23 Abstract

24 The advanced snow data assimilation is developed in this study with satellite remote-
25 sensing retrievals of snow water equivalent(SWE) and snow cover fraction(SCF) utilizing the
26 local ensemble transform Kalman filter based on the Joint U.K. Land Environment
27 Simulator(JULES) land model. The system assimilates SWE from the Advanced Microwave
28 Scanning Radiometer 2(AMSR2) and SCF from the Interactive Multisensor Snow and Ice
29 Mapping System(IMS) during April 2013-2020. The performance is evaluated by the
30 validations with independent data assimilation products derived from in-situ observation.

31 The baseline model simulation from JULES without satellite data assimilation shows a
32 superior performance in high-latitude regions with heavy snow accumulation, but relatively
33 inferior in the transition regions with less snow and high spatial and temporal variation.
34 Contrastingly, the AMSR2 satellite data exhibit a superior performance in the transition regions,
35 but poor performance in the high latitudes, presumably due to the limitation in the penetrating
36 depth of satellite retrieval. The data assimilation(DA) that combines AMSR2 and IMS satellite
37 data with the JULES model backgrounds demonstrates the positive impacts by reducing
38 uncertainty in both satellite-derived snow data in penetrating deep snow and the model
39 simulations in the transition regions. While DA shows superior performance in most regions,
40 it specifically improves the analysis in the mid-latitude transition regions where the model
41 background errors from the ensemble runs are significantly larger than the observation errors,
42 emphasizing the substantial influence of satellite information. The long-term analysis of snow
43 manifests a pronounced variability in the continental interior at the interannual timescales,
44 which implies large uncertainty in the snow initialization for the sub-seasonal to seasonal
45 predictions of the climate models, potentially degrading prediction skills without satellite snow
46 data assimilation.

47

48 1. Introduction

49 Snow plays a crucial role in regulating the water, energy, and carbon exchange between the
50 land surface and atmosphere(e.g., Dutra et al., 2011; Thomas et al., 2016). A snowpack tends
51 to increase surface albedo and soil moisture as the snow melts. It has an impact on the climate
52 system with the water balance by the soil moisture change and the energy balance by albedo
53 variations. In addition to local impacts, the continental snowpack over Eurasia can influence
54 the large scale circulation during winter(e.g., Li and Wang, 2014) or in spring(e.g., Broxton et
55 al., 2017). Especillaly, the Eurasian autumn snow can affect upward-propagating stationary
56 Rossby-wave activity, leading to stratospheric warming and weakening of stratospheric polar
57 vortex and jet stream, which in turn emerges as a negative Arctic oscillation(AO)-like pattern
58 at the surface during winter due to downward propagation through the troposphere. Its impact
59 is shown in both observation and model experiments(e.g., Allen and Zender 2011; Cohen et al.
60 2007). Therefore, the snow initialization process in climate models is closely related to the
61 improvement of prediction performance.

62 In the short and medium forecasts, snow is simply prescribed based on
63 climatological values because the forecasts are significantly influenced by the accuracy of the
64 initial atmospheric states in climate models. To extend the accurate prediction to subseasonal
65 to seasonal(S2S) timescales, the atmospheric and the more slowly evolving initial conditions
66 need to be carefully considered. Land initial states such as snow are crucial components in the
67 S2S timescale predictions due to their climatic memory lasting 1-2 months(e.g., Chen et al.,
68 2010). The realistic snow initial states can contribute to improving S2S prediction skills, as
69 proven in several modeling studies(e.g., Orsolini et al., 2013; Li et al., 2019).

70 Snow states are generally provided from in-situ observations data, remote-sensing
71 retrievals from satellites, or numerical models such as the land surface model(LSM) operated
72 based on the observed atmospheric variables. In the case of the in-situ data, the primary source

73 of snow depth(SD) is ~~obtained from~~ surface synoptic observations(SYNOP). These
74 observations are provided almost in real-time through the global telecommunication
75 system(GTS). In addition to SYNOP, there are some regional snow measurement networks.
76 For instance, the snowpack telemetry(SNOTEL) network collects data on SD over 900
77 automated observation points located in the western United States, and the National Oceanic
78 and Atmospheric Administration (NOAA) Cooperative Observer Program gathers SD data in
79 North American region. Nevertheless, data collected from these national networks cannot be
80 utilized in the almost real-time GTS. Directly measured in-situ data provide the most reliable
81 snow information but have relatively coarse temporal and spatial resolutions over the limited
82 area because of spatial heterogeneities of snow(Helmert et al., 2018). **Recently, in order to**
83 **obtain high-resolution and high-quality snow water equivalent(SWE) analysis,** artificial
84 intelligence(AI) such as long short-term memory(LSTM) has been utilized with the given
85 meteorological conditions from SNOTEL observations as input data, but it is still insufficient
86 to cover the entire globe(Meyal et al., 2020).

87 Satellite-derived observations using conical scanning microwave instruments may provide
88 spatially consistent data coverage across the globe. Cho et al.(2017) showed the SWE retrieval
89 results from two passive microwave sensors, the advanced microwave scanning radiometer
90 2(AMSR2) and the special sensor microwave imager sounder(SSMIS). However, the
91 algorithms for SWE retrieval exhibit a degree of sensitivity to a variety of parameters such as
92 snow liquid water content and snow grain size distribution(De Rosnay et al., 2014). Hence,
93 satellite-based SWE data still have limitations in accuracy, especially under deep snow
94 conditions due to the **restrictions in** penetration depth(Gan et al., 2021). On the other hand,
95 satellite retrieval can estimate snow cover accurately under clear sky conditions (Brubaker et
96 al., 2009). The moderate resolution imaging spectroradiometer(MODIS) instrument observes
97 daily snow cover, while a multi-satellite-based interactive multi-sensor snow and ice mapping

98 system(IMS) provided by the United States National Snow and Ice Data Center produces the
99 snow cover by combining in-situ observations and satellite data from microwave, infrared, and
100 visible sensors.

