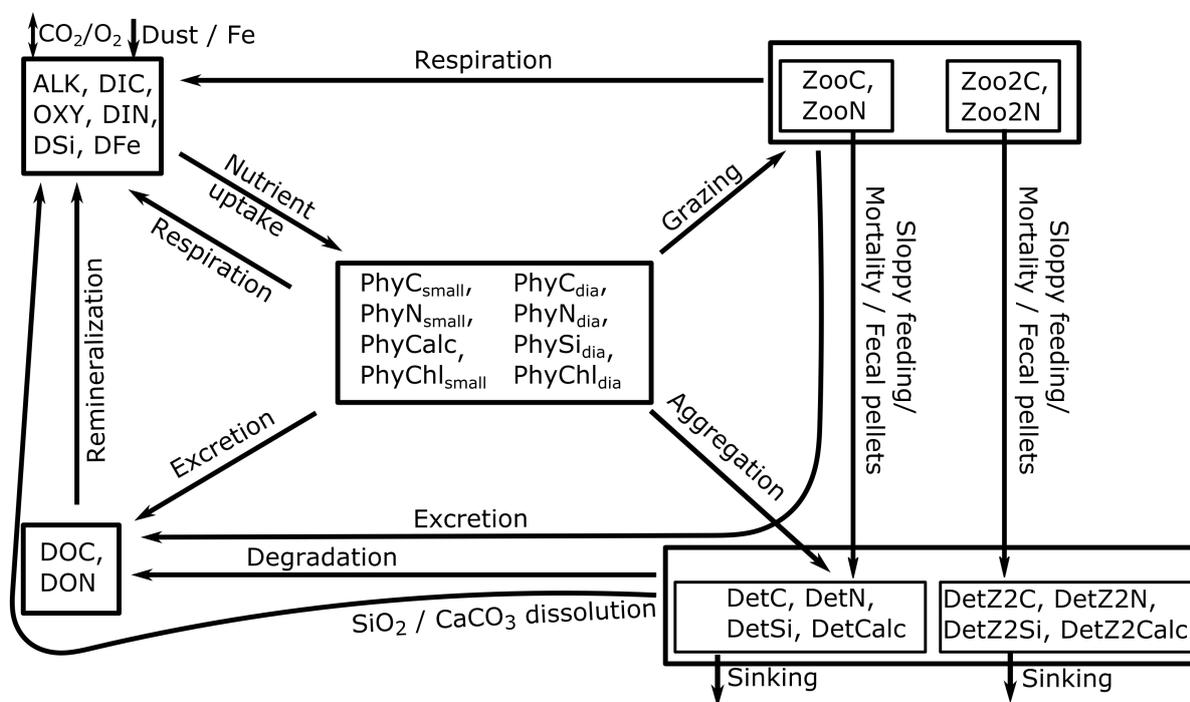

Figure A2. Conceptual diagram of the ocean biogeochemical model REcoM3. The 28 tracers can be grouped (indicated by boxes) into dissolved nutrients, carbonate system parameters and oxygen (upper left), phytoplankton functional types (center), zooplankton functional types (upper right), two detritus classes (lower right), and dissolved organic material (lower left). Source and sink terms are depicted by arrows. For reasons of diagrammatic clarity, connections of dissolved oxygen (Oxy) to other state variables are omitted here. Similarly, the release of alkalinity, dissolved inorganic nutrients and organic matter from the sediment are not shown.

Appendix A: Equations

This appendix provides an overview of the underlying model equations and lists all biogeochemical variables of FESOM2.1-REcoM3. Changes in state variables in REcoM3 are controlled by biological and chemical processes, in addition to the changes induced by ocean circulation, mixing, diffusion and advection computed by FESOM2.1. While some variables exchange across the ocean surface and/or the sea floor, others, like dead organic matter (detritus) sink through the water column. The concentration change for a state variable S is formulated as follows:

$$\frac{\partial S}{\partial t} = -\mathbf{U} \cdot \nabla S + \nabla \cdot (\kappa \cdot \nabla S) + SMS(S), \quad (\text{A1})$$

where S is the volumetric concentration of a state variable, \mathbf{U} is the three-dimensional advection velocity and κ is the diffusivity. The term $SMS(S)$ represents the biogeochemical sources minus sinks. The slow-sinking detritus class is assumed to sink with a velocity, which increases linearly with depth as a first-order description of the shift to larger and faster-sinking particles with increasing depth (Kriest and Oschlies, 2008). A constant sinking rate is applied to the fast-sinking detritus class. REcoM3 has 28 oceanic and four explicit benthic state variables (Tables A1 and A2).

A1 Sources minus sinks

A1.1 Nutrients

595 A1.1.1 Dissolved inorganic nitrate (DIN)

The simulated DIN conceptually represents the concentrations of nitrate, nitrite and ammonia, while in practice only nitrate is considered. The concentration of DIN in the water column rises when DON is remineralized and diminishes as a consequence of assimilation by small phytoplankton and diatoms:

$$SMS(\text{DIN}) = \underbrace{\rho_{\text{DON}} \cdot f_T \cdot \text{DON}}_{\text{DON remineralization}} - \underbrace{V_{\text{small}}^{\text{N}} \cdot \text{PhyC}_{\text{small}}}_{\text{N-assimilation, small phytoplankton}} - \underbrace{V_{\text{dia}}^{\text{N}} \cdot \text{PhyC}_{\text{dia}}}_{\text{N-assimilation, diatoms}}. \quad (\text{A2})$$

600 The state variables DON , $\text{PhyC}_{\text{small}}$ and PhyC_{dia} are listed in Table A1. The value of the remineralization rate constant (ρ_{DON}) is given in Table A8. The temperature dependency of remineralization (f_T) is calculated in Eq. A43. See Section A3.4 for details on the carbon-specific nitrogen-assimilation rates $V_{\text{small}}^{\text{N}}$ and $V_{\text{dia}}^{\text{N}}$ (Table A5).

A1.1.2 Dissolved silicic acid (DSi)

silicon assimilation (Si-assimilation) and increases when biogenic silica from one of the two detritus classes dissolves.

$$605 \quad SMS(\text{DSi}) = \underbrace{\rho_{\text{Si}}^{\text{T}} \cdot \text{DetSi}}_{\text{Remineralization, slow-sinking detritus}} + \underbrace{\rho_{\text{Si}}^{\text{T}} \cdot \text{DetZ2Si}}_{\text{Remineralization, fast-sinking detritus}} - \underbrace{V^{\text{Si}} \cdot \text{PhyC}_{\text{dia}}}_{\text{Si-assimilation, diatoms}} \quad (\text{A3})$$

The state variables PhyC_{dia} , DetSi and DetZ2Si are listed in Table A1. The temperature dependent remineralization rate of silicon ($\rho_{\text{Si}}^{\text{T}}$) and the carbon-specific Si-assimilation rate (V^{Si}) are calculated in Eqs. A45 and A51, respectively (Table A5).

A1.1.3 Dissolved iron (DFe)

Excretion of phyto- and zooplankton and remineralization of detritus release iron with a fixed iron:nitrate ratio ($q^{\text{Fe:N}}$). Unlike
 610 for nitrogen, which is released as dissolved organic nitrogen and needs to be remineralized further to become available as nu-
 trient again, the released iron is directly put into the dissolved pool iron, basically assuming that all dissolved iron is ultimately
 bio-available. Iron assimilation (again assumed to be proportional to nitrogen assimilation, from now on N-assimilation) by
 both phytoplankton classes lower the level of dissolved iron. In addition, free inorganic iron Fe' is scavenged onto sinking
 615 particles, with a rate that is proportional to particle concentration. We take detrital carbon as a proxy for the mass of sinking
 particles.

$$\begin{aligned}
 \text{SMS}(\text{DFe}) = & q^{\text{Fe:N}} \cdot \left(\underbrace{\epsilon_{\text{phy}}^{\text{N}} \cdot f_{\text{lim,small}}^{\text{N:Cmax}} \cdot \text{PhyN}_{\text{small}}}_{\text{Excretion, small phytoplankton}} + \underbrace{\epsilon_{\text{phy}}^{\text{N}} \cdot f_{\text{lim,dia}}^{\text{N:Cmax}} \cdot \text{PhyN}_{\text{dia}}}_{\text{Excretion, diatoms}} \right) \\
 & + \underbrace{\rho_{\text{DetN}} \cdot f_T \cdot \text{DetN}}_{\text{Remineralization, slow-sinking detritus}} + \underbrace{\rho_{\text{DetN}} \cdot f_T \cdot \text{DetZ2N}}_{\text{Remineralization, fast-sinking detritus}} \\
 & + \underbrace{\epsilon_{\text{zoo}}^{\text{N}} \cdot \text{ZooN}}_{\text{Excretion, small zooplankton}} + \underbrace{\epsilon_{\text{zoo2}}^{\text{N}} \cdot \text{Zoo2N}}_{\text{Excretion, macrozooplankton}} \\
 & - \left(\underbrace{V_{\text{small}}^{\text{N}} \cdot \text{PhyC}_{\text{small}}}_{\text{N-assimilation, small phytoplankton}} - \underbrace{V_{\text{dia}}^{\text{N}} \cdot \text{PhyC}_{\text{dia}}}_{\text{N-assimilation, diatom}} \right) \\
 & - \underbrace{\kappa_{\text{Fe}} \cdot \text{DetC} \cdot \text{Fe}'}_{\text{Scavenging, slow-sinking detritus}} - \underbrace{\kappa_{\text{Fe}} \cdot \text{DetZ2C} \cdot \text{Fe}'}_{\text{Scavenging, fast-sinking detritus}}
 \end{aligned} \tag{A4}$$

The state variables $\text{PhyC}_{\text{small}}$, PhyC_{dia} , $\text{PhyN}_{\text{small}}$, PhyN_{dia} , DetC , DetN , DetZ2C , DetZ2N , ZooN , Zoo2N are listed in
 Table A1. Intracellular Fe:N ratio ($q^{\text{Fe:N}}$) and scavenging rate of iron (κ_{Fe}) are given in Table A4. Excretion rates ($\epsilon_{\text{phy}}^{\text{N}}$,
 $\epsilon_{\text{zoo}}^{\text{N}}$ and $\epsilon_{\text{zoo2}}^{\text{N}}$) and the degradation rate for detritus N (ρ_{DetN}) are listed in Table A8. The temperature dependency (f_T) is
 620 calculated in Eq. A43. The limitation by intracellular nitrogen ($f_{\text{lim,small}}^{\text{N:Cmax}}$, $f_{\text{lim,dia}}^{\text{N:Cmax}}$) is described in Eq. A55. Scavenging is
 calculated following Parekh et al. (2004). The total concentration of dissolved iron (Fe_T) is separated into free iron (Fe') and
 iron complexed with organic ligands (Fe_L), which is not scavenged. Complexation reactions are fast (Tagliabue and Völker,
 2011), so we assume instantaneous equilibrium between free iron and free ligand (L') which is computed using a constant
 $K_{\text{Fe}_L} = \frac{[\text{Fe}'] \cdot [L']}{[\text{Fe}_L]}$, by solving

$$625 \quad \text{Fe}_T = \text{Fe}' + \text{Fe}_L \quad L_T = \text{Fe}_L + L' \tag{A5}$$

For simplicity we assume here a constant total ligand concentration L_T , unlike in Völker and Tagliabue (2015). Variable ligand
 concentration, like in Misumi et al. (2011) or Völker and Tagliabue (2015), or variable ligand binding strength, like in Ye et al.
 (2020) will be explored in the future. The values for K_{Fe_L} and L_T are listed in Table A4.

A1.2 Carbon cycle

630 A1.2.1 Dissolved inorganic carbon (DIC)

DIC concentration increases with respiration of phyto- and zooplankton, remineralization of semi-labile dissolved organic carbon, dissolution of calcitic detritus and dissolution of CaCO_3 in zooplankton guts. Loss terms are carbon fixation by primary producers and the formation of calcium carbonate. In addition, sea–air flux of CO_2 leads to an exchange of carbon with the atmosphere, depending on the partial pressure difference of CO_2 between ocean and atmosphere. This exchange is
 635 treated separately as a boundary condition. The partial pressure of surface ocean CO_2 is computed using the mocsy-2.0 routines (Orr and Epitalon, 2015).

$$\begin{aligned}
 \text{SMS(DIC)} = & \underbrace{(r_{\text{small}} - P_{\text{small}}) \cdot \text{PhyC}_{\text{small}}}_{\text{Net respiration, small phytoplankton}} + \underbrace{(r_{\text{dia}} - P_{\text{dia}}) \cdot \text{PhyC}_{\text{dia}}}_{\text{Net respiration, diatom}} + \underbrace{\rho_{\text{DOC}} \cdot f_T \cdot \text{DOC}}_{\text{Remineralization of DOC}} \\
 & + \underbrace{r_{\text{zoo}} \cdot \text{ZooC}}_{\text{Respiration, small zoo}} + \underbrace{r_{\text{zoo2}} \cdot \text{Zoo2C}}_{\text{Respiration, macrozoo}} + \underbrace{\text{Diss}_{\text{calc}} \cdot \text{DetCalc}}_{\text{Calcite dissolution, slow-sinking detritus}} + \underbrace{G_{\text{small}}^{\text{zoo}} \cdot q_{\text{small}}^{\text{CaCO}_3:N} \cdot \text{Diss}_{\text{calc_guts}}}_{\text{CaCO}_3 \text{ dissolution in guts, small zoo}} \\
 & - \underbrace{\psi \cdot P_{\text{small}} \cdot \text{PhyC}_{\text{small}}}_{\text{Calcification}} + \underbrace{\text{Diss}_{\text{calc2}} \cdot \text{DetZ2Calc}}_{\text{Calcite dissolution, fast-sinking detritus}} + \underbrace{G_{\text{small}}^{\text{zoo2}} \cdot q_{\text{small}}^{\text{CaCO}_3:N} \cdot \text{Diss}_{\text{calc_guts}}}_{\text{CaCO}_3 \text{ dissolution in guts, macrozoo}}
 \end{aligned} \quad (\text{A6})$$

The state variables $\text{PhyC}_{\text{small}}$, PhyC_{dia} , DOC , ZooC , Zoo2C , DetCalc , DetZ2Calc are listed in Table A1. Respiration rate constants of small phytoplankton (r_{small}), diatoms (r_{dia}) and zooplankton groups (r_{zoo} and r_{zoo2}) are computed in Sections A3.2
 640 and A4.1, respectively. Photosynthesis terms (P_{small} and P_{dia}) are calculated in Eq. A46. The remineralization rate constant (ρ_{DOC}) is listed in Table A8 and the temperature dependency (f_T) is given in Eq. A43. Calcite dissolution by detritus ($\text{Diss}_{\text{calc}}$, $\text{Diss}_{\text{calc2}}$) is calculated in Eq. A38. The constant for dissolution of calcium carbonate in zooplankton guts ($\text{Diss}_{\text{calc_guts}}$) is listed in Table A5. $G_{\text{small}}^{\text{zoo}}$ and $G_{\text{small}}^{\text{zoo2}}$ are grazing terms and explained in Section A4.2. The value of the calcite production ratio (ψ) is given in Table A3.

