16 **Abstract**

17 Global urban expansion has altered surface aerodynamics and hydrothermal dynamics, aggravating
18 environmental challenges such as urban heat/dry islands. To identify such environmental responses,
19 various physical models, including urban canyon models (UCMs) and land surface models (LSMs),
20 have been developed to represent surface hydrothermal processes. However, UCMs often treat a city as
21 a unified entity and overlook subcity heterogeneity. LSMs are generally designed for natural land covers
22 and lack the capability to capture urban characteristics. To address these limitations, the aim of this study
23 is to couple an urban module with a sophisticated LSM, i.e., the Variable Infiltration Capacity (VIC)
24 model. This coupled model, i.e., the VIC-urban model, is characterized by its ability to coordinate certain
25 critical urban features, including the urban geometry, radiative interactions, and human impacts.
26 Adopting Beijing as an evaluation site, the VIC-urban model shows higher performance than the original
27 version, with excellent accuracy in simulating sensible heat, latent heat, runoff, and land surface
28 temperature (LST). The absolute error is smaller than 25% for the sensible heat and latent heat, and
29 smaller than 12% and 30% for the LST and runoff, respectively, which indicates that VIC-urban can
30 effectively simulate hydrological and thermal fluxes in urban systems. Sensitivity analysis reveals that
31 the roof emissivity and interception capacity exert the greatest impact on the roof temperature and
32 evaporation, and the height-width ratio has the greatest influence on the canyon. Our work introduces a
33 reliable option for large-scale land surface simulations that accounts for urban environments, and is
34 among the first attempts to establish a systematic urban modelling framework of the VIC model. The
35 VIC-urban model enables the analysis of urbanization-induced environmental changes and
36 quantification of environmental variations among different urban configurations. The proposed model
37 can thus offer invaluable insights for urban planners and landscape designers.

38 **Key words:** Urban canyon models; VIC model; Hydrothermal processes; Urban system; Sensitivity
39 analysis

40 **1. Introduction**

41 Urban areas have been expanding globally and are characterized by increasing impervious surfaces
42 and decreasing natural land coverage. This land cover change has led to alterations in surface
43 aerodynamics and hydrothermal dynamics, resulting in decreased local evaporation and an exacerbation
44 of temperature and extreme precipitation events (Yang et al., 2021). It has caused numerous
45 environmental issues, such as urban heat islands (Morabito et al., 2021; Yao et al., 2021), urban dry
46 islands (Meili et al., 2022; Li et al., 2021) and inundation problems (Huang et al., 2022b; Mu et al.,
47 2020). Moreover, cities encompass unique land surface processes, which differ from those of natural
48 land surfaces. The difference results from the diverse urban configurations, varied building materials,
49 and human interventions (Oh and Sushama, 2021). Therefore, it is necessary to accurately quantify the
50 impacts of urbanization and develop proper mitigation strategies (Yao et al., 2021).

51 As efficient tools, various land surface models (LSMs) have been rapidly developed in recent
52 decades, providing unprecedented opportunities to obtain detailed information on the storage and
53 movement of surface energy and water cycles (Bierkens et al., 2015). LSMs have been used for various
54 applications, such as land-climate interactions (Zhong et al., 2020; Wang et al., 2020), hydrothermal
55 environment quantifications (Zhao et al., 2019; Huang et al., 2022a), and dataset productions (Hersbach
56 et al., 2020; Rodell et al., 2004). However, LSMs are generally formulated for natural land surfaces
57 (Best and Grimmond, 2015), and often overlook the unique characteristics (e.g., urban configurations
58 and buildings) of urban systems. Specific models should be developed or improved by considering the
59 complexity and uniqueness within cities.

60 The existing urban parameterization schemes in LSMs mainly involve the bulk approach and
61 coupling with urban canopy models (UCMs) (Ji et al., 2021; Meng, 2015). The bulk approach treats