101 **Model simulations** can cover complete spatiotemporal resolution but involve potentially
102 large uncertainties due to the deficiencies in the physical parameterizations and meteorological
103 forcing data(Dirmeyer et al., 2006; Seo et al., 2020). To reduce the uncertainties from model
104 simulations, previous studies have used satellite-based snow cover and in-situ observation such
105 as SYNOP SD available on the GTS, in conjunction with the model simulation(e.g., Brasnett,
106 1999; Dee et al., 2011; Meng et al., 2012; Pullen et al., 2011; De Rosnay et al., 2014). **For**
107 **example, the snow analysis for the Canadian Meteorological Center(CMC) utilizes a 2-**
108 **dimensional optimal interpolation(2D-OI) scheme with in-situ observations and the outputs**
109 **from a simple snow model(Brown et al., 2003). The National Centers for Environmental**
110 **Prediction (NCEP) climate forecast system reanalysis(CFSR) combines the IMS as satellite-**
111 **based snow cover retrieval and the outputs from the global SD model of the Air Force Weather**
112 **Agency(Meng et al., 2012). At the European Center for Medium Weather Forecast (ECMWF),**
113 **the ECMWF reanalysis (ERA)-Interim and ERA5 for the snow analysis employ a Cressman**
114 **interpolation and 2D-OI, respectively, with the IMS, in-situ observation, and the results from**
115 **a land surface model(Dee et al. 2011; De Rosnay et al., 2014). The Japanese 55-year**
116 **Reanalysis(JRA55) also utilizes the 2D-OI with in-situ observation, satellite-based snow cover**
117 **from SSMIS, and the results from an LSM(Kobayashi et al., 2015).**

118 The most commonly employed approach to obtain reasonable estimates of land initial states
119 for predictions is running atmospheric general circulation models(AGCMs; Pullen et al., 2011)
120 or offline mode of LSMs with observed atmospheric conditions(Dirmeyer et al., 2006). Climate
121 prediction systems in operational centers such as the Meteorological Office(Met Office) (~~Met~~
122 ~~Office~~) in the United Kingdom and the Korean Meteorological Administration(KMA) conduct

123 the snow initialization by utilizing the results of the operational global unified model(UM) and
124 the IMS snow cover(Pullen et al., 2011). The initialization at NCEP also performs a similar
125 approach using input data combined from IMS snow cover and results from the global SD
126 model(SNODEP; Meng et al., 2012). Furthermore, the snow initialization of ECMWF employs
127 optimal interpolation with a combination of results from the LSM, IMS snow cover, and in-
128 situ observation from SYNOP and national networks available on the GTS. However, in areas
129 where ground observations are not available, the results of the snow model are relied upon,
130 **which still exists significant uncertainty in snow accumulation** because of uncertainties in the
131 atmospheric forcing and **imperfect model parameterizations**(Boone et al., 2004; Essery et al.,
132 2009). It would be useful to to accurately initialize the snow amount including vertical depth,
133 which is more important in estimating energy and water budgets, by using the satellite-derived
134 snow amounts with **comparatively uniform spatial and temporal resolution**.

135 However, the SWE retrievals from satellites still have considerable uncertainties(De
136 Lannoy et al., 2010; Dawson et al., 2018), which can arise from vegetation and terrain
137 interference, sensor signal saturation, snowfall amount, and simplifications in the underlying
138 assumptions of the retrieval algorithms(Liu et al., 2015). In particular, a region with heavy
139 snow accumulation leads to a significant underestimation of SWE due to the limitations in
140 penetration depth from satellites(Gan et al., 2021). For this reason, satellite-derived SWE is not
141 employed in the land initialization process. Nevertheless, the SWE retrieval shows important
142 advantages such as high performance in shallow snow areas with temporal and spatial
143 homogeneity(Gan et al., 2021). In previous studies, various approaches have been attempted
144 to improve SWE product performance, such as combining satellite-derived SWE with ground
145 observations(Pulliainen et al., 2020), different satellite data sets(Gan et al., 2021), simple snow
146 models(Dziubanski and Franz, 2016), or LSMs(Kwon et al., 2017). For instance, Kumar et
147 al.(2019) show the improvement of the SD estimation over the contiguous United States by

148 assimilating satellite snow SD into the Noah LSM, indicating that these model-based products
149 are generally superior to stand-alone satellite-based SWE retrievals. Thus, a globally advanced
150 snow initialization such as data assimilation using satellite snow amount is ideal for providing
151 realistic snow initial states related to S2S prediction skills.

152 Therefore, the purpose of this study is to develop an advanced snow assimilation system
153 utilizing the Local Ensemble Transform Kalman Filter(LETKF) with satellite-derived
154 observations of SWE, IMS snow cover, as well as the Joint U.K. Land Environment
155 Simulator(JULES). In this context, our focus is on SWE rather than SD, because the former
156 can be used directly for hydrological analysis and initial states of the model(Gan et al., 2021).
157 From this novel assimilation system, we endeavor to achieve the following objectives. The
158 primary aim is to assess the enhancement in SWE performance through the assimilation with
159 satellite remote sensing data. The satellite data show high performance in the transition regions
160 with climatologically shallow conditions, termed by Koster et al.(2004) as “hot spots” of
161 atmosphere-land coupling. The second goal is to reveal the reason for skill improvement with
162 the snow data assimilation, based on the Kalman gain analysis that measures the ratio of the
163 model errors with respect to the observation errors. From these perspectives, it would be
164 possible to know how much the satellite has affected the transition regions, and how the
165 assimilation system deals with the regions of deep snow accumulation where the satellite has
166 difficulty in accurate retrieval. The final goal is to evaluate the advantages of assimilating
167 satellite retrievals in extreme high-temperature events, specifically over Eurasia in April 2020.
168 In this regard, we expect that the data assimilation of satellite-derived snow information can be
169 an alternative to produce optimal snow initial states for improving the S2S prediction skill in
170 the climate models.

171

172 2. Data and model

173 **2.1. Satellite data**

174 The snow information including snow cover and SWE can be derived from satellite
175 measurements offering global coverage and high temporal as well as spatial resolution. For
176 data assimilation, this study uses SWE calculated from brightness temperature measurements
177 obtained by the AMSR2 on board the Japanese Aerospace Exploration Agency (JAXA) global
178 change observation mission-water(GCOM-W) satellite. This AMSR2 Unified Level-3(L3)
179 dataset offers daily estimation of SWE at 25 km resolutions from July 2012 to the present.
180 AMSR2 has a sensor designed to detect microwave radiation naturally emitted from the surface
181 and atmosphere, employing six frequency bands ranging from 6.9 to 89 GHz. Through this
182 conical scanning mechanism, AMSR2 can acquire day and night datasets with nearly constant
183 spatial resolution over more than 99% of the global coverage every two days. Comprehensive
184 explanations of AMSR2 characteristics are available in Imaoka et al.(2010). AMSR2 is
185 selected for the assimilation because it produces **more skilled** results by assimilating data from
186 modern sensors(e.g., AMSR2) compared to data from conventional sensors(e.g., AMSR-
187 E)(Cho et al., 2017).