645 A1.2.2 Total alkalinity (Alk)

The balance of alkalinity is affected by primary production, remineralization of dissolved organic matter, dissolution of calcitic detritus and dissolution of CaCO_3 in zooplankton guts. Alkalinity increases when nitrogen is assimilated and when CaCO_3 is dissolved (Wolf-Gladrow et al., 2007). Simultaneously, it is reduced by calcification as well as remineralization of dissolved organic nitrogen. The effect of phosphate assimilation and remineralization onto alkalinity is taken into account assuming a
 650 constant N:P Redfield ratio (16:1).

$$\text{SMS}(\text{Alk}) = (1 + 1/16) \cdot \underbrace{V_{\text{small}}^{\text{N}} \cdot \text{PhyC}_{\text{small}}}_{\text{N-assimilation, small phytoplankton}} + (1 + 1/16) \cdot \underbrace{V_{\text{dia}}^{\text{N}} \cdot \text{PhyC}_{\text{dia}}}_{\text{N-assimilation, diatom}} \quad (\text{A7})$$

$$\begin{aligned} & - (1 + 1/16) \cdot \underbrace{\rho_{\text{DON}} \cdot f_T \cdot \text{DON}}_{\text{Remineralization of DON}} - 2 \cdot \underbrace{\psi \cdot P_{\text{small}} \cdot \text{PhyC}_{\text{small}}}_{\text{Calcification}} \\ & + 2 \cdot \underbrace{\text{Diss}_{\text{calc}} \cdot \text{DetCalc}}_{\text{Calcite dissolution, slow-sinking detritus}} + 2 \cdot \underbrace{G_{\text{small}}^{\text{zoo}} \cdot q_{\text{small}}^{\text{CaCO}_3:\text{N}} \cdot \text{Diss}_{\text{calc_guts}}}_{\text{CaCO}_3 \text{ dissolution in guts, small zoo}} \\ & + 2 \cdot \underbrace{\text{Diss}_{\text{calc}2} \cdot \text{DetZ2Calc}}_{\text{Calcite dissolution, fast-sinking detritus}} + 2 \cdot \underbrace{G_{\text{small}}^{\text{zoo}2} \cdot q_{\text{small}}^{\text{CaCO}_3:\text{N}} \cdot \text{Diss}_{\text{calc_guts}}}_{\text{CaCO}_3 \text{ dissolution in guts, macrozoo}} \end{aligned} \quad (\text{A8})$$

655 The state variables $\text{PhyC}_{\text{small}}$, PhyC_{dia} , DON , DetCalc , DetZ2Calc are listed in Table A1. The N-assimilation ($V_{\text{small}}^{\text{N}}$ and $V_{\text{dia}}^{\text{N}}$) is calculated in Section A3.4. The remineralization rate constant (ρ_{DON}) is given in Table A8. The temperature dependency (f_T) is calculated in Eq. A43. The value of the calcite production ratio (ψ) is given in Table A3. The photosynthesis term (P_{small}) is calculated in Eq. A46. The calcite dissolution by detritus ($\text{Diss}_{\text{calc}}$, $\text{Diss}_{\text{calc}2}$) is calculated in Eq. A38. Dissolution of calcium carbonate in guts ($\text{Diss}_{\text{calc_guts}}$) is listed in Table A5. $G_{\text{small}}^{\text{zoo}}$ and $G_{\text{small}}^{\text{zoo}2}$ are grazing terms and explained in Section A4.2.

660 A1.3 Phytoplankton

A1.3.1 Nitrogen

The phytoplankton nitrogen pools increase through N-assimilation. The assimilation process is assumed to be proportional to carbon biomass, with a carbon-specific uptake rate that depends on the C:N ratio of phytoplankton and the external DIN concentration (Geider et al., 1998). Excretion of biogenic nitrogen to semi-labile DON drains the pool. At high intracellular C : N
 665 ratio, excretion is downregulated. Aggregation and grazing by the two zooplankton groups transfer nitrogen to the zooplankton and detritus pools.

$$\text{SMS}(\text{PhyN}_{\text{small}}) = \underbrace{V_{\text{small}}^{\text{N}} \cdot \text{PhyC}_{\text{small}}}_{\text{N-assimilation}} \quad (\text{A9})$$

$$- \underbrace{\epsilon_{\text{phy}}^{\text{N}} \cdot f_{\text{lim,small}}^{\text{N:Cmax}} \cdot \text{PhyN}_{\text{small}}}_{\text{DON excretion}} - \underbrace{\text{Agg} \cdot \text{PhyN}_{\text{small}}}_{\text{Aggregation loss}} - \underbrace{G_{\text{small}}^{\text{zoo}}}_{\text{Grazing loss by small zoo}} - \underbrace{G_{\text{small}}^{\text{zoo}2}}_{\text{Grazing loss by macrozoo}} \quad (\text{A10})$$

$$\text{SMS}(\text{PhyN}_{\text{dia}}) = \underbrace{V_{\text{dia}}^{\text{N}} \cdot \text{PhyC}_{\text{dia}}}_{\text{N-assimilation}} \quad (\text{A11})$$

$$- \underbrace{\epsilon_{\text{phy}}^{\text{N}} \cdot f_{\text{lim,dia}}^{\text{N:Cmax}} \cdot \text{PhyN}_{\text{dia}}}_{\text{DON excretion}} - \underbrace{\text{Agg} \cdot \text{PhyN}_{\text{dia}}}_{\text{Aggregation loss}} - \underbrace{G_{\text{dia}}^{\text{zoo}}}_{\text{Grazing loss by small zoo}} - \underbrace{G_{\text{dia}}^{\text{zoo}2}}_{\text{Grazing loss by macrozoo}} \quad (\text{A12})$$

670 The state variables $\text{PhyC}_{\text{small}}$, $\text{PhyN}_{\text{small}}$, PhyC_{dia} , and PhyN_{dia} are listed in Table A1. The N-assimilation ($V_{\text{small}}^{\text{N}}$ and $V_{\text{dia}}^{\text{N}}$) is explained in Section A3.4. The constant excretion rate constant ($\epsilon_{\text{phy}}^{\text{N}}$) is given in Table A8. When the C : N ratio of the cells becomes too high, excretion of DON is downregulated by the limiter function ($f_{\text{lim,small}}^{\text{N:Cmax}}$, $f_{\text{lim,dia}}^{\text{N:Cmax}}$) that is described in Eq. A55.

Phytoplankton aggregation (Agg) defines the transfer of nitrogen into the detritus pools which depends quadratically on detris
 675 and phytoplankton concentrations (Eq. A52). Grazing loss terms ($G_{\text{small}}^{\text{zoo}}$, $G_{\text{small}}^{\text{zoo2}}$, $G_{\text{dia}}^{\text{zoo}}$ and $G_{\text{dia}}^{\text{zoo2}}$) are explained in Section A4.2.

A1.3.2 Carbon

The carbon biomass of small phytoplankton and diatoms increases as a result of carbon assimilation during photosynthesis. Loss terms include excretion of DOC, which is limited by the availability of proteins as in the nitrogen pool, respiration, aggregation, and grazing.

$$680 \quad \text{SMS}(\text{PhyC}_{\text{small}}) = \underbrace{(P_{\text{small}} - r_{\text{small}}) \cdot \text{PhyC}_{\text{small}}}_{\text{Net photosynthesis}} \quad (\text{A13})$$

$$- \underbrace{\text{Agg} \cdot \text{PhyC}_{\text{small}}}_{\text{Aggregation loss}} - \underbrace{\epsilon_{\text{phy}}^{\text{C}} \cdot f_{\text{lim,small}}^{\text{N:Cmax}} \cdot \text{PhyC}_{\text{small}}}_{\text{Excretion of DOC}} - \underbrace{q_{\text{small}}^{\text{C:N}} \cdot G_{\text{small}}^{\text{zoo}}}_{\text{Grazing loss by small zoo}} - \underbrace{q_{\text{small}}^{\text{C:N}} \cdot G_{\text{small}}^{\text{zoo2}}}_{\text{Grazing loss by macrozoo}}$$

$$\text{SMS}(\text{PhyC}_{\text{dia}}) = \underbrace{(P_{\text{dia}} - r_{\text{dia}}) \cdot \text{PhyC}_{\text{dia}}}_{\text{Net photosynthesis}} \quad (\text{A14})$$

$$- \underbrace{\text{Agg} \cdot \text{PhyC}_{\text{dia}}}_{\text{Aggregation loss}} - \underbrace{\epsilon_{\text{phy}}^{\text{C}} \cdot f_{\text{lim,dia}}^{\text{N:Cmax}} \cdot \text{PhyC}_{\text{dia}}}_{\text{Excretion of DOC}} - \underbrace{q_{\text{dia}}^{\text{C:N}} \cdot G_{\text{dia}}^{\text{zoo}}}_{\text{Grazing loss by small zoo}} - \underbrace{q_{\text{dia}}^{\text{C:N}} \cdot G_{\text{dia}}^{\text{zoo2}}}_{\text{Grazing loss by macrozoo}}$$

The state variables $\text{PhyC}_{\text{small}}$ and PhyC_{dia} are listed in Table A1. The photosynthesis terms (P_{small} and P_{dia}) are calculated
 685 in Eq. A46. Rates of respiration by small phytoplankton (r_{small}), diatoms (r_{dia}) are explained in Section A3.2. The constant for DOC excretion rate of phytoplankton ($\epsilon_{\text{phy}}^{\text{C}}$, Table A8) is downregulated by the limiter factor ($f_{\text{lim,small}}^{\text{N:Cmax}}$, $f_{\text{lim,dia}}^{\text{N:Cmax}}$) when the N:C ratio becomes too high (Eq. A55). Phytoplankton aggregation (Agg) is calculated in Eq. A52. Grazing terms ($G_{\text{small}}^{\text{zoo}}$, $G_{\text{small}}^{\text{zoo2}}$, $G_{\text{dia}}^{\text{zoo}}$ and $G_{\text{dia}}^{\text{zoo2}}$) are explained in Section A4.2. $q^{\text{C:N}} = \text{PhyC}/\text{PhyN}$, is used to convert the grazing units from mmol N to mmol C.

690 A1.3.3 CaCO_3

The formation of biogenic calcium carbonate in our model is limited to coccolithophores only, which are assumed to form a constant fraction of the non-diatom phytoplankton. Formation of CaCO_3 by heterotrophs, such as foraminifera or pteropods is neglected. Biogenic CaCO_3 produced by coccolithophores is transformed into detritus CaCO_3 with all forms of organic carbon loss, i.e. organic matter excretion, respiration, aggregation and grazing. Calcifiers are assumed to comprise a certain
 695 fraction of the total small phytoplankton concentration, specified by the parameter ψ (Table A3), tying the calcite production of calcifiers to the growth of small phytoplankton.

$$\text{SMS}(\text{PhyCalc}) = \underbrace{\psi \cdot P_{\text{small}} \cdot \text{PhyC}_{\text{small}}}_{\text{Calcification}} - \underbrace{r_{\text{small}} \cdot \text{PhyCalc}}_{\text{Respiration}} - \underbrace{G_{\text{small}}^{\text{zoo}} \cdot q_{\text{small}}^{\text{CaCO}_3:\text{N}}}_{\text{Grazing loss, small zoo}} - \underbrace{G_{\text{small}}^{\text{zoo2}} \cdot q_{\text{small}}^{\text{CaCO}_3:\text{N}}}_{\text{Grazing loss, macrozoo}} \quad (\text{A15})$$

$$- \underbrace{\epsilon_{\text{phy}}^{\text{C}} \cdot f_{\text{lim,small}}^{\text{N:Cmax}} \cdot \text{PhyCalc}}_{\text{Excretion loss}} - \underbrace{\text{Agg} \cdot \text{PhyCalc}}_{\text{Aggregation loss}}$$

The state variables $\text{PhyC}_{\text{small}}$ and PhyCalc are listed in Table A1. The value of the calcite production ratio (ψ) is given in Table A3. The constant excretion rate ($\epsilon_{\text{phy}}^{\text{C}}$, Table A8) is downregulated by the limiter factor $f_{\text{lim,small}}^{\text{N:Cmax}}$ (Eq. A55) when the N : C ratio becomes too high. Photosynthesis (P_{small}), respiration (r_{small}) and the aggregation of phytoplankton (Agg) rates are calculated in Eqs. A46, A48 and A52, respectively. Grazing terms ($G_{\text{small}}^{\text{zoo}}$ and $G_{\text{small}}^{\text{zoo2}}$) are explained in Section A4.2. $q_{\text{small}}^{\text{CaCO}_3:\text{N}} = \text{PhyCalc}/\text{PhyN}_{\text{small}}$ is used to convert the grazing units from mmol N to mmol CaCO_3 .