62 urban surfaces as a regular land cover category with modified thermal and hydrological parameters (e.g.,
63 albedo and infiltration) (Wang et al., 2020; Yang et al., 2010), but still lacks consideration of urban-
64 specific characteristics, such as building blocking, radiative interactions (Salvadore et al., 2015),
65 artificial heating and irrigation (Chen et al., 2022). Coupling LSMs with UCMs (hereafter referred to as
66 LSM-UCMs) is also a popular strategy for capturing land surface processes in urban systems. Various
67 LSM-UCMs have been favorably applied in studies (Meng, 2015; McNorton et al., 2021; Yang et al.,
68 2010), including the Met Office–Reading Urban Surface Exchange Scheme (MORUSES) (Simón-
69 Moral et al., 2019), Community Land Model-Urban (CLMU) (Oleson and Feddema, 2020), and
70 Geophysical Fluid Dynamics Laboratory land model LM3 (LM3-UCM) (Li et al., 2016b). However,
71 there remains a shortage of LSM-UCM models, typically oversimplifying the dynamics of land cover
72 and climate change by using constant parameters in simulations (Kusaka et al., 2001).

73 To better represent urban environments, more suitable methodologies are needed (Yao et al., 2021).
74 Among the various LSM models, the Variable Infiltration Capacity (VIC) model is widely used for
75 identifying thermal and hydrological processes on land surfaces (Meng et al., 2019; Meng et al., 2020;
76 Zhu et al., 2020). VIC is characterized by grid-independent calculation and favorable consideration of
77 multiple layers along both horizontal (i.e., land cover types) and vertical (i.e., soil layers) directions
78 (Liang and Xie, 2001; Liang et al., 1996). The model can be coupled with multiple remote sensing data
79 (e.g., shortwave/longwave radiation, albedo, and leaf area index [LAI]) (Jiang et al., 2022; Meng et al.,
80 2020; Wang et al., 2022), to consider the realistic dynamics in land surface properties and atmospheric
81 conditions. The VIC model has been implemented in several urban-related studies based on the bulk
82 approach, and has provided an acceptable performance in simulating energy and hydrological fluxes
83 (Yang et al., 2010; Mishra et al., 2010; Wang et al., 2020). Yet a systematic urban calculation method

84 that considers the unique urban characteristics within VIC is still lacking.

85 In this study, we developed an urban module within the VIC model based on the Urban Tethys-
86 Chloris model (UT&C) (Meili et al., 2020), namely, the VIC-urban model. The coupled model can
87 efficiently identify urban hydrothermal processes when solving the water and energy balance and
88 consider unique urban characteristics, including urban geometry, radiative interactions among urban
89 surfaces (i.e., roof, canyon, walls, and ground), and human interference (e.g., irrigation and inner
90 building temperature). VIC-urban can facilitate multiple urban-related researches, such as identifying
91 long-term hydrothermal processes in urban systems, quantifying environmental changes resulting from
92 urban expansion, and comparing environmental variations among different urban configurations. In this
93 article, we first provide a technical description of the model coupling, process and evaluate the model
94 in Beijing regarding the land surface temperature (LST), turbulent heat fluxes, and runoff. Further, we
95 examine the sensitivity of the urban model input parameters to the urban environment (i.e., roof
96 evaporation and temperature, canyon evaporation and temperature).