188

189 **2.2. Reference data for SWE and SCF**

190 The CMC daily estimated SWE is used for verification. The SWE data is processed using
191 statistical interpolation between a background field derived from a simple snow model and in-
192 situ daily SD(Brown and Brasnett, 2010). In detail, this dataset utilizes optimal interpolation
193 methods to acquire spatial SD from the in-situ data, involving SYNOP, special aviation reports
194 from the World Meteorological Organization(WMO), and meteorological aviation
195 reports(METAR). In areas with scant in-situ data, a simple snow accumulation and melt model
196 is employed to create an optimal interpolation that estimates snowmelt and snowfall worldwide,
197 assuming the persistence of the snowpack mass between snowfall and melting

198 events(Brasnett, 1999). Although the average elevation of snow measurement stations used in
199 CMC is biased toward low elevations(< 400m), leading to a **potential negative** bias at high
200 elevations, the CMC dataset is often considered the premier snow analysis accessible in the
201 Northern Hemisphere(Su et al. 2010) and has still been widely used to evaluate model
202 outputs(e.g., Reichle et al., 2011; Reichle et al., 2017; Toure et al, 2018). Therefore, the SWE
203 of CMC produced without the satellite-derived data is selected for verification as an
204 independent dataset for evaluating the assimilated analysis with remote sensing snow retrievals.
205 Since only daily SD analysis is provided in CMC, it is converted to daily SWE based on the
206 snow bulk density methods(e.g., Sturm et al., 2010). It is available from 12 March 1998 to the
207 present and offers comprehensive coverage of the entire Northern Hemisphere with a
208 horizontal resolution of 24 km. The SWE of CMC at its native horizontal resolution is
209 interpolated onto the LSM grid through local area averaging.

210 The widely used multisensor-derived snow cover is IMS(e.g., Ramsay 1998; Helfrich et
211 al., 2007) produced by NOAA the National Environmental Satellite Data and Information
212 Service(NESDIS) for the Northern Hemisphere from February 2004 to the present at 4 km
213 resolutions. This dataset is generated using various data products, including multi-satellite
214 images and in-situ observations(U.S. National Ice Center, 2008). Since IMS provides binary(0:
215 no snow or 1: snow covered) snow cover information, we transform the IMS snow cover at 4
216 km grids to the snow cover fraction(SCF) within a 50-km LSM grid by counting the snow pixel
217 number with a value of 1. A 50-km LSM grid is declared as snow-covered when more than 50%
218 of the 4km pixels within the grid are covered with snow. **In this study, the IMS-based SCF is**
219 **employed to mask the SWE, considering the higher reliability of IMS data (e.g., Brown et al.,**
220 **2014).**

221

222 **2.3. JULES LSM**

223 This study utilizes the JULES LSM from the Met Office(Best et al., 2011), a component
224 land model of the global seasonal forecasting system version 6(GloSea6) global, fully-coupled
225 atmosphere, ocean, land, and sea-ice model. The surface types(or snow tiles) in the JULES
226 LSM consist of four non-vegetated types: urban, land-ice, inland water, and bare soil, as well
227 as five vegetation functional types: C3 temperate grass, needleleaf trees, shrubs, C4 tropical
228 grass, and broadleaf trees. For each surface tile, a separate energy balance is computed, and the
229 average energy balance in the grid cells is determined by applying weights to the values of each
230 surface tile. Two schemes are used within JULES to represent surface snow. The simple
231 method involves a zero-layer approach, which modifies the top soil level without using explicit
232 model layers to represent snow processes. **The other is the multi-layer approach which is more**
233 **comprehensive.** In the case of vegetated surfaces, snow can be separated into ground snow and
234 canopy snow or stored in a single effective reservoir. As both the zero-layer and multi-layer
235 snow models provide similar results under various conditions(e.g., Best et al., 2011), this study
236 used the zero-layer snow model with constant thermal conductivity and density for snow.
237 Although the heat capacity of snow is ignored, the bulk thermal conductivity in the surface
238 layer is reduced as the thermal conductivity of snow differs from that of the soil and the layer
239 thickness increases. As long as snow persists on the ground, the skin temperature cannot exceed
240 0°C, yet the heat flux utilized for melting the snow is **diagnosed through the residual surface**
241 **energy balance.** The melted water is immediately drained from the snow, divided into runoff
242 and soil infiltration, and liquid water is not stored or frozen in the snow. A detailed description
243 of the energy and water cycling in the JULES LSM can be referenced in Best et al.(2011).

244 The prognostic variables(e.g., SWE) in the LSM are determined by meteorological forcing
245 variables such as 2-m air temperature, humidity, 10-m wind speed, precipitation, surface
246 pressure, and radiative fluxes. The 3-hourly, JRA55 reanalysis at 0.56° spatial resolution is
247 employed for the meteorological forcing variables, which is linearly interpolated to a 50 km

248 resolution of the LSM. The model background error needed for data assimilation is estimated
249 by JULES ensemble runs with perturbed initial and boundary conditions. Following the
250 previous studies(Reichle et al., 2008; Seo et al., 2021), meteorological forcing variables are
251 perturbed due to randomness, especially precipitation, downward shortwave, and downward
252 longwave. Perturbations are applied using additive adjustments assuming a normal distribution
253 for longwave radiation and multiplicative adjustments following a log-normal distribution for
254 shortwave radiation and precipitation. Here, the ensemble means of additional and
255 multiplicative perturbations are zero and one, respectively. The relationship between disturbed
256 precipitation and radiative flux ensures the physical consistency among atmospheric forcing
257 variables(Reichle et al., 2008). For instance, a negative anomaly in precipitation and downward
258 longwave-radiation is statistically linked to a positive anomaly of downward shortwave-
259 radiation. Detailed explanations regarding the perturbation of atmospheric forcings can be
260 found in Reichle et al.(2008).

261

262 **3. Methodology**

263 **3.1. Bias correction**

264 **The discrepancies in SWE between remote sensing and LSMs are often caused by uncertainties**
265 **in the model physics and meteorological forcing data.** These differences can lead to significant
266 biases in the variance and mean of SWE between model simulations and satellite remote-
267 sensing retrievals, and such biases can result in poor performance. In previous studies(e.g.,
268 Reichle and Koster, 2004; Seo et al., 2021), a scaling method of the nonlinear cumulative
269 distribution function(CDF) matching is used to account for the systematic bias of soil moisture
270 in the model backgrounds. **However, in this study, it is difficult to apply it as the CDF**
271 **distribution of SWE could not be clearly simulated due to the insufficient sample size.** To
272 address this issue, we attempted to apply a simple and effective standard normal deviation
273 scaling to **satellite-derived SWE.** Based on the climatology and standard deviation for the
274 model and remote sensing retrievals, the scaled SWE(O_{new}) from the satellite can be derived
275 from the following relation:

276

$$277 \quad O_{new} = \left(\frac{O - \bar{O}}{\sigma_o} \times \sigma_m \right) + \bar{M} \quad (1)$$

278

279 , where $\bar{O}(\sigma_o)$ and $\bar{M}(\sigma_m)$ indicate climatology(standard deviation) of remote sensing
280 retrievals and the model, respectively. This approach has been widely utilized in observation-
281 based land initialization and has proven to be effective(e.g., Koster et al., 2011; Jeong et al.,
282 2013).