A1.3.4 Diatom silicon

The silica frustule of diatoms is built through Si-assimilation, which we assume to be carbon-specific, and regulated by cellular quotas (see below). Any decrease in N-biomass through excretion, grazing or aggregation leads to a corresponding transfer of silica to the detritus silica pool.

$$\begin{aligned} \text{SMS}(\text{PhySi}) = & \underbrace{V^{\text{Si}} \cdot \text{PhyC}_{\text{dia}}}_{\text{Diatom Si-assimilation}} \\ & - \underbrace{\epsilon_{\text{phy}}^{\text{N}} \cdot f_{\text{lim,dia}}^{\text{N:Cmax}} \cdot \text{PhySi}_{\text{dia}}}_{\text{Excretion to detritus}} - \underbrace{\text{Agg} \cdot \text{PhySi}_{\text{dia}}}_{\text{Aggregation loss}} - \underbrace{G_{\text{dia}}^{\text{zoo}} \cdot q_{\text{dia}}^{\text{Si:N}}}_{\text{Grazing loss, small zoo}} - \underbrace{G_{\text{dia}}^{\text{zoo2}} \cdot q_{\text{dia}}^{\text{Si:N}}}_{\text{Grazing loss, macrozoo}} \end{aligned} \quad (\text{A16})$$

The state variables PhyC_{dia} and $\text{PhySi}_{\text{dia}}$ are described in Table A1. Si-assimilation (V^{Si}) and aggregation rates (Agg) are calculated in Eqs. A51 and A52, respectively. The constant excretion rate ($\epsilon_{\text{phy}}^{\text{N}}$, Table A8) is downregulated by the limiter factor $f_{\text{lim,dia}}^{\text{N:Cmax}}$ (Eq. A55) when the N : C ratio becomes too high. Grazing terms ($G_{\text{dia}}^{\text{zoo}}$ and $G_{\text{dia}}^{\text{zoo2}}$) are explained in Section A4.2. The intracellular ratio between diatom silicon and nitrate is defined as $q^{\text{Si:N}} = \text{PhySi}_{\text{dia}}/\text{PhyN}_{\text{dia}}$.

A1.3.5 Chlorophyll *a*

Chlorophyll *a* synthesis is structured as a function of irradiance and of N-assimilation, following Geider et al. (1998). Chlorophyll *a* is degraded at a light-dependent rate (See Álvarez et al. (2018)), and lost via aggregation and grazing. The grazing losses in terms of nitrogen biomass are converted to chlorophyll loss using the intracellular Chl : N ratio.

$$\text{SMS}(\text{PhyChl}_{\text{small}}) = \underbrace{S_{\text{small}}^{\text{chl}} \cdot \text{PhyC}_{\text{small}}}_{\text{Chlorophyll } a \text{ synthesis}} \quad (\text{A17})$$

$$- \underbrace{G_{\text{small}}^{\text{zoo}} \cdot q_{\text{small}}^{\text{Chl:N}}}_{\text{Grazing loss, small zoo}} - \underbrace{G_{\text{small}}^{\text{zoo2}} \cdot q_{\text{small}}^{\text{Chl:N}}}_{\text{Grazing loss, macrozoo}} - \underbrace{\text{deg}_{\text{small}}^{\text{chl}} \cdot \text{PhyChl}_{\text{small}}}_{\text{Degradation loss}} - \underbrace{\text{Agg} \cdot \text{PhyChl}_{\text{small}}}_{\text{Aggregation loss}} \quad (\text{A18})$$

$$\text{SMS}(\text{PhyChl}_{\text{dia}}) = \underbrace{S_{\text{dia}}^{\text{chl}} \cdot \text{PhyC}_{\text{dia}}}_{\text{Chlorophyll } a \text{ synthesis}} \quad (\text{A19})$$

$$- \underbrace{G_{\text{dia}}^{\text{zoo}} \cdot q_{\text{dia}}^{\text{Chl:N}}}_{\text{Grazing loss, small zoo}} - \underbrace{G_{\text{dia}}^{\text{zoo2}} \cdot q_{\text{dia}}^{\text{Chl:N}}}_{\text{Grazing loss, macrozoo}} - \underbrace{\text{deg}_{\text{dia}}^{\text{chl}} \cdot \text{PhyChl}_{\text{dia}}}_{\text{Degradation loss}} - \underbrace{\text{Agg} \cdot \text{PhyChl}_{\text{dia}}}_{\text{Aggregation loss}} \quad (\text{A20})$$

The state variables $\text{PhyC}_{\text{small}}$, PhyC_{dia} , $\text{PhyChl}_{\text{small}}$ and $\text{PhyChl}_{\text{dia}}$ are listed in Table A1. The chlorophyll *a* synthesis ($S_{\text{small}}^{\text{chl}}$, $S_{\text{dia}}^{\text{chl}}$) and the aggregation (Agg) terms are calculated in Eqs. A49 and A52, respectively. The degradation parameters ($\text{deg}_{\text{small}}^{\text{chl}}$, $\text{deg}_{\text{dia}}^{\text{chl}}$)

$\text{deg}_{\text{dia}}^{\text{chl}}$) are given in Table A8. Grazing terms ($G_{\text{small}}^{\text{zoo}}$, $G_{\text{small}}^{\text{zoo2}}$, $G_{\text{dia}}^{\text{zoo}}$, and $G_{\text{dia}}^{\text{zoo2}}$) are explained in Section A4.2. The conversion factor from mmol N to mg Chl *a* is defined as $q^{\text{Chl:N}} = \text{PhyChl}/\text{PhyN}$.

725 A1.4 Zooplankton

A1.4.1 Nitrogen

Both zooplankton classes increase their nitrogen biomass via grazing on phytoplankton and detritus while mortality and excretion of DON reduce it. Macrozooplankton further feeds on small zooplankton and releases nitrogen via fecal pellet production.

$$\text{SMS}(\text{ZooN}) = \underbrace{\gamma_{\text{zoo}} \cdot G_{\text{tot}}^{\text{zoo}}}_{\text{Grazing}} - \underbrace{G_{\text{zoo}}}_{\text{Grazing loss, macrozoo}} - \underbrace{m_{\text{zoo}} \cdot \text{ZooN}^2}_{\text{Mortality}} - \underbrace{\epsilon_{\text{zoo}}^{\text{N}} \cdot \text{ZooN}}_{\text{Excretion of DON}} \quad (\text{A21})$$

$$730 \quad \text{SMS}(\text{Zoo2N}) = \underbrace{\gamma_{\text{zoo2}} \cdot G_{\text{tot}}^{\text{zoo2}}}_{\text{Grazing}} - \underbrace{m_{\text{zoo2}} \cdot \text{Zoo2N}^2}_{\text{Mortality}} - \underbrace{\epsilon_{\text{zoo2}}^{\text{N}} \cdot \text{Zoo2N}}_{\text{Excretion of DON}} - \underbrace{f_{\text{n}} \cdot G_{\text{tot}}^{\text{zoo2}}}_{\text{Fecal pellet}} \quad (\text{A22})$$

The state variables ZooN and Zoo2N are listed in Table A1. Only a fraction of the grazed phytoplankton (γ_{zoo} , γ_{zoo2} , Table A3) enters the zooplankton biomass. The rest is transferred to detritus due to sloppy feeding. The grazing terms ($G_{\text{tot}}^{\text{zoo}}$, $G_{\text{tot}}^{\text{zoo2}}$) are calculated in Section A4.2. The mortality parameter (m_{zoo} , m_{zoo2}) and fecal pellet production rate constant (f_{n}) are listed in Table A3. The DON excretion terms ($\epsilon_{\text{zoo}}^{\text{N}}$, $\epsilon_{\text{zoo2}}^{\text{N}}$) are given in Table A8.

735 A1.4.2 Carbon

The zooplankton carbon biomass increases with carbon uptake via grazing and decreases through carbon losses through mortality, respiration and carbon excretion to the semi-labile DOC pool. Macrozooplankton further gains carbon by grazing on small zooplankton and loses it via fecal pellet production.

$$\text{SMS}(\text{ZooC}) = \underbrace{\gamma_{\text{zoo}} \cdot (G_{\text{small}}^{\text{zoo}} \cdot q_{\text{small}}^{\text{C:N}} + G_{\text{dia}}^{\text{zoo}} \cdot q_{\text{dia}}^{\text{C:N}})}_{\text{Grazing on phytoplankton}} + \underbrace{\gamma_{\text{zoo}} \cdot (G_{\text{det}}^{\text{zoo}} \cdot q_{\text{det}}^{\text{C:N}} + G_{\text{detZ2}}^{\text{zoo}} \cdot q_{\text{detZ2}}^{\text{C:N}})}_{\text{Grazing on detritus}} - \underbrace{G_{\text{zoo}} \cdot q_{\text{zoo}}^{\text{C:N}}}_{\text{Grazing loss by macrozoo}} \quad (\text{A23})$$

$$740 \quad - \underbrace{m_{\text{zoo}} \cdot \text{ZooN}^2 \cdot q_{\text{zoo}}^{\text{C:N}}}_{\text{Zooplankton mortality}} - \underbrace{r_{\text{zoo}} \cdot \text{ZooC}}_{\text{Respiration loss}} - \underbrace{\epsilon_{\text{zoo}}^{\text{C}} \cdot \text{ZooC}}_{\text{Excretion of DOC}} \quad (\text{A24})$$

$$\text{SMS}(\text{Zoo2C}) = \underbrace{\gamma_{\text{zoo2}} \cdot (G_{\text{small}}^{\text{zoo2}} \cdot q_{\text{small}}^{\text{C:N}} + G_{\text{dia}}^{\text{zoo2}} \cdot q_{\text{dia}}^{\text{C:N}})}_{\text{Grazing on phytoplankton}} + \underbrace{\gamma_{\text{zoo2}} \cdot (G_{\text{det}}^{\text{zoo2}} \cdot q_{\text{det}}^{\text{C:N}} + G_{\text{detZ2}}^{\text{zoo2}} \cdot q_{\text{detZ2}}^{\text{C:N}})}_{\text{Grazing on detritus}} + \underbrace{\gamma_{\text{zoo2}} \cdot (G_{\text{zoo}} \cdot q_{\text{zoo}}^{\text{C:N}})}_{\text{Grazing on small zoo}} \quad (\text{A25})$$

$$- \underbrace{m_{\text{zoo2}} \cdot \text{Zoo2N}^2 \cdot q_{\text{zoo2}}^{\text{C:N}}}_{\text{Zooplankton mortality}} - \underbrace{r_{\text{zoo2}} \cdot \text{Zoo2C}}_{\text{Respiration loss}} - \underbrace{\epsilon_{\text{zoo2}}^{\text{C}} \cdot \text{Zoo2C}}_{\text{Excretion of DOC}} - \underbrace{f_{\text{c}} \cdot G_{\text{cflux}}}_{\text{Fecal pellet}} \quad (\text{A26})$$

The state variables ZooN, ZooC, Zoo2N and Zoo2C are listed in Table A1. A fraction of the grazed phytoplankton (γ_{zoo} and γ_{zoo2} , Table A3) is kept in the zooplankton biomass while the remainder is returned back to detritus pool as a consequence of sloppy feeding. Grazing terms ($G_{\text{small}}^{\text{zoo}}$, $G_{\text{dia}}^{\text{zoo}}$, $G_{\text{det}}^{\text{zoo}}$, $G_{\text{detZ2}}^{\text{zoo}}$, $G_{\text{small}}^{\text{zoo2}}$, $G_{\text{dia}}^{\text{zoo2}}$, $G_{\text{det}}^{\text{zoo2}}$, $G_{\text{detZ2}}^{\text{zoo2}}$ and G_{zoo}) are calculated in Section A4.2. The respiration terms of zooplankton (r_{zoo} and r_{zoo2}) are calculated in Eqs. A60 and A61. Mortality parameters (m_{zoo} , m_{zoo2}) are listed in Table A3. The DOC excretion terms ($\epsilon_{\text{zoo}}^{\text{C}}$, $\epsilon_{\text{zoo2}}^{\text{C}}$) are in Table A8. The grazing flux in terms of

nitrogen biomass is converted to carbon biomass using the respective intracellular C:N ratios ($q_{\text{small}}^{\text{C:N}}$, $q_{\text{dia}}^{\text{C:N}}$, $q_{\text{det}}^{\text{C:N}}$, $q_{\text{detZ2}}^{\text{C:N}}$, $q_{\text{zoo}}^{\text{C:N}}$ and $q_{\text{zoo2}}^{\text{C:N}}$) where, $q_{\text{small}}^{\text{C:N}} = \text{PhyC}_{\text{small}}/\text{PhyN}_{\text{small}}$, $q_{\text{dia}}^{\text{C:N}} = \text{PhyC}_{\text{dia}}/\text{PhyN}_{\text{dia}}$, $q_{\text{det}}^{\text{C:N}} = \text{DetC}/\text{DetN}$, $q_{\text{detZ2}}^{\text{C:N}} = \text{DetZ2C}/\text{DetZ2N}$, $q_{\text{zoo}}^{\text{C:N}} = \text{ZooC}/\text{ZooN}$ and $q_{\text{zoo2}}^{\text{C:N}} = \text{Zoo2C}/\text{Zoo2N}$. Total grazed carbon biomass (G_{flux}) and the fecal pellet production rate constant (f_c , Table A3) together determine the fraction of carbon being lost to the large detritus carbon pool via fecal pellets.