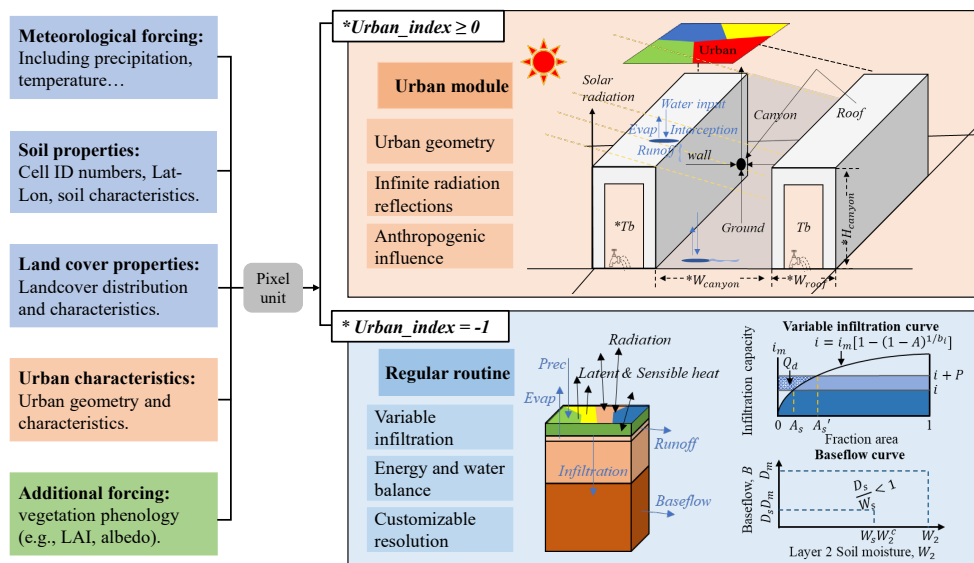

97 **2. Methodology**

98 **2.1 Urban module coupled with VIC**

99 The VIC model divides a study area into Latitude-Longitude grids, with each grid representing
100 multiple land cover types and soil layers. It estimates hydrological and thermal processes for each
101 subgrid land cover type in the solution of water and energy balance (Liang et al., 1994; Liang et al.,
102 1996). However, the existing parameterization scheme ignores the unique characteristics of urban areas, such
103 as building blockage and human influence (e.g., indoor temperature, anthropogenic heat and water inputs).
104 Fortunately, VIC assigns a unique ID number to each grid, and labels each vegetation type within the target
105 grid. This enables VIC to identify and compute the subgrid land cover with individual parameters, offering

106 advantages for establishing the urban module channel.
 107 We integrate an urban module into the VIC model (VIC-urban). It executes the urban module for
 108 urban tiles, and follows the same calculation routine as the original VIC model for the other land cover
 109 tiles. Specifically, the model uses two parameters (i.e., Gridcell and Urban_index) to identify urban tiles,
 110 as shown in Figure 1. Gridcell is the ID number of the target grid. Urban_index serves as an index to
 111 ascertain the presence of an urban tile, and to identify the urban tile label in the target grid. Urban_index
 112 is equal to $n-1$ if the urban tile is the n th land cover type of the target grid, and equal to -1 if there is no
 113 urban tile in the grid. The VIC-urban model can thus identify the target grid and urban tile, and obtain
 114 the parameters of the urban tile (i.e., the parameters of the $[\text{Urban_index}+1]$ th land cover type in the
 115 target grid).

116 **Figure 1.** Diagram of the urban module coupled with the VIC model. $*W_{canyon}$, $*W_{roof}$, $*H_{canyon}$ are
 117 parameters that describe the urban geometry (canyon width, roof width, and canyon height). $*T_b$ is the inner
 118 building temperature. The parameters including A_s and D_s are defined by the original VIC model, and
 119 detailed information can be found on the VIC website.
 120

121 The urban module implemented in our study is based on the methods described in Meili et al.
 122 (2020). The urban tile is parameterized by three urban geometry parameters (canyon height, canyon

123 width, and roof width) and four urban surfaces (roof, impervious ground, sunlit and shaded walls). The
124 hydrothermal fluxes and states (e.g., turbulent heat fluxes and land surface temperature) are individually
125 calculated for each urban surface, considering the urban geometry, radiative interaction, and water and
126 energy budgets. In addition, the urban module accounts for human impacts, including inner building
127 temperature, and artificial heating and irrigation. We present core formulations of the urban processes
128 and related parameters in Subsections 2.2-2.5. A more detailed explanation is included in the
129 Supplementary Document and Meili et al. (2020).

130 **2.2 Energy balance in the urban module**

131 The newly developed urban module in VIC-urban treats the energy balance differently between
132 the upper (i.e., roof) and lower canyon surfaces (i.e., ground and walls). For the roof surface, both short-
133 and longwave radiation values are calculated similar to those on bare soil, as the model assumes no
134 obstruction or radiative interaction on roofs (Supplementary Section 1.1). For the ground and walls, the
135 model first computes the incoming direct shortwave radiation as a function of the urban geometry, solar
136 position, and grid location (Supplementary Section 1.2). Then, it estimates the temperature, net absorbed
137 radiation, and turbulent fluxes of each surface according to the sky-view factor (Supplementary Section
138 1.5) and infinite radiation reflections among the various surfaces (i.e., ground, sunlit and shaded walls,
139 and sky) based on energy and water budgets. The detailed calculation method for the radiation can be
140 found in Supplementary Section 1, and that for the turbulent fluxes can be found in Supplementary
141 Section 2.