283

284 **3.2. Snow assimilation method**

285 The snow assimilation is conducted based on the LETKF(e.g., Hunt et al., 2007), which is

286 utilized to combine satellite remote-sensing retrievals with the LSM model outputs(a.k.a.
287 backgrounds) to produce a snow analysis. LETKF is a powerful data assimilation method and
288 has several advantages over other methods. First, LETKF can efficiently handle large datasets
289 and high-dimensional state variables by localizing the covariance matrix. This offers efficiency
290 in parallel computing, making it suitable for real-time forecasting and high-resolution data
291 assimilation. Secondly, the method utilizes model simulation ensembles to capture the
292 uncertainty in the initial states and model errors, which allows for a better representation of the
293 true probability distribution of the state variables that vary in time and space. Third, LETKF
294 applies an adaptive inflation scheme, which adjusts the ensemble spread to account for the
295 observational and model errors, ensuring that the uncertainty estimates are realistic and not
296 underestimated nor overestimated. In LETKF, the analysis states(X^a) are obtained by

$$297 \quad X^a = \bar{X}^a + \delta X^a \quad (2)$$

298 , where \bar{X}^a and δX^a are the matrices of analysis ensemble means and perturbations,
299 respectively. They are defined by

$$300 \quad \bar{X}^a = \bar{X}^f + \delta \tilde{x}^a \quad (3)$$

$$301 \quad \delta X^a = \delta X^f [(K - 1)\tilde{P}^a]^{1/2}. \quad (4)$$

302 Here, the analysis ensemble means(\bar{X}^a) is determined by gathering the analysis increment($\delta \tilde{x}^a$)
303 to the model ensemble mean(\bar{X}^f) produced by the JULES land surface model. The analysis
304 ensemble perturbation(δX^a) is computed considering the model perturbation(δX^f), the
305 number of model ensembles(K), and the analysis error covariance(\tilde{P}^a) in the ensemble space.
306 The analysis increment($\delta \tilde{x}^a$) is acquired by considering the difference between the SWE of
307 AMSR2 used as observation and the model ensembles produced by the JULES LSM and
308 determined by

$$309 \quad \delta \tilde{x}^a = \delta X^f \tilde{P}^a \delta Y^T R^{-1} (y^o - \overline{H(X^f)}), \text{ and} \quad (5)$$

310
$$\tilde{P}^a = \left[\frac{(K-1)I}{\rho} + \delta Y^T R^{-1} \delta Y \right]^{-1}. \quad (6)$$

311 It consists of the model ensemble perturbation(δX^f), the analysis error covariance(\tilde{P}^a),
312 observation error covariance(R), model ensemble perturbation in the observation grid(δY), and
313 observation innovation ($y^o - \overline{H(X^f)}$) derived from the difference between the model
314 ensemble in the observation grid($\overline{H(X^f)}$) and the observation(y^o). Here, H represents the
315 observation operator, projecting the modeled snow background onto the satellite observation
316 locations using bilinear interpolation. ρ denotes the covariance inflation factor for the \tilde{P}^a ,
317 aiding in preventing underestimation of the covariance. This study applies multiplication-based
318 20% inflation(ρ) for the ensemble spread derived from 24 member ensembles. Therefore, the
319 final analysis state(X^a) is written as

320
$$X^a = \bar{X}^f + \delta X^f \left[\tilde{P}^a \delta Y^T R^{-1} (y^o - \overline{H(X^f)}) + [(K-1)\tilde{P}^a]^{\frac{1}{2}} \right]. \quad (7)$$

321 This approach involves the weight function($w(d_j)$) for the covariance localization within
322 the local patch centered at the analysis grid(e.g., Houtekamer and Mitchell, 2001; Hamill et al.,
323 2001). This function assigns larger errors to observations located farther away from the center
324 of the local patch, as proposed by Miyoshi and Yamane(2007), depending on the Gaussian
325 function as

326
$$w(d_j) = e^{\frac{-d_j^2}{2\sigma^2}} \quad (8)$$

327 where σ denotes a parameter of the localization length scale and d_j indicates the distance of
328 j -th observed value from the center of each local patch. In this study, the horizontal local patch
329 size and the localization length scale parameters are defined as 150 km and 30 km(Table 1),
330 respectively. Detailed information about the LETKF algorithm and its implementation can be
331 referenced in Hunt et al.(2007) and Shlyayeva et al.(2013).

332

333 3.3. Snow data assimilation design

334 This study conducts the advanced snow data assimilation experiment at a daily cycle based
335 on LETKF with the satellite data and the JULES LSM model outputs driven by 3-hourly JRA55
336 reanalysis atmospheric forcing. The snow assimilation processes are illustrated in Fig. 1, with
337 a more detailed description in Table 1. Since data assimilation is conducted by considering the
338 error of SWE in both the model and the observation, it is important to accurately understand
339 the observation and model errors to improve the performance of data assimilation. The
340 experiment calculates the model error from the 24 ensemble member spreads generated by
341 perturbing atmospheric forcings such as longwave radiation, shortwave radiation, and
342 precipitation in JULES LSM, as provided in section 2.3. The observation error is
343 conservatively prescribed as 10% of AMSR2 SWE for each grid compared to the previous
344 study(Lee et al., 2015), because it usually increases during the snow accumulation period with
345 the developing deep snowpack(Foster et al., 2005; Cho et al., 2017). Here, the bias-corrected
346 AMSR2 satellite data as described in section 3.1 is used as the observation data, and the updated
347 analysis state(X^a) through data assimilation becomes a new initial state for the next integration
348 in JULES LSM(Fig. 1). In addition, the analysis state of this method is calculated based on the
349 IMS snow cover fraction as a reference in the following way(Fig. 1); where the SCF of IMS is
350 zero, the snow amount analysis is set to zero, and in other cases, it is derived from data
351 assimilation. The reason for this is due to the importance of the presence or absence of snow
352 in the climate system, as well as the high reliability of the IMS data. A background experiment
353 of JULES LSM without satellite data assimilation as a baseline(referred to hereafter as
354 “Openloop”) is also achieved by employing the same ensemble perturbations, thereby
355 measuring the skill improvement from the snow analysis state through the assimilation of
356 satellite-derived SWE and IMS SCF from satellite and surface observations(referred to
357 hereafter as “DA”). All experiments are conducted in April from 2013 to 2020, which is one

358 of the months with low snow performance in the LSM when the snow begins to melt in the
359 Northern Hemisphere(e.g., Toure et al., 2018; You et al., 2020).