A1.5 Detritus

A1.5.1 Nitrogen

Detrital nitrogen pool increases as a result of sloppy feeding and mortality. Sloppy feeding is outlined as a function of grazing fluxes and grazing efficiency of macrozooplankton. In other words, the grazed phytoplankton partly goes to the macrozooplankton biomass depending on the grazing efficiency. The phytoplankton aggregation contributes only to slow-sinking detritus. Fecal pellet production is defined only for macrozooplankton group. Detritus is degraded to DON based on temperature and a remineralisation rate.

$$\begin{aligned} \text{SMS}(\text{DetN}) = & \underbrace{(G_{\text{small}}^{\text{zoo}} + G_{\text{dia}}^{\text{zoo}}) \cdot (1 - \gamma_{\text{zoo}})}_{\text{Sloppy feeding}} + \underbrace{m_{\text{zoo}} \cdot \text{ZooN}^2}_{\text{Zooplankton mortality}} - \underbrace{\gamma_{\text{zoo}} \cdot (G_{\text{det}}^{\text{zoo}} + G_{\text{detZ2}}^{\text{zoo}})}_{\text{Grazing loss, small zoo}} \\ & + \underbrace{\text{Agg} \cdot (\text{PhyN}_{\text{small}} + \text{PhyN}_{\text{dia}})}_{\text{Phytoplankton aggregation}} - \underbrace{\rho_{\text{DetN}} \cdot f_T \cdot \text{DetN}}_{\text{Degradation to DON}} \end{aligned} \quad (\text{A27})$$

$$\text{SMS}(\text{DetZ2N}) = \underbrace{(G_{\text{small}}^{\text{zoo2}} + G_{\text{dia}}^{\text{zoo2}} + G_{\text{zoo}})}_{\text{Sloppy feeding}} \cdot (1 - \gamma_{\text{zoo2}}) - \underbrace{\gamma_{\text{zoo2}} \cdot (G_{\text{det}}^{\text{zoo2}} + G_{\text{detZ2}}^{\text{zoo2}})}_{\text{Grazing loss, macrozoo}} \quad (\text{A28})$$

$$\begin{aligned} & + \underbrace{m_{\text{zoo2}} \cdot \text{Zoo2N}^2}_{\text{Mortality}} + \underbrace{f_n \cdot G_{\text{tot}}}_{\text{Fecal pellet}} - \underbrace{\rho_{\text{DetN}} \cdot f_T \cdot \text{DetZ2N}}_{\text{Degradation to DON}} \end{aligned} \quad (\text{A29})$$

The state variables $\text{PhyN}_{\text{small}}$, PhyN_{dia} , ZooN , DetN , Zoo2N and DetZ2N are listed in Table A1. The grazing efficiency (γ_{zoo} and γ_{zoo2}), mortality (m_{zoo} , m_{zoo2}) and fecal pellet production rate constant (f_n) are listed in Table A3. Grazing terms ($G_{\text{small}}^{\text{zoo}}$, $G_{\text{dia}}^{\text{zoo}}$, $G_{\text{det}}^{\text{zoo}}$, $G_{\text{detZ2}}^{\text{zoo}}$, $G_{\text{small}}^{\text{zoo2}}$, $G_{\text{dia}}^{\text{zoo2}}$, $G_{\text{det}}^{\text{zoo2}}$, $G_{\text{detZ2}}^{\text{zoo2}}$ and G_{zoo}) are calculated in Section A4.2. The remineralisation rate constant of DON (ρ_{DetN}) is listed in Table A8. The temperature dependency f_T is calculated in Eq. A43. The aggregation (Agg) term is calculated in Eq. A52.

A1.5.2 Carbon

Detrital carbon sources are associated with sloppy feeding, aggregation of phytoplankton, mortality of small zooplankton and fecal pellet production by macrozooplankton. Degradation of DetC and DetZ2C to DOC is the only loss term.

$$\text{SMS}(\text{DetC}) = \underbrace{(G_{\text{small}}^{\text{Zoo}} \cdot q_{\text{small}}^{\text{C:N}} + G_{\text{dia}}^{\text{Zoo}} \cdot q_{\text{dia}}^{\text{C:N}})}_{\text{Sloppy feeding}} \cdot (1 - \gamma_{\text{zoo}}) + \underbrace{m_{\text{zoo}} \cdot \text{ZooN}^2 \cdot q_{\text{zoo}}^{\text{C:N}}}_{\text{small zoo mortality}} - \underbrace{\gamma_{\text{zoo}} \cdot (G_{\text{det}}^{\text{Zoo}} \cdot q_{\text{det}}^{\text{C:N}} + G_{\text{detZ2}}^{\text{Zoo}} \cdot q_{\text{detZ2}}^{\text{C:N}})}_{\text{Grazing loss by macro zoo}} \quad (\text{A30})$$

$$+ \underbrace{\text{Agg} \cdot (\text{PhyC}_{\text{small}} + \text{PhyC}_{\text{dia}})}_{\text{Phytoplankton aggregation}} - \underbrace{\rho_{\text{DetC}} \cdot f_T \cdot \text{DetC}}_{\text{Degradation to DOC}}$$

$$\text{SMS}(\text{DetZ2C}) = \underbrace{(G_{\text{small}}^{\text{Zoo2}} \cdot q_{\text{small}}^{\text{C:N}} + G_{\text{dia}}^{\text{Zoo2}} \cdot q_{\text{dia}}^{\text{C:N}} + G_{\text{zoo}} \cdot q_{\text{zoo}}^{\text{C:N}})}_{\text{Sloppy feeding}} \cdot (1 - \gamma_{\text{zoo2}}) - \underbrace{\gamma_{\text{zoo2}} \cdot (G_{\text{det}}^{\text{Zoo2}} \cdot q_{\text{det}}^{\text{C:N}} + G_{\text{detZ2}}^{\text{Zoo2}} \cdot q_{\text{detZ2}}^{\text{C:N}})}_{\text{Grazing loss by macro zoo}} \quad (\text{A31})$$

$$+ \underbrace{m_{\text{zoo2}} \cdot \text{Zoo2N}^2 \cdot q_{\text{zoo2}}^{\text{C:N}}}_{\text{Mortality}} + \underbrace{f_c \cdot G_{\text{cflux}}}_{\text{Fecal pellet}} - \underbrace{\rho_{\text{DetC}} \cdot f_T \cdot \text{DetZ2C}}_{\text{Degradation to DOC}} \quad (\text{A32})$$

775 The state variables $\text{PhyC}_{\text{small}}$, PhyC_{dia} , ZooN , DetC , Zoo2N and DetZ2C are listed in Table A1. The grazing efficiency (γ_{zoo} and γ_{zoo2}) and mortality (m_{zoo} m_{zoo2}) parameters are listed in Table A3. Grazing terms ($G_{\text{small}}^{\text{Zoo}}$, $G_{\text{dia}}^{\text{Zoo}}$, $G_{\text{det}}^{\text{Zoo}}$, $G_{\text{detZ2}}^{\text{Zoo}}$, $G_{\text{small}}^{\text{Zoo2}}$, $G_{\text{dia}}^{\text{Zoo2}}$, $G_{\text{detZ2}}^{\text{Zoo2}}$ and G_{zoo}) are calculated in Section A4.2. The remineralisation rate of DOC (ρ_{DetC}) is listed in Table A8. Temperature dependency f_T is calculated in Eq. A43. The aggregation (Agg) term is calculated in Eq. A52. Total grazed carbon biomass (G_{cflux}) and the fecal pellet production rate constant (f_c , Table A3) together determine the fraction of carbon
 780 being lost to the large detritus carbon pool via fecal pellets. The quotas $q_{\text{small}}^{\text{C:N}} = \text{PhyC}_{\text{small}}/\text{PhyN}_{\text{small}}$, $q_{\text{dia}}^{\text{C:N}} = \text{PhyC}_{\text{dia}}/\text{PhyN}_{\text{dia}}$, $q_{\text{zoo}}^{\text{C:N}} = \text{ZooC}/\text{ZooN}$, $q_{\text{zoo2}}^{\text{C:N}} = \text{Zoo2C}/\text{Zoo2N}$, $q_{\text{det}}^{\text{C:N}} = \text{DetC}/\text{DetN}$ and $q_{\text{detZ2}}^{\text{C:N}} = \text{DetZ2C}/\text{DetZ2N}$ are used to convert the units from mmol N to mmol C.

A1.5.3 Silica

Biogenic detrital silica increases with excretion fluxes from diatoms to detritus, aggregation and grazing and decreases with
 785 silica dissolution from DetSi and DetZ2Si .

$$\text{SMS}(\text{DetSi}) = \underbrace{(\epsilon_{\text{phy}}^{\text{N}} \cdot f_{\text{lim,dia}}^{\text{N:Cmax}})}_{\text{Diatom excretion}} + \underbrace{\text{Agg}}_{\text{Aggregation}} \cdot \text{DiaSi} + \underbrace{G_{\text{dia}}^{\text{Zoo}} \cdot q_{\text{dia}}^{\text{Si:N}}}_{\text{Sloppy feeding}} - \underbrace{\rho_{\text{Si}}^{\text{T}} \cdot \text{DetSi}}_{\text{Remineralization to DSi}} \quad (\text{A33})$$

$$\text{SMS}(\text{DetZ2Si}) = \underbrace{G_{\text{dia}}^{\text{Zoo2}} \cdot q_{\text{dia}}^{\text{Si:N}}}_{\text{Sloppy feeding}} - \underbrace{\rho_{\text{Si}}^{\text{T}} \cdot \text{DetZ2Si}}_{\text{Remineralization to DSi}} \quad (\text{A34})$$

The state variables DiaSi , DetSi and DetZ2Si are listed in Table A1. The constant excretion rate ($\epsilon_{\text{phy}}^{\text{N}}$, Table A8) is down-regulated by the limiter factor $f_{\text{lim,dia}}^{\text{N:Cmax}}$ (Eq. A55) when the N:C ratio becomes too high. The remineralization rates ($\rho_{\text{Si}}^{\text{T}}$),
 790 the aggregation (Agg) and the grazing on diatoms ($G_{\text{dia}}^{\text{Zoo}}$, $G_{\text{dia}}^{\text{Zoo2}}$) are calculated in Eqs. A45, A52 and A65, respectively. The intracellular ratio between diatom silicon and carbon is defined as $q_{\text{dia}}^{\text{Si:N}} = \text{PhySi}_{\text{dia}}/\text{PhyN}_{\text{dia}}$.

A1.5.4 CaCO_3

The coccolithophore fraction of small phytoplankton loses biogenic CaCO_3 to the detrital CaCO_3 pool along with excretion, aggregation, respiration and grazing. Dissolution of CaCO_3 leads to an increase in DIC and alkalinity.

$$795 \quad \text{SMS}(\text{DetCalc}) = \underbrace{\epsilon_C^{\text{phy}} \cdot f_{\text{lim,small}}^{\text{N:Cmax}} \cdot \text{PhyCalc}}_{\text{Small phytoplankton, excretion}} + \left(\underbrace{\text{Agg}}_{\text{Aggregation}} + \underbrace{r_{\text{small}}}_{\text{Respiration}} \right) \cdot \text{PhyCalc} + \underbrace{G_{\text{small}}^{\text{zoo}} \cdot q_{\text{small}}^{\text{CaCO}_3:\text{N}}}_{\text{Grazing loss}} \quad (\text{A35})$$

$$- \underbrace{G_{\text{small}}^{\text{zoo}} \cdot q_{\text{small}}^{\text{CaCO}_3:\text{N}} \cdot \text{Diss}_{\text{calc-guts}}}_{\text{CaCO}_3 \text{ dissolution in guts}} - \underbrace{\text{Diss}_{\text{calc}} \cdot \text{DetCalc}}_{\text{CaCO}_3 \text{ dissolution, slow-sinking detritus}}$$

$$\text{SMS}(\text{DetZ2Calc}) = \underbrace{G_{\text{small}}^{\text{zoo2}} \cdot q_{\text{small}}^{\text{CaCO}_3:\text{N}}}_{\text{Grazing loss}} \quad (\text{A36})$$

$$- \underbrace{G_{\text{small}}^{\text{zoo2}} \cdot q_{\text{small}}^{\text{CaCO}_3:\text{N}} \cdot \text{Diss}_{\text{calc-guts}}}_{\text{CaCO}_3 \text{ dissolution in guts}} - \underbrace{\text{Diss}_{\text{calc2}} \cdot \text{DetZ2Calc}}_{\text{CaCO}_3 \text{ dissolution, fast-sinking detritus}} \quad (\text{A37})$$

The state variables PhyCalc, DetCalc and DetZ2Calc are listed in Table A1. The constant excretion rate (ϵ_C^{phy} , Table A8) is downregulated by the limiter factor $f_{\text{lim,small}}^{\text{N:Cmax}}$ (Eq. A55) when the N:C ratio becomes too high. The respiration (r_{small}), the aggregation (Agg) and the grazing on small phytoplankton ($G_{\text{small}}^{\text{zoo}}$ and $G_{\text{small}}^{\text{zoo2}}$) are calculated in Eqs. A48, A52 and A64, respectively. The ratio $q_{\text{small}}^{\text{CaCO}_3:\text{N}} = \text{PhyCalc}/\text{PhyN}_{\text{small}}$.

Calcite dissolution: As the detritus calcite sinks through the water column it is subject to dissolution. We follow Yamanaka and Tajika (1996) assuming an exponential decrease of the CaCO_3 flux with depth. As we also assume an increasing sinking speed of small detritus with depth, following Kriest and Oschlies (2008), the dissolution rate is scaled with the sinking velocity.

$$\text{Diss}_{\text{calc}} = \text{Diss}_{\text{calc_rate}} \cdot w_{\text{det}} \quad \text{Diss}_{\text{calc2}} = \text{Diss}_{\text{calc_rate}} \quad (\text{A38})$$

$\text{Diss}_{\text{calc}}$ and $\text{Diss}_{\text{calc2}}$ are the dissolution rate constants for slow- and fast-sinking detritus classes (Table A5). The reference dissolution rate ($\text{Diss}_{\text{calc_rate}}$, Table A8) is based on a length scale of 3500 m and velocity of 20 m d^{-1} . The sinking speed at depth z (w_{det} , Table A5) is calculated as follows:

$$810 \quad w_{\text{det}} = 0.0288 \cdot z + w_0 \quad (\text{A39})$$

Here, z denotes the depth and w_0 is the sinking speed at the ocean surface (Table A3). The dissolution rate for fast-sinking detritus class ($\text{Diss}_{\text{calc2}}$) is assumed to be constant throughout the water column and is set to the value of $\text{Diss}_{\text{calc_rate}}$ (Table A8).