142 The energy balance of the roof, ground and wall can be calculated as:

$$143 \quad EB_i = S_{abs,i} + L_{abs,i} - G_i - H_i - LE_i, \quad (1)$$

144 where EB_i is the energy balance of surface i , and $S_{abs,i}$ and $L_{abs,i}$ [W m^{-2}] are the net absorbed short-

145 and longwave radiation values, respectively, of surface i (roof, ground, and wall). G_i , H_i , and LE_i are
146 the conductive heat, sensible heat and latent heat fluxes, respectively, of surface i , and they can be
147 calculated as:

$$148 \quad H_i = \rho_a C_p \frac{T_i - T_a}{r}, \quad (2)$$

$$149 \quad LE_i = \lambda \rho_a \frac{q_{sat, T_i} - q_a}{r}, \quad (3)$$

$$150 \quad G = -\lambda g \frac{(T_{int} - T_i)}{z}, \quad (4)$$

151 where ρ_a [kg m^{-3}] is the air density, C_p [$\text{J kg}^{-1} \text{K}^{-1}$] is the specific heat capacity of air at a constant pressure,
152 T_i [K] is the temperature of surface i , [s m^{-1}] is the sum of the resistance values, λ [J kg^{-1}] is the latent heat
153 of vaporization, and q_{sat, T_i} [-] is the saturation specific humidity at temperature T_i . Notably, for the surface
154 above the canyon (i.e., canyon roof), T_a [K] and q_a [-] are the air temperature and specific humidity,
155 respectively, and for the ground and walls, T_a [K] and q_a [-] are the canyon temperature and specific
156 humidity at the canyon reference height, respectively (Supplementary Section 2.5). Moreover, λg [J K^{-1}
157 $\text{m}^{-1} \text{s}^{-1}$] is the heat conductivity, and z is the thickness of the layer. T_{int} is the interior building temperature,
158 which can be calculated from the outdoor and indoor temperatures based on the thermal conductivity
159 parameters (Supplementary Section 2.2).

160 The energy balance of an urban canyon can be expressed as:

$$161 \quad EB_{can} = Q_{can} + H_g + h_{can}(H_{wsun} + H_{wshd}) + LE_g - H_{can} - LE_{can}, \quad (5)$$

162 where EB_{can} is the energy balance of the canyon, Q_{can} is anthropogenic heat, H and LE are the sensible
163 heat and latent heat fluxes, respectively, and the subscripts g , can , $wsun$, and $wshd$ denote the ground,
164 canyon, sunlit wall, and shaded wall, respectively. h_{can} [-] is the canyon height normalized by the canyon
165 width (H_{can} / W_{can}).

166 The turbulent heat fluxes of canyon can be calculated as the area-weighted average of the walls and
167 ground and directly include the anthropogenic heat input (Equation 6), and the total turbulent fluxes of

168 an urban tile can be calculated as the area-weighted average of the roof and urban canyon (Equation 7):

$$169 \quad X_{can} = w_{can} X_g + h_{can} (X_{wsun} + X_{wshd}) + Q_{can}, \quad (6)$$

$$170 \quad X_{urban} = f_{roof} X_{roof} + f_{can} X_{can}, \quad (7)$$

171 where X [W m^{-2}] denotes the turbulent heat fluxes (i.e., latent or sensible heat fluxes), f_{roof} and f_{can}
172 [-] are the roof and canyon fractions, respectively, and Q_{can} [W m^{-2}] is the anthropogenic heat input.
173 The subscripts g , can , $wsun$, and $wshd$ denote the ground, canyon, sunlit wall, and shaded wall,
174 respectively.

175 2.3 Water balance in the urban module

176 The urban module computes the water mass balance for the roof and ground individually. For the
177 roof, the incoming water is initially consumed by evaporation. Subsequently, runoff occurs when the
178 remaining water exceeds the maximum water interception capacity. Runoff can be further divided into
179 outflow runoff and runoff according to a certain ratio defined by experience. Outflow runoff flows off
180 the roof and turns into incoming water for the ground, while runoff remains on the roof as the incoming
181 water for the roof at the next time step. Therefore, the incoming water is equal to the precipitation and
182 runoff of the previous time step.

$$183 \quad Int_t - Int_{t-1} = P_t + Runon_{t-1} - E_t - Runoff_t - Runon_t, \quad (8)$$

184 where Int [mm h^{-1}] is the interception water, P [mm h^{-1}] is the precipitation, and E [mm h^{-1}] is the
185 evaporation.