360 4. Results

361 4.1. Skill Verification

362 Figure 2 displays the climatological-mean SCF from the IMS multi-satellite data (Brown et
363 al., 2014) and the differences from AMSR2, Openloop, JRA55, and DA for April 2013-2020.
364 April is a season when the accumulated snow during the cold season begins to melt. This study
365 defines the transitional region with a climatological-mean SWE of less than 16 mm as in
366 previous studies (e.g., Gan et al., 2021), the boundary of these transition regions is represented
367 by the black lines in Fig. 2. The transitional regions exhibit large variability in space and time,
368 and they are mainly located at mid-latitudes. The SCF climatology patterns show negligible
369 differences in high latitudes of heavy snow accumulation but noticeable differences in the
370 transitional mid-latitude regions of less snow. SCF from JRA55 tends to be underestimated
371 compared to IMS, whereas AMSR2 and Openloop tend to overestimate. There is a clear
372 difference in SCF between AMSR2 and IMS satellite data. **This study gives more credibility**
373 **to IMS than AMSR2, as the former is based on multiple satellite data sources.** As we used the
374 IMS SCF to define the snow region to be assimilated by AMSR2 SWE, it is natural that DA
375 shows better consistency with IMS and reduces overestimation biases in Openloop.
376 Quantitatively, the root mean square differences (**accuracy**) for AMSR2, Openloop, JRA55, and
377 DA with (from) IMS are 0.23(0.91), 0.18(0.91), 0.13(0.93), and 0.13(0.97), respectively,
378 **showing the best consistency in DA.**

379 The SWE climatology from AMSR2, Openloop, JRA55, and DA is also compared with
380 CMC as a reference in Fig. 3. The SWE derived from AMSR2 shows a significant
381 underestimation compared to CMC, particularly in the regions with heavy snow accumulation
382 at high latitudes. This is presumed to be due to limitations in satellite sensors detecting the
383 depth of snow (Gan et al., 2021). On the other hand, the climatological SWEs from Openloop
384 and DA exhibit higher correspondence to CMC, even higher than JRA55. **Specifically, DA**

385 demonstrates a higher agreement with CMC. Quantitatively, the pattern correlation
386 coefficients (root mean square differences) for AMSR2, Openloop, JRA55, and DA with (from)
387 CMC are 0.63(80.7 kg/m²), 0.80(50.1 kg/m²), 0.60(100.8 kg/m²), and 0.80(49.9 kg/m²),
388 respectively. DA with snow data assimilation displays the highest correlation and the smallest
389 root mean square difference among the datasets, indicating the benefit of assimilating the
390 AMSR2 SWE despite the relatively lower performance of the satellite data itself.

391 Next, we compare the temporal variation of SWE as measured by the Spearman rank
392 correlation coefficient with CMC, which is regarded as more appropriate than the Pearson
393 correlation coefficient for describing nonlinear variables such as snow in both time and space.
394 Figure 4 compares the distribution of correlation skills from AMSR2, Openloop, JRA55, and
395 DA. Openloop has a high performance in regions with heavy snow accumulation but relatively
396 low performance in transition regions with significant snow changes. In contrast, the results
397 from the AMSR2 satellite data represent poor performance in high-latitude areas with heavy
398 snow accumulation but high performance in transitional regions, consistent with the previous
399 studies (Gan et al., 2021). DA shows high performance not only in high-latitude areas with
400 heavy snow accumulation but also in transition regions. Even compared to JRA55 used as the
401 atmospheric forcing, DA performs better in temporal variation. The quantitative results in the
402 correlation in the Northern Hemisphere over 40°N (the transition region) are 0.41(0.54) for
403 AMSR2, 0.61(0.48) for Openloop, 0.58(0.58) for JRA55, and 0.67(0.61) for DA, respectively.
404 The findings indicate that satellite retrievals offer additional value in capturing temporal
405 variations through data assimilation.

406 The performance improvement by DA is also evident in the zonally-averaged correlation
407 coefficient shown in Fig. 5. The AMSR2 satellite data shows higher performance than
408 Openloop in the transition region around latitude 45 °N–55 °N, although performance sharply
409 decreases with increasing snow accumulation. Openloop indicates gradually increasing

410 performance as the latitude increases, with the highest performance at around 60°N. DA
411 denotes superior performance across the Northern Hemisphere, especially in the mid-latitude
412 transition region than AMSR2 or JRA55. An exception is for 35-40°N in the Tibetan Plateau,
413 where JRA55 used in-situ observations. The results suggest that the developed snow data
414 assimilation system represents well not only the transitional regions but also the satellite-
415 limited regions with heavy snow.

416 Figure 6 presents the Spearman rank correlation depending on the SWE amount in the
417 Northern Hemisphere. AMSR2 exhibits higher performance than Openloop for SWE up to 16
418 mm. However, the performance of AMSR2 sharply declines beyond that threshold, and
419 Openloop shows a better performance. Consistent with the results illustrated in Figs. 4 and 5,
420 DA demonstrates superior performance compared to others. Note that DA performs
421 significantly better in the transition region of less than 16 mm of SWE. Considering that the
422 area below 16 mm of SWE accounts for approximately 53% of the entire area of the Northern
423 Hemisphere(as shown in the pie chart in Fig. 6), the data assimilation impact is identifiable,
424 and it can contribute substantially to the increase in the prediction skill through improving the
425 simulation of the albedo changes and surface energy balance.

426 This study conducted a further sensitivity test to investigate the influence of incorporating
427 IMS snow cover in snow assimilation. Figure 7 compares the correlation differences between
428 Openloop and the data assimilation result employing both AMSR2 and IMS(DA), as well as
429 the data assimilation result utilizing solely AMSR2 and excluding IMS(hereafter referred to as
430 DA_AMSR2). The results obtained from the snow assimilation show the improvements in the
431 transitional regions where AMSR2 denotes a better agreement with the observations compared
432 to Openloop. Notably, the skill is enhanced significantly in DA by incorporating the IMS SCF.
433 There are exceptional areas where DA performs inferior to Openloop, which are associated
434 with the differences in SCF between IMS and CMC. Moreover, the performance of SWE

435 improves even when only AMSR2 is used, but incorporating IMS leads to a substantial
436 improvement in the transitional regions. This implies that IMS has a positive influence on the
437 snow data assimilation.

438

439

440 **4.2 Kalman gain analysis**

441 In order to better understand the skill enhancement through snow assimilation of satellite
442 data, this section examines the Kalman gain, which represents the weights of the assimilated
443 observations in the analysis update of LETKF. Figure 8 illustrates the spatial distribution of
444 observation error, model background error, and the Kalman gain. A high value of the Kalman
445 gain denotes that the assimilated result is closer to the AMSR2 observation than the model
446 background. The Kalman gain is large when the model error becomes large, or the observation
447 error is small. As this study specifies the observation error as a conservative 10% of SWE
448 compared to the previous study(Lee et al., 2015), the observation error basically follows the
449 distribution similar to the climatological-mean values. The background errors, originating from
450 the 24 ensemble members, have higher values in high-latitude regions and mid-latitude regions.
451 Data assimilation methods such as LETKF used in this study often face challenges in accurately
452 representing background errors when the ensemble spread is insufficient. Generally, the
453 magnitude of ensemble spread is frequently compared to the root mean square error(RMSE).
454 The background error in this study demonstrates a sufficiently valid magnitude in comparison
455 with the RMSE, as illustrated in SFig. 1, indicating that it is well estimated. In the spatial
456 distribution of Kalman gain in Fig. 8c, significant performance improvement is observed in
457 transition regions, where Kalman gains exhibit larger values. However, in high-latitude areas
458 with substantial snow accumulation, there is a tendency for Kalman gain to have lower values.
459 These findings agree well with the bar graph in Fig. 9, which illustrates the Kalman gain as a