A1.6 Dissolved oxygen (O_{xy})

O_{xy} concentration increases with carbon fixation by primary producers. It decreases with respiration of phyto- and zooplank-
 815 tons, remineralization of dissolved organic carbon. In addition, sea–air flux of O_2 leads to an exchange of oxygen with the atmosphere, depending on the partial pressure difference of O_2 between ocean and atmosphere. This exchange is treated separately as a boundary condition. The partial pressure of surface ocean O_2 is computed using the mocsy-2.0 routines (Orr and

Epitalon, 2015).

$$\begin{aligned} \text{SMS}(\text{Oxy}) = & \underbrace{(P_{\text{small}} - r_{\text{small}}) \cdot \text{PhyC}_{\text{small}}}_{\text{Net production, small phytoplankton}} + \underbrace{(P_{\text{dia}} - r_{\text{dia}}) \cdot \text{PhyC}_{\text{dia}}}_{\text{Net production, diatom}} \\ & - \underbrace{\rho_{\text{DOC}} \cdot f_T \cdot \text{DOC}}_{\text{Remineralization of DOC}} - \underbrace{r_{\text{zoo}} \cdot \text{ZooC}}_{\text{Respiration, small zoo}} - \underbrace{r_{\text{zoo2}} \cdot \text{Zoo2C}}_{\text{Respiration, macrozoo}} \end{aligned} \quad (\text{A40})$$

820 The state variables $\text{PhyC}_{\text{small}}$, PhyC_{dia} , DOC , ZooC and Zoo2C are listed in Table A1. Respiration rate constants of small phytoplankton (r_{small}), diatoms (r_{dia}) and zooplankton groups (r_{zoo} and r_{zoo2}) are computed in Sections A3.2 and A4.1, respectively. Photosynthesis terms (P_{small} and P_{dia}) are calculated in Eq. A46. The remineralization rate constant ρ_{DOC} is listed in Table A8 and the temperature dependency (f_T) is given in Eq. A43.

A1.7 Dissolved organic material

825 Dissolved organic matter in our model is a representation of the semi-labile fraction only, the refractory and labile fractions are not included.

A1.7.1 Dissolved organic nitrogen (DON)

DON is produced via nitrogen excretion by phytoplankton, zooplankton and by degradation of detrital nitrogen. DON is turned into DIN by remineralization which is the only sink term.

$$\begin{aligned} \text{SMS}(\text{DON}) = & \underbrace{\epsilon_{\text{phy}}^{\text{N}} \cdot f_{\text{lim,small}}^{\text{N:Cmax}} \cdot \text{PhyN}_{\text{small}}}_{\text{Excretion, small phytoplankton}} + \underbrace{\epsilon_{\text{dia}}^{\text{N}} \cdot f_{\text{lim,dia}}^{\text{N:Cmax}} \cdot \text{PhyN}_{\text{dia}}}_{\text{Excretion, diatom}} \\ & + \underbrace{\epsilon_{\text{zoo}}^{\text{N}} \cdot \text{ZooN}}_{\text{Excretion, small zoo}} + \underbrace{\epsilon_{\text{zoo2}}^{\text{N}} \cdot \text{Zoo2N}}_{\text{Excretion, macrozoo}} + \underbrace{\rho_{\text{DetN}} \cdot f_T \cdot \text{DetN}}_{\text{Detritus degradation, slow-sinking}} + \underbrace{\rho_{\text{Det2ZN}} \cdot f_T \cdot \text{Det2ZN}}_{\text{Detritus degradation, fast sinking}} - \underbrace{\rho_{\text{DON}} \cdot f_T \cdot \text{DON}}_{\text{Remineralization}} \end{aligned} \quad (\text{A41})$$

The state variables $\text{PhyN}_{\text{small}}$, PhyN_{dia} , ZooN , DetN , Zoo2N , Det2ZN and DON are listed in Table A1. The constant excretion rate of nitrogen from phytoplankton and zooplankton classes ($\epsilon_{\text{phy}}^{\text{N}}$, $\epsilon_{\text{dia}}^{\text{N}}$, $\epsilon_{\text{zoo}}^{\text{N}}$ and $\epsilon_{\text{zoo2}}^{\text{N}}$), the degradation rate of detritus (ρ_{DetN} , ρ_{Det2ZN}) and the remineralization rate of DON (ρ_{DON}) are listed in Table A8. The constant excretion rate of phytoplankton
 835 is downregulated by the limiter function ($f_{\text{lim,small}}^{\text{N:Cmax}}$, $f_{\text{lim,dia}}^{\text{N:Cmax}}$, Eq. A55) when the N : C ratio becomes too high. The temperature dependency f_T is calculated in Eq. A43.

A1.7.2 Dissolved organic carbon (DOC)

DOC is produced via carbon excretion by phytoplankton and zooplankton and by degradation of detrital carbon. DOC is turned into DIC by remineralization which is the only sink term.

$$\begin{aligned} \text{SMS}(\text{DOC}) = & \underbrace{\epsilon_{\text{phy}}^{\text{C}} \cdot f_{\text{lim,small}}^{\text{N:Cmax}} \cdot \text{PhyC}_{\text{small}}}_{\text{Excretion, small phytoplankton}} + \underbrace{\epsilon_{\text{dia}}^{\text{C}} \cdot f_{\text{lim,dia}}^{\text{N:Cmax}} \cdot \text{PhyC}_{\text{dia}}}_{\text{Excretion, diatom}} \\ & + \underbrace{\epsilon_{\text{zoo}}^{\text{C}} \cdot \text{ZooC}}_{\text{Excretion, small zoo}} + \underbrace{\epsilon_{\text{zoo2}}^{\text{C}} \cdot \text{Zoo2C}}_{\text{Excretion, macrozoo}} + \underbrace{\rho_{\text{DetC}} \cdot f_T \cdot \text{DetC}}_{\text{Detritus degradation, slow sinking}} + \underbrace{\rho_{\text{Det2C}} \cdot f_T \cdot \text{Det2C}}_{\text{Detritus degradation, fast sinking}} - \underbrace{\rho_{\text{DOC}} \cdot f_T \cdot \text{DOC}}_{\text{Remineralization}} \end{aligned} \quad (\text{A42})$$

The state variables $\text{PhyC}_{\text{small}}$, PhyC_{dia} , ZooC , DetC , Zoo2C , Det2C and DOC are listed in Table A1. The constant excretion rate of nitrogen from phytoplankton and zooplankton classes ($\epsilon_{\text{phy}}^{\text{C}}$, $\epsilon_{\text{dia}}^{\text{C}}$, $\epsilon_{\text{zoo}}^{\text{C}}$ and $\epsilon_{\text{zoo2}}^{\text{C}}$), the degradation rate of detritus (ρ_{DetC} , ρ_{Det2C}) and the remineralization rate of DOC (ρ_{DOC}) are listed in Table A8. The constant excretion rate of phytoplankton is downregulated by the limiter factor ($f_{\text{lim,small}}^{\text{N:Cmax}}$, $f_{\text{lim,dia}}^{\text{N:Cmax}}$, Eq. A55) when the N:C ratio becomes too high. Temperature dependency f_T is calculated in Eq. A43.

A2 Temperature dependence of rates

Arrhenius function: Most metabolic processes are faster at higher temperatures. This temperature dependence is defined relative to a reference temperature.

$$f_T = \exp\left(-4500 \cdot \left(\frac{1}{T} - \frac{1}{T_{\text{ref}}}\right)\right) \quad (\text{A43})$$

T and T_{ref} are the local and reference temperature in K, respectively (Table A6).

Macrozooplankton grazing: Macrozooplankton grazing is temperature dependent. A dimensionless exponential temperature function (Butzin and Pörtner, 2016) is used for the parameterization of the temperature dependency ($f_{T_{\text{zoo2}}}$, Table A5). Specifically, the following parameterization provides an optimum curve with a maximum at 0.5°C as described in Karakuş et al. (2021).

$$f_{T_{\text{zoo2}}} = \frac{\exp\left(\frac{Q_a}{T_r} - \frac{Q_a}{T}\right)}{1 + \exp\left(\frac{Q_h}{T_h} - \frac{Q_h}{T}\right)} \quad (\text{A44})$$

T_r is the intrinsic optimum temperature for development and T_h is the temperature above which inhibitive processes dominate. Q_a and Q_h are the temperatures for the uninhibited and inhibited reaction kinetics, respectively (Table A9). T is the local temperature in K.

Silicon dissolution: The temperature dependent dissolution rate of silicon (ρ_{Si}^T , Table A5) is calculated following Maerz et al. (2020), but with a minimum dissolution rate.

$$\rho_{\text{Si}}^T = \max\left(0.023 \cdot 2.6^{\frac{T-10}{10}}, \rho_{\text{Si}}\right) \quad (\text{A45})$$

T is the local temperature in $^\circ\text{C}$. The minimum dissolution rate (ρ_{Si}) is listed in Table A8.

A3 Phytoplankton processes

Phytoplankton growth equations are based on Geider et al. (1998) with small modifications for diatom silicon uptake, following Hohn (2009).

A3.1 Photosynthesis

The rate of the carbon specific (C-specific from now on) photosynthesis for phytoplankton ($P_{\text{small}}, P_{\text{dia}}$) is parameterized as follows:

$$870 \quad P_{\text{small}} = P_{\text{max}}^{\text{small}} \cdot \left(1.0 - \exp \left(\frac{-\alpha_{\text{small}} \cdot q^{\text{Chl:C}} \cdot \text{PAR}}{P_{\text{max}}^{\text{small}}} \right) \right), \quad P_{\text{dia}} = P_{\text{max}}^{\text{dia}} \cdot \left(1.0 - \exp \left(\frac{-\alpha_{\text{dia}} \cdot q^{\text{Chl:C}} \cdot \text{PAR}}{P_{\text{max}}^{\text{dia}}} \right) \right) \quad (\text{A46})$$

The light harvesting efficiency ($\alpha_{\text{small}}, \alpha_{\text{dia}}$) per chlorophyll is listed in Table A7. PAR is the photosynthetically available radiation (Table A5). The intracellular Chl to C ratio ($q^{\text{Chl:C}}$) is defined as PhyChl/PhyC and varies as a result of photoacclimation. The apparent maximum photosynthetic rate ($P_{\text{max}}^{\text{small}}, P_{\text{max}}^{\text{dia}}$) is defined below.

$$P_{\text{max}}^{\text{small}} = \mu_{\text{C,small}}^{\text{max}} \cdot \min (f_{\text{lim,small}}^{\text{Fe}}, f_{\text{lim,small}}^{\text{N:Cmin}}) \cdot f_T, \quad P_{\text{max}}^{\text{dia}} = \mu_{\text{C,dia}}^{\text{max}} \cdot \min (f_{\text{lim,dia}}^{\text{Fe}}, f_{\text{lim,dia}}^{\text{N:Cmin}}, f_{\text{lim,dia}}^{\text{Si:Cmin}}) \cdot f_T \quad (\text{A47})$$

875 The value of $\mu_{\text{C,small}}^{\text{max}}, \mu_{\text{C,dia}}^{\text{max}}$ is listed in Table A7. The limitation terms ($f_{\text{lim,small}}^{\text{N:Cmin}}, f_{\text{lim,dia}}^{\text{N:Cmin}}, f_{\text{lim,dia}}^{\text{Si:Cmin}}, f_{\text{lim,small}}^{\text{Fe}}$ and $f_{\text{lim,dia}}^{\text{Fe}}$) are presented in Section A3.6 and the temperature dependency (f_T) is calculated in Eq. A43.

A3.2 Respiration

The phytoplankton respiration rate (r_{small} and r_{dia} , Table A5) is calculated as a base respiration plus a second term proportional to N-assimilation, as a measure of biosynthesis:

$$880 \quad r_{\text{small}} = \underbrace{\text{res}_{\text{small}} \cdot f_{\text{lim,small}}^{\text{N:Cmax}}}_{\text{Maintenance}} + \underbrace{\zeta \cdot V_{\text{small}}^{\text{N}}}_{\text{N-assim}}, \quad r_{\text{dia}} = \underbrace{\text{res}_{\text{dia}} \cdot f_{\text{lim,dia}}^{\text{N:Cmax}}}_{\text{Maintenance}} + \underbrace{\zeta \cdot V_{\text{dia}}^{\text{N}}}_{\text{N-assim}} \quad (\text{A48})$$

The values for the maintenance respiration rate ($\text{res}_{\text{small}}, \text{res}_{\text{dia}}$) and the cost of biosynthesis (ζ) are listed in Table A7. Si-assimilation is assumed to be inexpensive, so it is not included as additional cost in the respiration (Hohn, 2009). The limiter function ($f_{\text{lim,small}}^{\text{N:Cmax}}$ and $f_{\text{lim,dia}}^{\text{N:Cmax}}$) is described in Eq. A55 and the N-assimilation rate ($V_{\text{small}}^{\text{N}}, V_{\text{dia}}^{\text{N}}$) is calculated in Eq. A50.