186 For the ground, the incoming water flux includes precipitation, roof runoff, anthropogenic water
187 input, and runoff of the previous time step. The incoming water is first consumed by evaporation and
188 leakage and then by runoff and runoff. Outflow runoff leaves the current cell, while runoff remains in
189 the cell as incoming water of the next time step. Notably, the model does not consider subsurface

190 hydrological fluxes within urban tiles, such as soil moisture and baseflow, since impermeable surfaces
 191 impede vertical hydrological interactions. Therefore, the grid-scale subsurface water fluxes are assumed
 192 to be equal to the areal-weighted mean value of the fluxes of the other land cover types in the grid.

$$193 \quad Int_t - Int_{t-1} = P_t + Runon_{t-1} + Runoff_{t,roof} + Q - E_t - Leak_t - Runoff_t - Runon_t, \quad (9)$$

194 where Q [mm h^{-1}] is the anthropogenic water input.

195 2.4 Parameters for the urban module

196 **Table 1.**
 197 Overview of datasets for urban module in VIC model

Parameter	Unit	Description
Gridcell	N/A	Grid cell number
Urban_index	N/A	Index of the veg tile containing the urban , with respect to the list of veg tiles given in the veg param file for the current grid cell. Ranges 0~(Nveg-1) for a grid cell that contain urban, and set to -1 to denote the grid cell exclude urban.
Theta_canyon	°	Canyon orientation
Zatm	m	Atmospheric forcing/reference height
Qf_canyon	W/m^2	Human interference: Anthropogenic heat input
Waterf_canyon	mm/h	Human interference: Anthropogenic water input
Height_canyon	m	Urban geometry: Height of urban canyon
Width_canyon	m	Urban geometry: Ground width of urban canyon
Width_roof	m	Urban geometry: Roof width of urban canyon
Perrunoff_R/G	N/A	Water budget: Percentage of excess water that leaves the roof/ground as runoff
In_max_R/G	mm	Water budget: Maximum interception capacity of roof/ground
Kimp_R/G	mm/h	Water budget: Hydraulic conductivity of roof/ground
Albedo_R/G/W	N/A	Energy budget: Albedo roof/ground/walls
Emissivity_R/G/W	N/A	Energy budget: Emissivity roof/ground/walls
Lan_dry_R/G/W	$\text{W}/(\text{m}^2\text{K})$	Energy budget: Thermal conductivity of roof/ground/walls
Cv_s_R/G/W	$\text{J}/(\text{m}^3\text{K})$	Energy budget: Volumetric heat capacity of roof/ground/walls
Dz1_R/W	m	Energy budget: Thickness of first roof/wall layer
Dz2_R/W	m	Energy budget: Thickness of second roof/wall layer

198 For the urban module, the input data include land cover maps and urban-related parameters. The
 199 land cover maps represent the locations of urban areas. The urban-related parameters are summarized
 200 in Table 1. Specifically, the Gridcell and Urban_index parameters are used to identify urban tiles,
 201 Qf_canyon and Waterf_canyon denote anthropogenic forcings, and the Theta_canyon, Zatm,
 202 Height_canyon, Width_canyon, and Width_roof parameters define the urban geometry. Parameters such
 203 as the hydraulic conductivity and maximum interception capacity albedo (i.e., Perrunoff, In_max, and

204 Kimp) are used for water budget calculation, while the other parameters (e.g., albedo, emissivity,
205 Lan_dry, Cv_s, and Dz) are used for energy budget calculation.

206 **2.5 Input data for VIC-urban**

207 In addition to the urban-related parameters listed in Table 1, the other needed input data of the VIC-
208 urban model are similar to those of the original VIC model, referring to Liang et al. (1994), Liang et al.
209 (1996), and Liang and Xie (2001). In general, the input data include topographical, meteorological
210 forcing, soil and land cover (i.e., vegetation) properties. The topographical dataset is used to delineate
211 river networks and interpolate meteorological data. Meteorological forcings provide information on
212 precipitation, maximum and minimum air temperatures, wind speed, and humidity. Soil data define the
213 initial soil moisture conditions, including variable infiltration curve and saturated hydrologic
214 conductivity, and land cover data provide vegetation conditions such as the root zone thickness and the
215 root fraction of each vegetation type.