460 function of SWE amount. In the region encompassing the transition region with SWE amounts
461 below 20 mm, the Kalman gain displays the highest values, particularly exceeding 0.8. As the
462 SWE amount increases, the Kalman gain decreases, with a significant decline observed when
463 the SWE amount reaches 80-100 mm or higher. Furthermore, in the areas where DA denotes
464 improved skill compared to Openloop, the Kalman gain shows values generally above 0.7. In
465 contrast, relatively lower values below 0.5 are observed in the areas with decreased skill. This
466 indicates that in the dominant areas of performance improvement, including the transition
467 region, the background error is significantly larger than the observation error, emphasizing the
468 substantial influence of observations in data assimilation. It is found that accurate remote
469 sensing retrievals are well reflected in regions with high uncertainty in the LSM through the
470 snow data assimilation system, leading to performance improvement.

471

472

473 **4.3 Validation of the SWE for the extreme event**

474 In April 2020, Siberia experienced a record-breaking heatwave with the highest observed
475 average temperature. This section investigates the potential benefits of snow assimilation using
476 satellite data for the case of the 2020 Siberian heatwave. Previous studies have identified the
477 strong polar vortex accompanied by the AO amplification during winter as a major cause of
478 the cold Eurasian(Overland and Wang, 2021). Additionally, it has been revealed that the
479 occurrence of high temperatures in the Siberian region is found to be closely related to the
480 development of large-scale atmospheric waves in the upper atmosphere of the Eurasian region,
481 indicating a significant influence on the strengthened land-atmosphere interaction in recent
482 years. As a result, remarkable snow melting occurred due to the high surface temperature over
483 the Siberian region in April 2020, leading to extremely low values of SWE and SCF as depicted
484 in SFig. 2. This is consistent with previous studies reporting a significant snow depletion in

485 2020 in the region(Gloege et al., 2022). Especially, as shown in Fig. 10, significant negative
486 anomalies in SWE and SCF are predominant over the transition region. **With a substantial snow**
487 **melting, it increases the sensible heat flux to the atmosphere, thereby strengthening the upper-**
488 **level waves by enhanced atmosphere-land interaction, leading to further intensification of**
489 **heatwaves.** This implies the importance of realistic snow initial states in the global coupled
490 model forecasts. For the Siberian region with extreme high-temperature events marked by the
491 red box in Fig. 10, DA shows a better agreement with the extremely dry snow conditions,
492 especially in the transitional region, compared to the Openloop. These results are evident when
493 considering the observation-to-model ratio in that region. The percentage of CMC(IMS) is
494 83%(78%) for Openloop and 93%(89%) for DA, indicating that DA with snow data
495 assimilation based on satellite data produces **more significant changes in snow** in comparison
496 with Openloop. Similarly to the 2020 case, we obtained another significant case in 2014
497 compared to Openloop, as shown in SFig. 3. Such extremely dry snow conditions can provide
498 significant heatwave events in the following months.

499

501

502

503

504

505 **5. Conclusions**

506 The advanced snow data assimilation is developed in this study with the LETKF data
507 assimilation method based on the JULES LSM. The system assimilates snow retrievals from
508 AMSR2 and IMS remote sensing observations. This study showed that the satellite-derived
509 snow data has limitations in penetrating deep snow, and exhibited much discrepancy from the
510 snow obtained from the Openloop LSM simulations. The snow assimilation framework
511 developed in this study proves the beneficial impacts of using satellite snow data, maintaining
512 better analysis quality both in the regions with low satellite data quality and the high satellite
513 data quality by dynamically balancing the errors from the satellite observations and the model
514 background forecasts. It is found that the simulation from Openloop as a baseline shows
515 superior performance in high-latitude regions with heavy snow accumulation but relatively
516 inferior performance in transition regions with significant snow changes. Contrastingly, the
517 results of the AMSR2 satellite data represent poor performance in high-latitude regions but
518 exhibit good performance in transition regions. AMSR2 demonstrates higher performance than
519 Openloop up to 16 mm of SWE, but beyond that threshold, the skill of AMSR2 sharply declines
520 while Openloop shows better performance. DA with snow data assimilation consistently
521 performs better in the climatological-mean pattern and temporal variation compared to other
522 results. Notably, the snow assimilation system in this study reflects well the errors and
523 advantages of land surface models and satellite-derived data, controlling not only the transition
524 regions but also the satellite-limited regions with heavy snow.

525 The significant improvement of SWE data assimilation is primarily observed in the
526 transition regions of less than 16 mm, which accounts for approximately 53% of the entire
527 areas of the Northern Hemisphere. A sensitivity test also revealed that the use of IMS SCF led
528 to a substantial improvement in the transitional regions, in addition to the use of AMSR2 SWE.
529 The sources contributing to the skill improvement of SWE in the snow assimilation system can

530 be explained through Kalman gain analysis, measuring the relative importance of observations
531 given the model background errors. Higher Kalman gains values above 0.7 were observed in
532 the transition regions, whereas they decreased below 0.5 in the high latitudes with heavy snow
533 accumulation. It found that in the dominant areas of performance improvement, including the
534 transition region, the background error is significantly larger than the observation error,
535 emphasizing the substantial influence of observations in the snow assimilation process.

536 In the case of the Siberian heatwave, remarkable snow melting occurred due to high surface
537 temperature over the Siberian region in April 2020. It resulted in extremely low values of SWE
538 and SCF, leading to a further intensification of the heatwave. The SWE anomalies from the
539 snow data assimilation with the AMSR2 satellite showed significant changes in snow that
540 seemed to better explain the heatwave episode than the Openloop.

541 The quality of the observation is crucial in the data assimilation system. Satellite-derived
542 snow cover exhibits a significantly higher accuracy compared to other data sources, while SWE
543 has restricted performance due to the limitations of penetration depth by satellite sensors and
544 relies heavily on estimation algorithms. Due to these problems, most previous studies and
545 operational centers primarily depend on satellite-derived snow cover for snow initialization.
546 However, the findings from this study highlighted the beneficial impacts of using satellite-
547 derived SWE, particularly in the rapidly changing transition areas, to find out which variable
548 is more important in closing surface energy and water balance changed by snow. Nevertheless,
549 areas of significance in large-scale circulation, such as the Tibetan region, which experiences
550 significant uncertainty and degraded performance in satellite data, do not exhibit substantial
551 data assimilation effects. As the performance of SWE derived from various satellites continues
552 to advance, these issues will be discussed more.