A3.3 Chlorophyll *a* synthesis

885 The chlorophyll synthesis rate ($S_{\text{small}}^{\text{chl}}, S_{\text{dia}}^{\text{chl}}$, Table A5) is proportional to N-assimilation, with the proportionality factor varying as a function of the C-specific photosynthesis rate, relative to the maximum possible photosynthetic rate at the current Chl:C ratio of the cell, which depends on photosynthetically available radiation and light harvesting efficiency.

$$S_{\text{small}}^{\text{chl}} = V_{\text{small}}^{\text{N}} \cdot q_{\text{max,small}}^{\text{Chl:N}} \cdot \min \left(1, \frac{P_{\text{small}}}{\alpha_{\text{small}} \cdot q^{\text{Chl:C}} \cdot \text{PAR}} \right), \quad S_{\text{dia}}^{\text{chl}} = V_{\text{dia}}^{\text{N}} \cdot q_{\text{max,dia}}^{\text{Chl:N}} \cdot \min \left(1, \frac{P_{\text{dia}}}{\alpha_{\text{dia}} \cdot q^{\text{Chl:C}} \cdot \text{PAR}} \right) \quad (\text{A49})$$

890 The N-assimilation ($V_{\text{small}}^{\text{N}}, V_{\text{dia}}^{\text{N}}$) is computed in Eq. A50. The conversion factor of the maximum Chl : N ratio ($q_{\text{max,small}}^{\text{Chl:N}}, q_{\text{max,dia}}^{\text{Chl:N}}$) and the light harvesting efficiency ($\alpha_{\text{small}}, \alpha_{\text{dia}}$) are listed in Table A7. The C-specific photosynthesis ($P_{\text{small}}, P_{\text{dia}}$) is given in Eq. A46. PAR is the photosynthetically available radiation (Table A5) and the intracellular Chl to C ratio ($q^{\text{Chl:C}}$) is defined as PhyChl/PhyC.

A3.4 N- and Si-assimilation

Nitrogen: The C-specific N-assimilation rate is a function of the maximum rate of C-specific photosynthesis and DIN concentration. N-assimilation depends on the DIN concentration in seawater via Michaelis–Menten kinetics. The N : C uptake ratio and a function of the intracellular quota between N and C further, which downregulates uptake under high N:C ratio further modify the N-assimilation.

$$V_{\text{small}}^{\text{N}} = V_{\text{cm}}^{\text{small}} \cdot P_{\text{max}}^{\text{small}} \cdot \sigma_{\text{N:C}}^{\text{small}} \cdot f_{\text{lim,small}}^{\text{N:Cmax}} \cdot \frac{\text{DIN}}{K_{\text{small}}^{\text{N}} + \text{DIN}}, \quad V_{\text{dia}}^{\text{N}} = V_{\text{cm}}^{\text{dia}} \cdot P_{\text{max}}^{\text{dia}} \cdot \sigma_{\text{N:C}}^{\text{dia}} \cdot f_{\text{lim,dia}}^{\text{N:Cmax}} \cdot \frac{\text{DIN}}{K_{\text{dia}}^{\text{N}} + \text{DIN}} \quad (\text{A50})$$

$V_{\text{cm}}^{\text{small}}, V_{\text{cm}}^{\text{dia}}, \sigma_{\text{N:C}}^{\text{small}}, \sigma_{\text{N:C}}^{\text{dia}}, K_{\text{small}}^{\text{N}}$ and $K_{\text{dia}}^{\text{N}}$ are listed in Table A7. The maximum rate of photosynthesis ($P_{\text{max}}^{\text{small}}$ and $P_{\text{max}}^{\text{dia}}$) is given in Eqs. A47. $f_{\text{lim,small}}^{\text{N:Cmax}}$ and $f_{\text{lim,dia}}^{\text{N:Cmax}}$ are described in Eq. A55. DIN corresponds to insitu concentration.

Silicon: The building of a silica frustule of diatoms requires silicate uptake. The C-specific Si-assimilation rate is a function of a factor for C-specific N-uptake, a rate constant of C-specific photosynthesis, maximum uptake ratio N : C for small phytoplankton and DSi concentration. The maximum Si : C ratio, temperature, and the scaling factor for the maximum nitrogen uptake further regulate the N-assimilation.

$$V_{\text{cm}}^{\text{Si}} = V_{\text{cm}}^{\text{dia}} \cdot \mu_{\text{C,dia}}^{\text{max}} \cdot f_T \cdot \sigma_{\text{Si:C}} \cdot f_{\text{lim}}^{\text{Si:Cmax}} \cdot f_{\text{lim,dia}}^{\text{N:Cmax}} \cdot \frac{\text{DSi}}{K_{\text{Si}} + \text{DSi}} \quad (\text{A51})$$

The scaling factor for the N-uptake ($V_{\text{cm}}^{\text{dia}}$), the maximum Rate constant of C-specific photosynthesis ($\mu_{\text{C,dia}}^{\text{max}}$), the uptake ratio of the maximum Si : C ($\sigma_{\text{Si:C}}$) and half-saturation constant for silicate uptake (K_{Si}) are listed in Table A7. The temperature dependency (f_T) is computed in Eq. A43. The limitation by the intracellular ratios N : C and Si : C ($f_{\text{lim,dia}}^{\text{N:Cmax}}, f_{\text{lim}}^{\text{Si:Cmax}}$) are described in Eqs. A55 and A56, respectively. DSi corresponds to in situ concentration.

910 A3.5 Aggregation loss

The aggregation rate (Agg, Table A5) is proportional to the concentration of small phytoplankton, diatoms and detritus. The effect of increased stickiness of diatoms under nutrient limitation (Waite et al., 1992; Aumont et al., 2015) is taken into account by multiplying the diatom biomass with $(1 - q_{\text{lim}}^{\text{dia}})$. When the nutrient limitation is high (i.e, low $q_{\text{lim}}^{\text{dia}}$), the aggregation rate increases in the model.

$$915 \quad \text{Agg} = \phi_{\text{phy}} \cdot (\text{PhyN}_{\text{small}} + (1 - q_{\text{lim}}^{\text{dia}}) \cdot \text{PhyN}_{\text{dia}}) + \phi_{\text{det}} \cdot (\text{DetN} + \text{DetZ2N}) \quad (\text{A52})$$

$$q_{\text{lim}}^{\text{dia}} = \min(f_{\text{lim,dia}}^{\text{Fe}}, f_{\text{lim,dia}}^{\text{N:Cmin}}, f_{\text{lim,dia}}^{\text{Si:Cmin}}) \quad (\text{A53})$$

The state variables $\text{PhyN}_{\text{small}}, \text{PhyN}_{\text{dia}}, \text{DetN}$ and DetZ2N are described in Table A1. The values of the maximum aggregation loss parameters (ϕ_{phy} and ϕ_{det}) are listed in Table A3. The limitation terms ($f_{\text{lim,dia}}^{\text{N:Cmin}}, f_{\text{lim,dia}}^{\text{Si:Cmin}}$ and $f_{\text{lim,dia}}^{\text{Fe}}$) are presented below (Section A3.6).

A3.6 Nutrient limitation

The metabolic processes such as C-specific photosynthesis, respiration rate and excretion losses are treated as functions of the intracellular nitrogen status (i.e., N : C ratios q) following Geider et al. (1998). Intracellular ratios between nutrients and carbon limit uptake of nitrogen and silicon which is modeled via a non-linear function as in Schourup-Kristensen et al. (2014).

$$925 \quad f_{\text{lim}}(\theta, q_1, q_2) = 1 - \exp(-\theta(|\Delta q| - \Delta q)^2) \quad (\text{A54})$$

Here, $\Delta q = q_1 - q_2$ is the difference between the current intracellular nutrient:C quota and a prescribed maximum or minimum quota. The dimensionless constant θ controls the limitation.

A3.6.1 $f_{\text{lim}}^{\text{N:Cmax}}$

The limiter $f_{\text{lim}}^{\text{N:Cmax}}$ downregulates the metabolic processes such as nitrogen and Si-assimilation, excretion and maintenance
 930 respiration of phytoplankton when the intracellular nitrogen quota ($q^{\text{N:C}}$) becomes too high. $f_{\text{lim}}^{\text{N:Cmax}}$ is one when the current $q^{\text{N:C}} < 0.151$ (i.e., Redfield ratio, 16N:106C) and zero for $q^{\text{N:C}} > 0.2$ (i.e., 21.2N:106C). It determines the end of the uptake of nitrogen and silicon in assimilation processes as well as the cease of carbon and nitrogen release during the respiration and excretion of DON/DOC and CaCO_3 processes of phytoplankton (See Section A1.5.4).

$$f_{\text{lim,small}}^{\text{N:Cmax}} = f_{\text{lim}}(\theta_{\text{max}}^{\text{N}}, q_{\text{small}}^{\text{N:C}}, q_{\text{small}}^{\text{N:Cmax}}), \quad f_{\text{lim,dia}}^{\text{N:Cmax}} = f_{\text{lim}}(\theta_{\text{max}}^{\text{N}}, q_{\text{dia}}^{\text{N:C}}, q_{\text{dia}}^{\text{N:Cmax}}) \quad (\text{A55})$$

935 The limitation function for quota regulation is calculated with Eq. A54. $q_{\text{small}}^{\text{N:C}}$ and $q_{\text{dia}}^{\text{N:C}}$ are the current intracellular nitrogen quota for small phytoplankton and diatoms, respectively. Dimensionless constants $\theta_{\text{max}}^{\text{N}}$, $q_{\text{small}}^{\text{N:Cmax}}$ and $q_{\text{dia}}^{\text{N:Cmax}}$ are listed in Table A6.

A3.6.2 $f_{\text{lim}}^{\text{Si:Cmax}}$

The limiter $f_{\text{lim}}^{\text{Si:Cmax}}$ downregulates the Si-assimilation of diatoms when the intracellular silicon quota (Si : C) becomes too
 940 high. $f_{\text{lim}}^{\text{Si:Cmax}}$ is one when the current $q^{\text{Si:C}} < 0.76$ and zero for $q^{\text{Si:C}} > 0.8$. It determines the end of the uptake of silicon in assimilation processes. The limiter function is described in Eq. A54 and is calculated as follows:

$$f_{\text{lim}}^{\text{Si:Cmax}} = f_{\text{lim}}(\theta_{\text{max}}^{\text{Si}}, q^{\text{Si:C}}, q^{\text{Si:Cmax}}) \quad (\text{A56})$$

Dimensionless constants $\theta_{\text{max}}^{\text{Si}}$ and $q^{\text{Si:Cmax}}$ are listed in Table A6.

A3.6.3 $f_{\text{lim}}^{\text{Si:Cmin}}$

945 Carbon fixation and aggregation loss in diatoms are further downregulated by a factor ($f_{\text{lim,dia}}^{\text{Si:Cmin}}$, see Eq. A54) when the intracellular silicon quota ($q^{\text{Si:C}}$) approaches a minimum value ($q^{\text{Si:Cmin}}$), mimicking the arrest of cellular division at low cellular Si (Claquin et al., 2002). $f_{\text{lim,dia}}^{\text{Si:Cmin}}$ is zero when the current $q^{\text{Si:C}} < 0.04$ and one for $q^{\text{Si:C}} > 0.08$.

$$f_{\text{lim,dia}}^{\text{Si:Cmin}} = f_{\text{lim}}(\theta_{\text{min}}^{\text{Si}}, q^{\text{Si:Cmin}}, q^{\text{Si:C}}) \quad (\text{A57})$$

Dimensionless constants $\theta_{\text{min}}^{\text{Si}}$ and $q^{\text{Si:Cmin}}$ are listed in Table A6.

950 **A3.6.4** $f_{\text{lim}}^{\text{Fe}}$

Growth-limitation by iron is modeled with Michaelis–Menten kinetics, implicitly assuming that all dissolved iron is ultimately bioavailable.

$$f_{\text{lim,small}}^{\text{Fe}} = \frac{\text{DFe}}{K_{\text{small}}^{\text{Fe}} + \text{DFe}}, \quad f_{\text{lim,dia}}^{\text{Fe}} = \frac{\text{DFe}}{K_{\text{dia}}^{\text{Fe}} + \text{DFe}} \quad (\text{A58})$$

Stat variable DFe is listed in Table A1. The half saturation constants ($K_{\text{small}}^{\text{Fe}}$ and $K_{\text{dia}}^{\text{Fe}}$) are given in Table A6.

955 **A3.6.5** $f_{\text{lim}}^{\text{N:Cmin}}$

In addition to iron limitation, photosynthesis is limited by nitrogen in small phytoplankton and diatoms using the Eq. A54. Nitrogen limitation ($f_{\text{lim,small}}^{\text{N:Cmin}}$, $f_{\text{lim,dia}}^{\text{N:Cmin}}$) is described as a function of the intracellular nitrogen quota ($q_{\text{small}}^{\text{N:C}}$, $q_{\text{dia}}^{\text{N:C}}$) with growth ending at a minimum quota ($q_{\text{small}}^{\text{N:Cmin}}$, $q_{\text{dia}}^{\text{N:Cmin}}$).

$$f_{\text{lim,small}}^{\text{N:Cmin}} = f_{\text{lim}}(\theta_{\text{min}}^{\text{N}}, q_{\text{small}}^{\text{N:Cmin}}, q_{\text{small}}^{\text{N:C}}), \quad f_{\text{lim,dia}}^{\text{N:Cmin}} = f_{\text{lim}}(\theta_{\text{min}}^{\text{N}}, q_{\text{dia}}^{\text{N:Cmin}}, q_{\text{dia}}^{\text{N:C}}) \quad (\text{A59})$$

960 Dimensionless constants $\theta_{\text{min}}^{\text{N}}$, $q_{\text{small}}^{\text{N:Cmin}}$ and $q_{\text{dia}}^{\text{N:Cmin}}$ are listed in Table A6.

A4 Zooplankton processes

A4.1 Zooplankton respiration

Small zooplankton: When the intracellular C:N ratio in zooplankton exceeds the Redfield ratio, a temperature dependent respiration (r_{zoo} , Table A5) is assumed to drive it back with a time scale τ .

$$965 \quad r_{\text{zoo}} = \frac{q_{\text{zoo}}^{\text{C:N}} - q_{\text{standard}}^{\text{C:N}}}{\tau} \cdot f_T \quad (\text{A60})$$

The time scale for respiration (τ) is listed in Table A7. The temperature dependence (f_T) is calculated in Eq. (A43). The ratios are defined as $q_{\text{zoo}}^{\text{C:N}} = \text{ZooC}/\text{ZooN}$ and $q_{\text{standard}}^{\text{C:N}} = 106\text{C}/16\text{N}$.