216 In addition to the needed forcing files, the VIC model can incorporate vegetation and radiation time
217 series data (e.g., LAI, albedo, and shortwave/longwave radiation), which are particularly useful because
218 they provide dynamic information on vegetation and radiation variables. By incorporating these data,
219 the VIC model can better capture realistic land surface dynamics and energy budgets.

220 **3. Case description**

221 **3.1. Study area and data input**

222 The VIC-urban model was evaluated in reproducing observation-based sensible and latent heat,
223 runoff and LST measurements in Beijing. Beijing is the capital of China, located between 39.43-41.05°N
224 and 115.42-117.50°E. The city has experienced rapid urbanization since 1980, with extensive urban
225 coverage since 2000 (Wang et al., 2020). Beijing can be divided into four functional zones with varying

226 degrees of urbanization: the Core Functional Zone (Core-Zone, with an urban fraction of ~90%), the
227 Urban Functional Extended Zone (Extended-Zone, ~70%), the New Urban Development Zone
228 (NewDev-Zone, ~30%), and the Ecological Conservation Zone (Eco-Zone, ~5%) (Figure 2). This
229 evaluation primarily focused on the three highly urbanized zones (Core-Zone, Extended-Zone, and
230 NewDev-Zone) to demonstrate the performance of VIC-urban.

231 The parameters used in the urban module were based on those reported by Jackson et al. (2010),
232 with manual calibration of the height-to-width ratio and the wall layer thickness based on MODIS LST
233 and runoff observation data. The height-to-width ratio is a highly sensitive parameter in LST modelling
234 and ranges from 0.5 to 1.1 according to the MODIS LST product. The prescribed wall layer thickness
235 ranged from 0.2 to 0.6. The values of these parameters are generally consistent with previous research
236 (McNorton et al., 2021; Li et al., 2016a), where the height-to-width ratio ranges from 0.75 to 1.5 and the
237 wall layer thickness ranges from 0.3 to 0.5.

238 Regarding the model input data of Beijing, topographical data (i.e., the digital elevation model)
239 were obtained from the USGS with a 90-m resolution. Meteorological forcing data were produced by
240 interpolating the data obtained from observation stations of the China Meteorological Administration
241 (CMA) (Xie et al., 2015; Zhu et al., 2021). A soil map was obtained based on a 30 arc-second-resolution
242 soil characteristics dataset. The soil parameters were derived based on a Chinese soil dataset (Shangguan
243 et al., 2013; Zhu et al., 2020) and Food and Agriculture Organization (FAO) (Nijssen et al., 2001). The
244 land cover maps included base maps and urban maps. The base maps were obtained from Liu et al.
245 (2010), which were created by merging Landsat TM digital images with a spatial resolution of 1 km and
246 12 land cover types. The urban maps were obtained from Wang et al. (2020), which were created by the
247 Classification Regression Tree (CART) method using Landsat images with a spatial resolution of 30 m.

248 The land cover parameters were obtained from Zhu et al. (2020). Moreover, four satellite datasets,
249 namely, Downward Shortwave Radiation (DSR), albedo, LAI, and Fraction of Vegetation Cover (FVC),
250 were incorporated in the modelling process (Zhang et al., 2019; Liang et al., 2021) to better identify land
251 conditions and calculate turbulent heat fluxes. The four datasets used in this study are at 0.05° spatial
252 resolution. The DSR dataset is at daily temporal resolution, while the other three datasets are at 8-day
253 temporal resolution. The four datasets were obtained from Global Land Surface Satellite (GLASS)
254 products (<http://www.geodata.cn/thematicView/GLASS.html>) (Liang et al., 2021).

255 3.2 Evaluation data and method

256 The VIC-urban model underwent calibration using streamflow data from two watersheds and
257 MODIS-based LST data. Then, it was validated against observations retrieved from gauge stations and
258 MODIS data regarding sensible and latent heat, runoff, and LST. The locations of the gauge stations are
259 shown in Figure 2, and detailed information is listed in Table 2. Four measures, namely, the Nash–
260 Sutcliffe efficiency (*NSE*), Root Mean Squared Error (*RMSE*), relative bias (*Er*), and correlation
261 coefficient (*R*) were used to evaluate the performance of VIC-urban.