553 Improved snow estimates from the snow assimilation system can enhance the initialization
554 of climate models used in most of the seasonal forecast operation centers. As snow significantly

555 influences energy and water balance at the atmosphere-land boundary, this approach allows for
556 a more accurate prediction of atmospheric conditions by realistically representing atmosphere-
557 land interactions. Specifically, this applies to transitional regions where the reliability of snow
558 estimation performance through model simulations is compromised. The long-term analysis of
559 snow manifests a pronounced variability in the continental interior at the interannual timescales,
560 potentially improving the prediction of extreme heatwave events by global couple models. This
561 study used the gridded CMC data as a validation reference, which is based on in-situ
562 observations. Despite much uncertainty and limitations of this dataset, we expect to obtain
563 comparable conclusions to this study through comparisons with other independent,
564 observation-based datasets.

768 observations and the land surface model outputs.

769

770

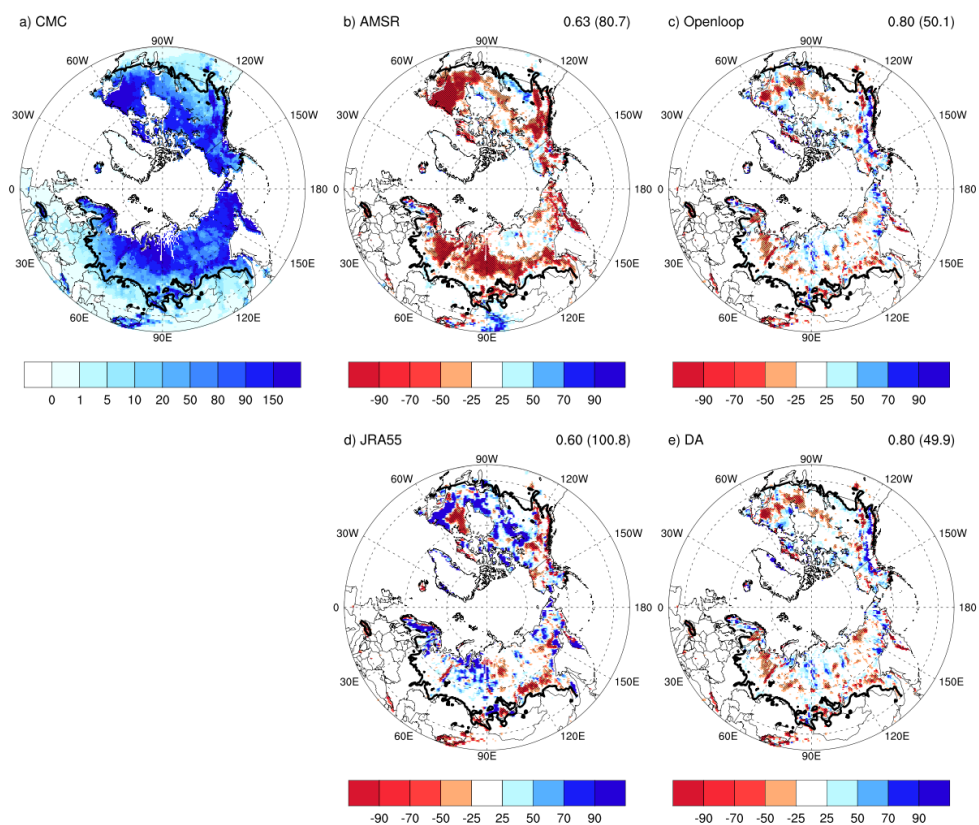

771

772 **Figure 2.** (a) Climatology of SCF from IMS used as reference and (b-e) the differences from
773 IMS for AMSR2, base-line model simulation (Openloop), JRA55, and the data
774 assimilation results (DA) for April during 2013-2020. The black line represents the
775 boundary of the transition region, defined as the climatological-mean SWE of less than
776 16mm. Each value on the top right is the root-mean-squared difference with IMS and
777 the accuracy from IMS (parenthesis) for 15323 pixels over 40-60°N. The accuracy is
778 defined in supplementary Table 1 as in previous study (Lee et al., 2015). **Negative**
779 **values are indicated with a diagonal line.**