Macrozooplankton: The daily respiration rate constant of macrozooplankton (r_{zoo2} , Table A5) is modeled following Karakuş et al. (2021).

$$970 \quad r_{\text{zoo2}} = R_s \cdot (1 + R_f + R_a) \quad (\text{A61})$$

The standard respiration rate (R_s) is listed in Table A3. The feeding activity factor (R_f , Table A5) is defined as the ratio of grazing flux to carbon biomass of macrozooplankton which increases linearly from 0 to 1 for ratio between 0% and 10% and is 1 otherwise. The respiration activity factor (R_a , Table A5) defines reduced macrozooplankton respiration rate in austral/boreal winter with the value of -0.5 .

975 A4.2 Grazing

In REcoM3, there are two zooplankton classes, small zooplankton (< 2cm) and macrozooplankton (2-20 cm). The small zooplankton group grazes on small phytoplankton and diatoms as well as on fast- and slow-sinking detrital particles. While macrozooplankton grazes on similarly both phytoplankton classes and detritus groups, it further grazes on small zooplankton. Total grazing of both zooplankton groups is based on the Holling type III ingestion function as follows:

$$980 \quad G_{\text{tot}}^{\text{zoo}} = \xi_{\text{zoo}} \cdot \frac{(\sum_i p_i \cdot N_i)^2}{\sigma_{\text{zoo}} + (\sum_i p_i \cdot N_i)^2} \cdot f_T \cdot \text{ZooN} \quad (\text{A62})$$

$G_{\text{tot}}^{\text{zoo}}$ ($G_{\text{tot}}^{\text{zoo2}}$) is the total grazing flux which is calculated for small (macro) zooplankton. ZooN (Zoo2N) is listed in Table A1. The maximum grazing rate (ξ_{zoo} , ξ_{zoo2}) and the half saturation constants (σ_{zoo} , σ_{zoo2}) are listed in Table A10. The temperature dependency terms (f_T , $f_{T_{\text{zoo2}}}$) are given in Eqs. A43 and A44. In the model, relative grazing preferences are implemented following Fasham et al. (1990). Variable relative grazing preferences (p_i) are calculated using the nominal preferences for small phytoplankton, diatoms, slow-/fast-sinking detritus and small zooplankton (Table A10) as follows:

$$985 \quad p_i = \frac{p'_i \cdot N_i}{\sum_i p'_i \cdot N_i} \quad (\text{A63})$$

Here, summation i is done over each food source to calculate the relative proportion of the food. Total grazing is used to calculate the grazing of zooplankton groups on individual food source, i.e., small phytoplankton ($i=1$, $\text{PhyN}_{\text{small}}$), diatoms ($i=2$, PhyN_{dia}), both detritus classes ($i=3$, DetN and $i=4$, DetZ2N) and ($i=5$, ZooN) in the case of macrozooplankton as the ratio of each food source to total food source (G_{small} , G_{dia} , G_{det} , G_{detZ2} and G_{zoo}).

$$990 \quad G_{\text{small}}^{\text{zoo}} = G_{\text{tot}}^{\text{zoo}} \cdot \frac{p_{\text{small}} \cdot \text{PhyN}_{\text{small}}}{\sum_i p_i \cdot N_i}, \quad G_{\text{small}}^{\text{zoo2}} = G_{\text{tot}}^{\text{zoo2}} \cdot \frac{p_{\text{small}} \cdot \text{PhyN}_{\text{small}}}{\sum_i p_i \cdot N_i} \quad (\text{A64})$$

$$G_{\text{dia}}^{\text{zoo}} = G_{\text{tot}}^{\text{zoo}} \cdot \frac{p_{\text{dia}} \cdot \text{PhyN}_{\text{dia}}}{\sum_i p_i \cdot N_i}, \quad G_{\text{dia}}^{\text{zoo2}} = G_{\text{tot}}^{\text{zoo2}} \cdot \frac{p_{\text{dia}} \cdot \text{PhyN}_{\text{dia}}}{\sum_i p_i \cdot N_i} \quad (\text{A65})$$

$$995 \quad G_{\text{det}}^{\text{zoo}} = G_{\text{tot}}^{\text{zoo}} \cdot \frac{p_{\text{det}} \cdot \text{DetN}}{\sum_i p_i \cdot N_i}, \quad G_{\text{det}}^{\text{zoo2}} = G_{\text{tot}}^{\text{zoo2}} \cdot \frac{p_{\text{det}} \cdot \text{DetN}}{\sum_i p_i \cdot N_i} \quad (\text{A66})$$

$$G_{\text{detZ2}}^{\text{zoo}} = G_{\text{tot}}^{\text{zoo}} \cdot \frac{p_{\text{detZ2}} \cdot \text{DetZ2N}}{\sum_i p_i \cdot N_i}, \quad G_{\text{detZ2}}^{\text{zoo2}} = G_{\text{tot}}^{\text{zoo2}} \cdot \frac{p_{\text{detZ2}} \cdot \text{DetZ2N}}{\sum_i p_i \cdot N_i} \quad (\text{A67})$$

$$G_{\text{zoo}} = G_{\text{tot}}^{\text{zoo2}} \cdot \frac{p_{\text{ZooN}} \cdot \text{ZooN}}{\sum_i p_i \cdot N_i} \quad (\text{A68})$$

where G_{zoo} is associated with macrozooplankton grazing on small zooplankton. $\text{PhyN}_{\text{small}}$, PhyN_{dia} , ZooN , DetN and DetZ2N are listed in Table A1.

A5 Bottom boundary fluxes

The model contains a benthic layer at the sea floor. Within this benthic layer, the total amounts of organic carbon, organic nitrogen, biogenic silica and CaCO₃ are modeled.

Loss to benthos: When the slow- and fast-sinking detritus reach the ocean bottom, they continue to sink into the benthic layer with the speed w_{det} (Eq. A39) and $w_{\text{detZ2}} = 200 \text{ m d}^{-1}$, respectively. This results in a detrital flux ($\text{BenF}_{\text{DetN}}$, $\text{BenF}_{\text{DetZ2N}}$, $\text{BenF}_{\text{DetC}}$, $\text{BenF}_{\text{DetZ2C}}$, $\text{BenF}_{\text{DetSi}}$, $\text{BenF}_{\text{DetZ2Si}}$, $\text{BenF}_{\text{DetCalc}}$ and $\text{BenF}_{\text{DetZ2Calc}}$, Table A11) from the water column to the benthos.

$$\text{BenF}_{\text{DetN}} = -w_{\text{det}} \cdot \text{DetN} \quad (\text{A69})$$

$$\text{BenF}_{\text{DetC}} = -w_{\text{det}} \cdot \text{DetC} \quad (\text{A70})$$

$$1010 \quad \text{BenF}_{\text{DetSi}} = -w_{\text{det}} \cdot \text{DetSi} \quad (\text{A71})$$

$$\text{BenF}_{\text{DetCalc}} = -w_{\text{det}} \cdot \text{DetCalc} \quad (\text{A72})$$

$$\text{BenF}_{\text{DetZ2N}} = -w_{\text{detZ2}} \cdot \text{DetZ2N} \quad (\text{A73})$$

$$\text{BenF}_{\text{DetZ2C}} = -w_{\text{detZ2}} \cdot \text{DetZ2C} \quad (\text{A74})$$

$$\text{BenF}_{\text{DetZ2Si}} = -w_{\text{detZ2}} \cdot \text{DetZ2Si} \quad (\text{A75})$$

$$1015 \quad \text{BenF}_{\text{DetZ2Calc}} = -w_{\text{detZ2}} \cdot \text{DetZ2Calc} \quad (\text{A76})$$

These fluxes increase the total amount of the different benthic state variables. The state variables DetN, DetC, DetSi, DetCalc, DetZ2N, DetZ2C, DetZ2Si and DetZ2Calc are described in Table A1.

Input from benthos: The lowermost ocean layer located next to the benthic layer receives remineralized inorganic matter back from the benthos. These fluxes, at the same time reduce the amount of the benthic variables. In addition, a sediment flux of Fe from the sediment is calculated from the nitrogen flux, but assuming a Fe:N ratio that is higher than in biomass. This parameterization models that the release of iron from the sediment is driven by redox processes, which are ultimately tied to their remineralization of organic matter.

$$\text{BenF}_{\text{DIN}} = \rho_{\text{ben}}^{\text{N}} \cdot \text{BenthosN} \quad (\text{A77})$$

$$\text{BenF}_{\text{DSi}} = \rho_{\text{ben}}^{\text{Si}} \cdot \text{BenthosSi} \quad (\text{A78})$$

$$1025 \quad \text{BenF}_{\text{DIC}} = \rho_{\text{ben}}^{\text{C}} \cdot \text{BenthosC} + \text{Diss}_{\text{calc}} \cdot \text{BenthosCalc} + \text{Diss}_{\text{calc}2} \cdot \text{BenthosCalc}2 \quad (\text{A79})$$

$$\text{BenF}_{\text{Alk}} = (1 + 1/16) \cdot \rho_{\text{ben}}^{\text{N}} \cdot \text{BenthosN} + 2 \cdot \text{Diss}_{\text{calc}} \cdot \text{BenthosCalc} \quad (\text{A80})$$

BenF_{DIN} , BenF_{DSi} , BenF_{DIC} and BenF_{Alk} (Table A11) denote the fluxes of DIN, DSi, DIC and Alk returned into the bottom layer of the ocean. Constant remineralization rates ($\rho_{\text{ben}}^{\text{N}}$, $\rho_{\text{ben}}^{\text{Si}}$ and $\rho_{\text{ben}}^{\text{C}}$) are listed in Table A8. The calcite dissolution rates $\text{Diss}_{\text{calc}}$ and $\text{Diss}_{\text{calc}2}$ are calculated in Eq. (A38). BenthosN, BenthosSi, BenthosC and BenthosCalc denote the vertically integrated benthos concentration of dissolved nitrogen, silicate, carbon and calcium carbonate, respectively (Table A2). The

1030

alkalinity of the lowermost ocean layer located next to the benthic layer is changed by the remineralization of DIN, dissolved inorganic phosphate converted from DIN with Redfield ratio) and dissolution of calcite from the benthos.

Table A1. List of oceanic state variables in REcoM3.

Variable	Description	Unit
DIN	Dissolved Inorganic Nitrogen	[mmol N m ⁻³]
DSi	Dissolved Inorganic Silicon	[mmol Si m ⁻³]
DFe	Dissolved Inorganic Iron	[μmol Fe m ⁻³]
DIC	Dissolved Inorganic Carbon	[mmol C m ⁻³]
Alk	Alkalinity	[mmol C m ⁻³]
PhyN _{small}	Intracellular nitrogen concentration in small phytoplankton	[mmol N m ⁻³]
PhyC _{small}	Intracellular carbon concentration in small phytoplankton	[mmol C m ⁻³]
PhyCalc	Intracellular calcite concentration in small phytoplankton	[mmol CaCO ₃ m ⁻³]
PhyChl _{small}	Intracellular chl <i>a</i> concentration in small phytoplankton	[mg Chl m ⁻³]
PhyN _{dia}	Intracellular nitrogen concentration in diatoms	[mmol N m ⁻³]
PhyC _{dia}	Intracellular carbon concentration in diatoms	[mmol C m ⁻³]
PhySi _{dia}	Intracellular silicon concentration in diatoms	[mmol Si m ⁻³]
PhyChl _{dia}	Intracellular chl <i>a</i> concentration in diatoms	[mg Chl m ⁻³]
ZooN	small zooplankton nitrogen concentration	[mmol N m ⁻³]
Zoo2N	Macrozooplankton nitrogen concentration	[mmol N m ⁻³]
ZooC	small zooplankton carbon concentration	[mmol C m ⁻³]
Zoo2C	Macrozooplankton carbon concentration	[mmol C m ⁻³]
DetN	Slow-sinking detritus nitrogen concentration	[mmol N m ⁻³]
DetZ2N	Fast-sinking detritus nitrogen concentration	[mmol N m ⁻³]
DetC	Slow-sinking detritus carbon concentration	[mmol C m ⁻³]
DetZ2C	Fast-sinking detritus carbon concentration	[mmol C m ⁻³]
DetCalc	Slow-sinking detritus calcite concentration	[mmol CaCO ₃ m ⁻³]
DetZ2Calc	Fast-sinking detritus calcite concentration	[mmol CaCO ₃ m ⁻³]
DetSi	Slow-sinking detritus silicon concentration	[mmol Si m ⁻³]
DetZ2Si	Fast-sinking detritus silicon concentration	[mmol Si m ⁻³]
DON	Extracellular dissolved organic nitrogen	[mmol N m ⁻³]
DOC	Extracellular dissolved organic carbon	[mmol C m ⁻³]
Oxy	Dissolved oxygen concentration	[mmol O m ⁻³]

Table A2. List of benthic state variables in REcoM3.

Variable	Description	Unit
BenthosN	Vertically integrated N concentration	[mmol N m ⁻²]
BenthosC	Vertically integrated C concentration	[mmol C m ⁻²]
BenthosSi	Vertically integrated Si concentration	[mmol Si m ⁻²]
BenthosCalc	Vertically integrated calcite concentration	[mmol CaCO ₃ m ⁻²]

Table A3. Parameters for sources-minus-sinks equations.