262 In regard to sensible and latent heat evaluation, three flux towers were used, namely, the Beijing,
263 Daxing, and Miyun stations. In particular, the Beijing station is located in the central part of Beijing and
264 is widely used to investigate urban turbulence characteristics (Liu et al., 2020b; Ji et al., 2021). To
265 calibrate and validate the simulated runoff, streamflow data from three stations were used, namely,
266 Boyachang (BYCH), Qianxinhuang (QXZH), and Wenyu (WY). Their corresponding watersheds are
267 located in the northern part of Beijing and contain various land cover types, including urban, forest, crop,
268 and grass (Figure 2). The observed discharge data of the QXZH and BYCH stations were separated into
269 two periods for model calibration and validation, whereas the observed discharge of the WY station was

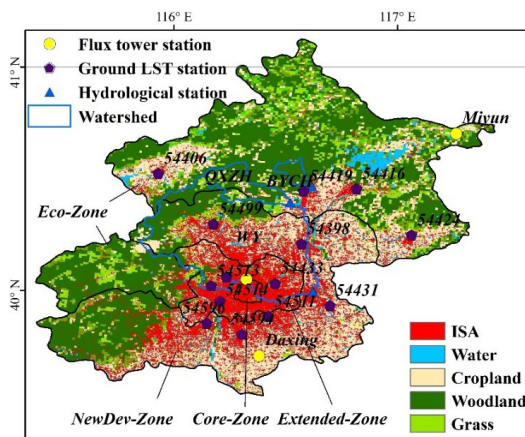

270 compared to the simulated runoff for the entire period due to the availability of only yearly data.

271 **Table 2.**

272 Validation data used in this work

Name	Source	Detailed information
Sensible heat	NCDDC, IAP	Beijing, 2011-2013, daily
Latent heat	NCDDC, IAP	Beijing, 2011-2013, monthly Miyun, 2018-2010, daily
Runoff	AHRPR	Daxing, 2018-2010, daily QXZH, 2006-2009, monthly BYCH, 2006-2014, monthly
LST	CMA, MODIS	WY, 2005-2017, yearly 14 ground stations, daily MOD11A2, eight-days

NCDDC, National Cryosphere Desert Data Center; IAP, Institute of Atmospheric Physics; AHRPRC, Annual Hydrological Report for the P.R. China, CMA, China Meteorological Administration; MODIS, MODerate-resolution Imaging Spectroradiometer; QXZH, Qianxinzhuan; BYCH, Boychang; WY, Wenyu.

273

274 **Figure 2.** Location of Beijing and the flux tower stations, hydrological stations and watersheds, and ground
 275 LST stations, with the 2015 land cover map as the background.

276 Regarding LST evaluation, we obtained data from fourteen ground-based stations and one satellite-
 277 based product. At the ground-based stations of the CMA, platinum resistance sensors are used that are
 278 semi-buried in soil to measure the daily temperature at the skin surface. Among the stations, three
 279 stations provide long-term coverage data for the 2005 to 2020 period, while the remaining stations
 280 provide data covering the 2016 and 2020 period. The satellite-based LST product of the Terra Moderate
 281 Resolution Imaging Spectroradiometer (MODIS) was adopted, i.e., MOD11A2 v006
 282 (<https://modis.gsfc.nasa.gov/>). MODIS LST data constitute one of the most widely used data for LST

283 studies (Bounoua et al., 2015; Zhou et al., 2010; Liu et al., 2020a; Morabito et al., 2021; Zhou et al.,
284 2018). The MODIS has provided two instantaneous LST estimates (10:30 and 22:30 local solar time)
285 every eight days since 2000, with a spatial resolution of 1 km. In our work, the simulated LST was
286 averaged every eight days for comparison with the MODIS data. The simulated LSTs from 9:00-12:00
287 and 21:00-24:00 were compared with the MODIS data for 10:30 and 22:30, assumed to represent the
288 morning and evening times, respectively. Notably, the gauge-based measurements were obtained at the
289 point scale, which is smaller than the model output resolution. To resolve the mismatch in the spatial
290 scale, the evaluation was conducted at the subgrid scale with the same land cover type in the
291 corresponding grid.

292 3.3 Sensitivity analysis

293 To examine the sensitivity of the model parameters to changes in the urban environment. Four
294 fluxes, namely, roof temperature, roof evaporation, canyon temperature, and canyon evaporation, were
295 used as indicators of the urban environment. A single grid cell with high urban coverage was selected,
296 and its input values were used as default values. The urban input parameters range from 70% to 130%
297 of the default values in 6% change steps. The specific parameters and their values are listed in
298 Supplementary Table 1.