780

781

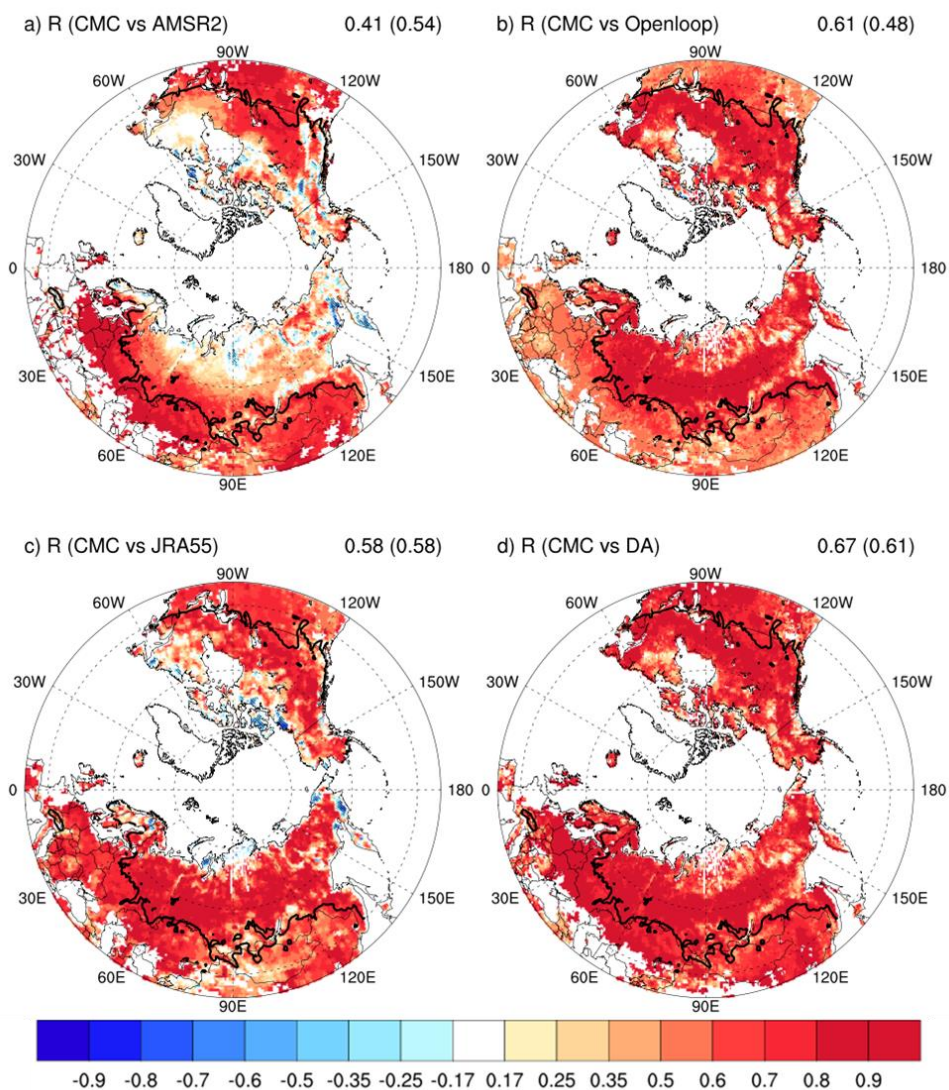

782

783 **Figure 3.** (a) Climatology of SWE from CMC used as reference and (b-e) the differences from
784 CMC for AMSR2, base-line model simulation (Openloop), JRA55, and the data
785 assimilation results (DA) for April during 2013-2020. The black line represents the
786 boundary of the transition region, defined as the climatological-mean SWE of less than
787 16mm. Each value on the top right is the pattern correlation with CMC for 26482 pixels
788 over 40 °N and the root-mean-squared difference (unit: kg/m²) from IMS (parenthesis)
789 for 15323 pixels over 40-60°N. Negative values are indicated with a diagonal line.

790

791

792

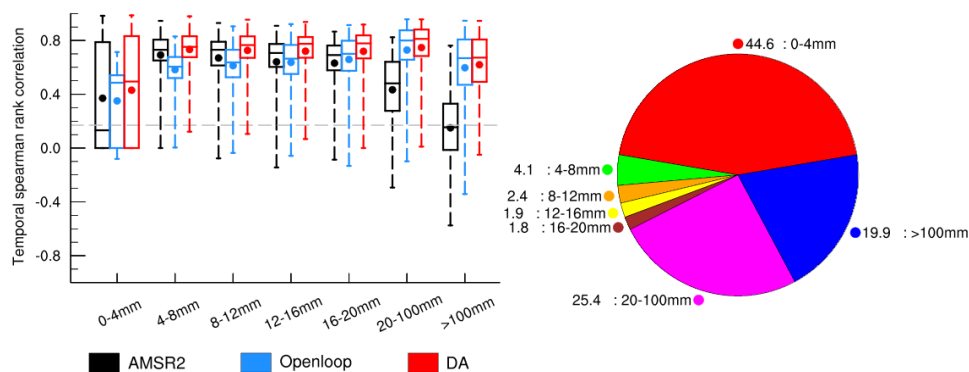

793 **Figure 4.** SWE skill measured as the Spearman rank correlation (R) with the CMC for AMSR2,
794 base-line model simulation (Openloop), JRA55, and the data assimilation result (DA).
795 The black line represents the boundary of the transition region, defined as the
796 climatological-mean SWE of less than 16mm. Each value on the top is the **area-average**
797 of North hemisphere for 26482 pixels over 40°N and for 8801 pixels over the transition
798 region (parenthesis). Negative values are indicated with a diagonal line.

799

800 **Figure 5.** Zonally-averaged Spearman rank correlation (R) along the latitude for SWE. The
801 yellow line indicates the climatology of SWE, and the black, blue, green, and red lines
802 denote the values of AMSR2, base-line model simulation (Openloop), JRA55, data
803 assimilation results (DA), respectively.

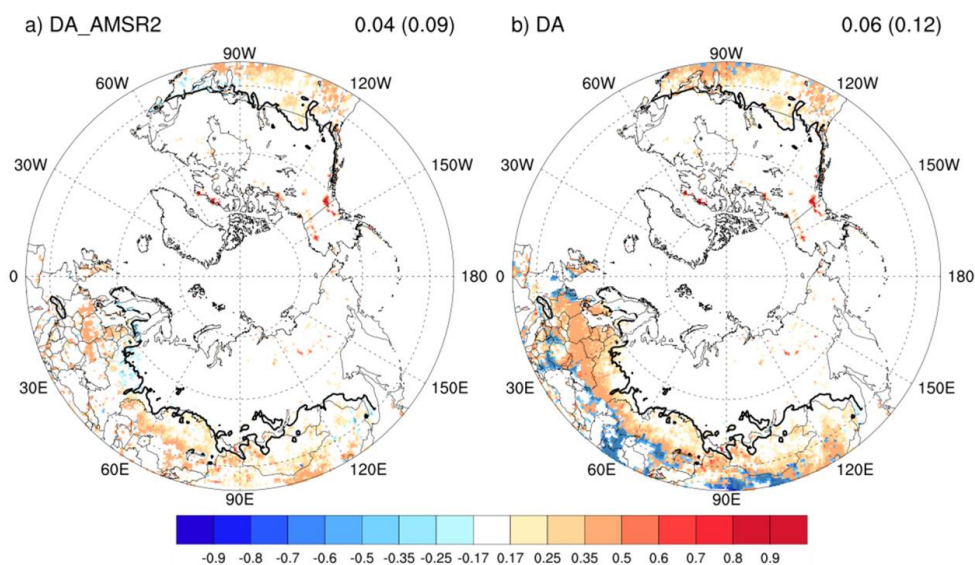

804

805

806 **Figure 6.** Box plots of the Spearman rank correlation (R) according to SWE. The pie chart
807 shows the total area ratio (%) as a function of SWE amount. The black, blue, and red
808 boxes denote the AMSR2, base-line model simulation (Openloop), and the data
809 assimilation results (DA), respectively. The boxes indicate 25 and 75% percentiles, and
810 the line and point in the boxes shows the median and the mean values. The upper and
811 lower whiskers denote the 10 and 90% percentiles, respectively.

812

813

814

Figure 7. Difference in SWE skill, measured as the Spearman rank correlation coefficient (R) with CMC, between the Openloop and the data assimilation result employing both AMSR2 and IMS (referred to as DA), as well as the data assimilation result utilizing solely AMSR2 and excluding IMS (referred to as DA_AMSR2), for April during 2013-2020. The black line represents the boundary of the transition region, defined as the climatological-mean SWE of less than 16mm. Each value on the top right is the area-average over 40°N and the transition region (parenthesis). Negative values are indicated with a diagonal line.

822

823

824

826 **Figure 8.** Spatial distribution of observation error, background error, and Kalman gain. The
827 black line represents the boundary of the transition region, defined as the
828 climatological-mean SWE of less than 16mm.

829

830

831 **Figure 9.** Bar chart of (left) the Kalman gain according to the SWE amount, and (right) the
832 Kalman gain (red line) and background error (blue line) according to the **difference of**
833 **the Spearman rank correlation (R) between Openloop and DA.**

834

835

836 **Figure 10.** Anomalies of a) SWE from CMC and b) SCF from IMS as well as the difference
837 (c, d) of variables between DA and openloop in April 2020. Bar chart (e, f) indicates
838 the ratio of DA and openloop to verification data such as CMC and IMS in the red box
839 (48–65°N and 55–120°E), which is the region associated with extreme high-temperature
840 events, focused on this study. Negative values are indicated with a diagonal line.