Parameter	Value	Description	Unit
ψ	0.02	Calcite production ratio	[dimensionless]
γ_{zoo}	0.4	Fraction of grazing flux to small zooplankton pool	[dimensionless]
γ_{zoo2}	0.8	Fraction of grazing flux to macrozooplankton pool	[dimensionless]
m_{zoo}	0.05	Small zooplankton mortality rate	[m ³ mmol N ⁻¹ d ⁻¹]
m_{zoo2}	0.003	Macrozooplankton mortality rate	[m ³ mmol N ⁻¹ d ⁻¹]
ϕ_{phy}	0.015	Max aggregation loss parameter for phytoplankton N	[m ³ mmol N ⁻¹ d ⁻¹]
ϕ_{det}	0.165	Max aggregation loss parameter for detritus N	[m ³ mmol N ⁻¹ d ⁻¹]
w_0	20.0	Detritus sinking speed at surface	[m d ⁻¹]
f_n	0.104	N fecal pellet production rate constant	[m ³ mmol N ⁻¹ d ⁻¹]
f_c	0.236	C fecal pellet production rate constant	[m ³ mmol C ⁻¹ d ⁻¹]

Table A4. Parameters for iron calculations.

Parameter	Value	Description	Unit
$q^{\text{Fe:N}}$	0.033	Intracellular Fe : N ratio	[$\mu\text{mol Fe mmol N}^{-1}$]
K_{FeL}	100.0	Iron stability constant	[m ⁻³ μmol]
L_T	1.0	Total ligand concentration	[$\mu\text{mol m}^{-3}$]
κ_{Fe}	0.07	Scavenging rate of iron	[m ³ mmol C ⁻¹ d ⁻¹]
$q^{\text{Fe:N}}$	0.033	Intracellular Fe : N ratio	[$\mu\text{mol Fe mmol N}^{-1}$]

Table A5. Model variables.

Variable	Description	Unit
Agg	Aggregation rate constant [d^{-1}]	
Dis_{calc}	The dissolution rate constant for slow-sinking detritus	$[d^{-1}]$
Dis_{calc2}	The dissolution rate constant for fast-sinking detritus	$[d^{-1}]$
Dis_{calc_guts}	Dissolution of calcium carbonate in guts constant	$[d^{-1}]$
w_{det}	Sinking velocity of detritus	$[m\ d^{-1}]$
f_T	Temperature dependence of rates	[dimensionless]
f_{Tzoo2}	Temperature dependence of macrozooplankton grazing rates	[dimensionless]
G_{tot}	Total zooplankton grazing rate	$[mmol\ N\ m^{-3}\ d^{-1}]$
G_{small}	Small phytoplankton specific zooplankton grazing rate	$[mmol\ N\ m^{-3}\ d^{-1}]$
G_{dia}	Diatom specific zooplankton grazing rate	$[mmol\ N\ m^{-3}\ d^{-1}]$
PAR	Photosynthetically Available Radiation	$[W\ m^{-2}]$
P_{small}, P_{dia}	C-specific actual rate constant of photosynthesis [d^{-1}]	
P_{max}	C-specific light saturated rate constant of photosynthesis	$[d^{-1}]$
r_{small}	Small phytoplankton respiration rate constant	$[d^{-1}]$
r_{dia}	Diatoms respiration rate constant	$[d^{-1}]$
r_{zoo}	small zooplankton respiration rate constant	$[d^{-1}]$
r_{zoo2}	Macrozooplankton respiration rate constant	$[d^{-1}]$
R_f	Macrozooplankton feeding activity factor	$[d^{-1}]$
R_a	Macrozooplankton respiration activity factor	$[d^{-1}]$
$S_{small}^{chl}, S_{dia}^{chl}$	Rate of chlorophyll <i>a</i> synthesis	$[mg\ Chl\ mmol\ C^{-1}\ d^{-1}]$
T	Local temperature	[K]
V_{small}^N, V_{dia}^N	N-assimilation	$[mmol\ N\ mmol\ C^{-1}\ d^{-1}]$
ρ_{Si}^T	Temperature dependent remineralization rate constant of Si	$[d^{-1}]$
V^{Si}	Si-assimilation	$[mmol\ Si\ mmol\ C^{-1}\ d^{-1}]$

Table A6. Parameters for limitation functions.

Parameter	Value	Description	Unit
$K_{\text{small}}^{\text{Fe}}$	0.04	Half saturation constant for small phytoplankton Fe uptake	$[\mu\text{mol Fe m}^{-3}]$
$K_{\text{dia}}^{\text{Fe}}$	0.12	Half saturation constant for diatom Fe uptake	$[\mu\text{mol Fe m}^{-3}]$
$q_{\text{small}}^{\text{N:Cmin}}$	0.04	Minimum intracellular N : C ratio for small phytoplankton	$[\text{mmol N mmol C}^{-1}]$
$q_{\text{dia}}^{\text{N:Cmin}}$	0.04	Minimum intracellular N : C ratio for diatoms	$[\text{mmol N mmol C}^{-1}]$
$q_{\text{small}}^{\text{N:Cmax}}$	0.2	Maximum intracellular N : C ratio for small phytoplankton	$[\text{mmol N mmol C}^{-1}]$
$q_{\text{dia}}^{\text{N:Cmax}}$	0.2	Maximum intracellular N : C ratio for diatoms	$[\text{mmol N mmol C}^{-1}]$
$q_{\text{dia}}^{\text{Si:Cmin}}$	0.04	Minimum intracellular Si : C ratio for diatoms	$[\text{mmol Si mmol C}^{-1}]$
$q_{\text{dia}}^{\text{Si:Cmax}}$	0.8	Maximum intracellular Si : C ratio for diatoms	$[\text{mmol Si mmol C}^{-1}]$
$\theta_{\text{min}}^{\text{N}}$	50	Minimum limiter regulator for N	$[\text{mmol C mmol N}^{-1}]$
$\theta_{\text{max}}^{\text{N}}$	1000	Maximum limiter regulator for N	$[\text{mmol C mmol N}^{-1}]$
$\theta_{\text{min}}^{\text{Si}}$	1000	Minimum limiter regulator for Si	$[\text{mmol C mmol N}^{-1}]$
$\theta_{\text{max}}^{\text{Si}}$	1000	Maximum limiter regulator for Si	$[\text{mmol C mmol N}^{-1}]$
T_{ref}	288.15	Reference temperature for Arrhenius function	[K]

Table A7. Parameters for phytoplankton processes.

Parameter	Value	Description	Unit
α_{small}	0.14	Light harvesting efficiency for small phytoplankton	$[\text{mmol C m}^2 (\text{mg Chl W d})^{-1}]$
α_{dia}	0.19	Light harvesting efficiency for diatoms	$[\text{mmol C m}^2 (\text{mg Chl W d})^{-1}]$
$\mu_{\text{C,small}}^{\text{max}}$	3.0	Rate constant of C-specific photosynthesis	$[\text{d}^{-1}]$
$\mu_{\text{C,dia}}^{\text{max}}$	3.5	Rate constant of C-specific photosynthesis	$[\text{d}^{-1}]$
$\text{reS}_{\text{small}}$	0.01	Maintenance respiration rate constant	$[\text{d}^{-1}]$
reS_{dia}	0.01	Maintenance respiration rate constant	$[\text{d}^{-1}]$
ζ	2.33	Cost of biosynthesis of N	$[\text{mmol C mmol N}^{-1}]$
$q_{\text{max,small}}^{\text{Chl:N}}$	3.15	Maximum Chl:N ratio for phytoplankton	$[\text{mg Chl mmol N}^{-1}]$
$q_{\text{max,dia}}^{\text{Chl:N}}$	4.2	Maximum Chl:N ratio for phytoplankton	$[\text{mg Chl mmol N}^{-1}]$
$K_{\text{small}}^{\text{N}}$	0.55	Half saturation constant for small phytoplankton N uptake	$[\text{mmol N m}^{-3}]$
$K_{\text{dia}}^{\text{N}}$	1.00	Half saturation constant for diatom N uptake	$[\text{mmol N m}^{-3}]$
$V_{\text{cm}}^{\text{small}}$	0.7	scaling factor for C-specific N-uptake for small phytoplankton	[dimensionless]
$V_{\text{cm}}^{\text{dia}}$	0.7	scaling factor for C-specific N-uptake for diatoms	[dimensionless]
$\sigma_{\text{N:C}}^{\text{small}}$	0.2	Maximum uptake ratio N : C for small phytoplankton	$[\text{mmol N mmol C}^{-1}]$
$\sigma_{\text{N:C}}^{\text{dia}}$	0.2	Maximum uptake ratio N : C for diatoms	$[\text{mmol N mmol C}^{-1}]$
K_{Si}	4.00	Half saturation constant for diatom Si uptake	$[\text{mmol Si m}^{-3}]$
$\sigma_{\text{Si:C}}$	0.2	Maximum uptake ratio Si : C	$[\text{mmol Si mmol C}^{-1}]$

Table A8. Degradation parameters for sources-minus-sinks equations.

Parameter	Value	Description	Unit
$\epsilon_{\text{phy}}^{\text{N}}$	0.05	Small phytoplankton excretion constant of organic N	$[\text{d}^{-1}]$
$\epsilon_{\text{dia}}^{\text{N}}$	0.05	Diatoms excretion constant of organic N	$[\text{d}^{-1}]$
$\epsilon_{\text{phy}}^{\text{C}}$	0.1	Small phytoplankton excretion constant of organic C	$[\text{d}^{-1}]$
$\epsilon_{\text{dia}}^{\text{C}}$	0.1	Diatoms excretion constant of organic C	$[\text{d}^{-1}]$
$\epsilon_{\text{zoo}}^{\text{N}}$	0.15	small zooplankton excretion constant of organic N	$[\text{d}^{-1}]$
$\epsilon_{\text{zoo}2}^{\text{N}}$	0.02	Macrozooplankton excretion constant of organic N	$[\text{d}^{-1}]$
$\epsilon_{\text{zoo}}^{\text{C}}$	0.15	small zooplankton excretion constant of organic C	$[\text{d}^{-1}]$
$\epsilon_{\text{zoo}2}^{\text{C}}$	0.02	Macrozooplankton excretion constant of organic C	$[\text{d}^{-1}]$

$\text{Diss}_{\text{calc_rate}}$	0.005714	Dissolution of calcium carbonate constant	$[\text{d}^{-1}]$

Table A9. Parameters for macrozooplankton grazing.

Parameter	Value	Description	Unit
Q_a	28145	Temperatures for the uninhibited reaction kinetics	$[\text{°K}]$
Q_h	105234	Temperatures for the inhibited reaction kinetics	$[\text{°K}]$
T_r	272.5	Intrinsic optimum temperature	$[\text{°K}]$
T_h	274.5	Temperature above which inhibitive processes dominate	$[\text{°K}]$

Table A10. Parameters for zooplankton processes.

Parameter	Value	Description	Unit
ξ_{zoo}	2.4	Maximum grazing rate constant, small zooplankton	$[d^{-1}]$
ξ_{zoo2}	0.1	Maximum grazing rate constant, macrozooplankton	$[d^{-1}]$
σ_{zoo}	0.35	Half saturation constant, small zooplankton	$[(\text{mmol N m}^{-3})^2]$
σ_{zoo2}	0.0144	Half saturation constant, macrozooplankton	$[(\text{mmol N m}^{-3})^2]$
τ	0.01	Time scale constant for zooplankton respiration	$[d^{-1}]$
R_s	0.0107	Standard respiration rate constant	$[d^{-1}]$
small zooplankton			
p'_{small}	1.0	Initial grazing preference for small phytoplankton	[dimensionless]
p'_{dia}	0.5	Initial grazing preference for diatoms	[dimensionless]
p'_{det}	0.5	Initial grazing preference for slow-sinking detritus	[dimensionless]
p'_{detZ2}	0.5	Initial grazing preference for fast-sinking detritus	[dimensionless]
Macrozooplankton			
p'_{small}	0.5	Initial grazing preference for small phytoplankton	[dimensionless]
p'_{dia}	1.0	Initial grazing preference for diatoms	[dimensionless]
p'_{zoo}	0.8	Initial grazing preference for zooplankton	[dimensionless]
p'_{det}	0.5	Initial grazing preference for slow-sinking detritus	[dimensionless]
p'_{detZ2}	0.5	Initial grazing preference for fast-sinking detritus	[dimensionless]

Table A11. Benthos variables.

Variable	Description	Unit
BenF _{Alk}	Flux of alkalinity from benthos to bottom water	$[\text{mmol m}^{-2} \text{d}^{-1}]$
BenF _{DIC}	Flux of C from benthos to bottom water	$[\text{mmol C m}^{-2} \text{d}^{-1}]$
BenF _{DIN}	Flux of N from benthos to bottom water	$[\text{mmol N m}^{-2} \text{d}^{-1}]$
BenF _{DSi}	Flux of Si from benthos to bottom water	$[\text{mmol Si m}^{-2} \text{d}^{-1}]$
BenF _{DetCalc}	Flux of slow-sinking detritus calcite from the water to the benthos	$[\text{mmol CaCO}_3 \text{ m}^{-2} \text{d}^{-1}]$
BenF _{DetC}	Flux of slow-sinking detritus C from the water to the benthos	$[\text{mmol C m}^{-2} \text{d}^{-1}]$
BenF _{DetN}	Flux of slow-sinking detritus N from the water to the benthos	$[\text{mmol N m}^{-2} \text{d}^{-1}]$
BenF _{DetSi}	Flux of slow-sinking detritus Si from the water to the benthos	$[\text{mmol Si m}^{-2} \text{d}^{-1}]$
BenF _{DetZ2Calc}	Flux of fast-sinking detritus calcite from the water to the benthos	$[\text{mmol CaCO}_3 \text{ m}^{-2} \text{d}^{-1}]$
BenF _{DetZ2C}	Flux of fast-sinking detritus C from the water to the benthos	$[\text{mmol C m}^{-2} \text{d}^{-1}]$
BenF _{DetZ2N}	Flux of fast-sinking detritus N from the water to the benthos	$[\text{mmol N m}^{-2} \text{d}^{-1}]$
BenF _{DetZ2Si}	Flux of fast-sinking detritus Si from the water to the benthos	$[\text{mmol Si m}^{-2} \text{d}^{-1}]$