299 The sensitivity analysis covered 6 years (2015-2020) and was conducted at the annual scale, as
300 well as for the winter (December to February of the next year) and summer (June to August) seasons.

301 The sensitivity coefficient Sc can be calculated as (Beven, 1979):

$$302 \quad Sc = \lim_{X \rightarrow 0} \frac{\Delta Y / Y}{\Delta X / X} \times 100\%, \quad (10)$$

303 where X is the input parameter that affects the urban environment (Y). A positive (or negative) Sc value
304 suggest that Y is enhanced (or reduced) with increasing X .

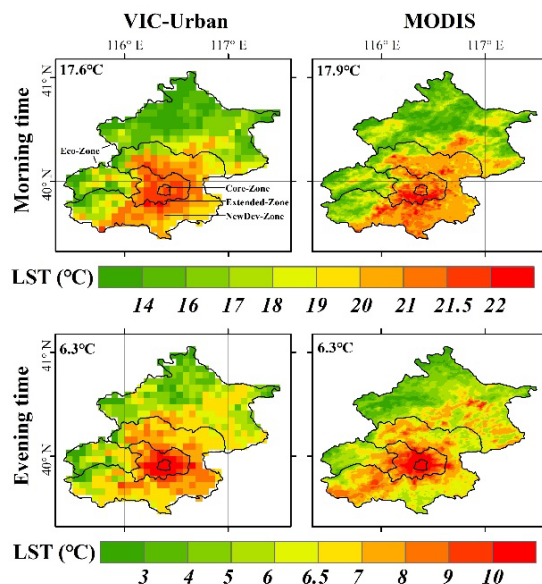

305 **4. Results**

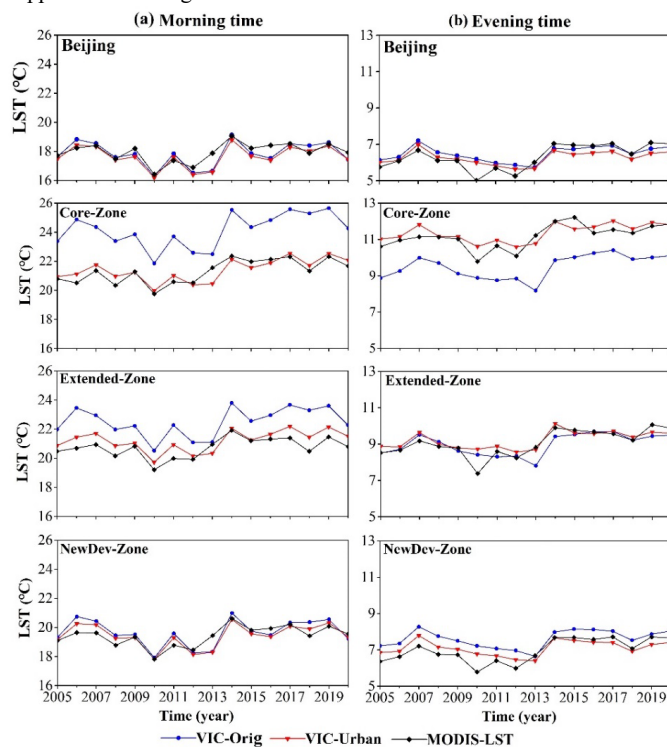

306 **4.1 Land surface temperature**

307 The simulated LST was calibrated against the MODIS LST and evaluated using two ground
308 observations and the MODIS LST dataset. As shown in Figure 3, the simulated LST exhibited similar
309 spatial patterns to those of the MODIS estimates for both the morning and evening times at the city
310 center. At the morning time, both the VIC-urban model and MODIS data exhibited high LST values in
311 Core-Zone and the southern part of Extended-Zone. At the evening time, the VIC-urban model
312 simulations failed to capture the scattered LST patterns in Eco-Zone and the southwestern part of
313 NewDev-Zone. This disagreement may be attributed to the relatively low urban fraction in these areas,
314 given that our work mainly focused on the calculation of urban-related processes. Other than in these
315 areas, the model could accurately produce a similar LST distribution relative to the MODIS LST data
316 in Core-Zone and Extended-Zone.

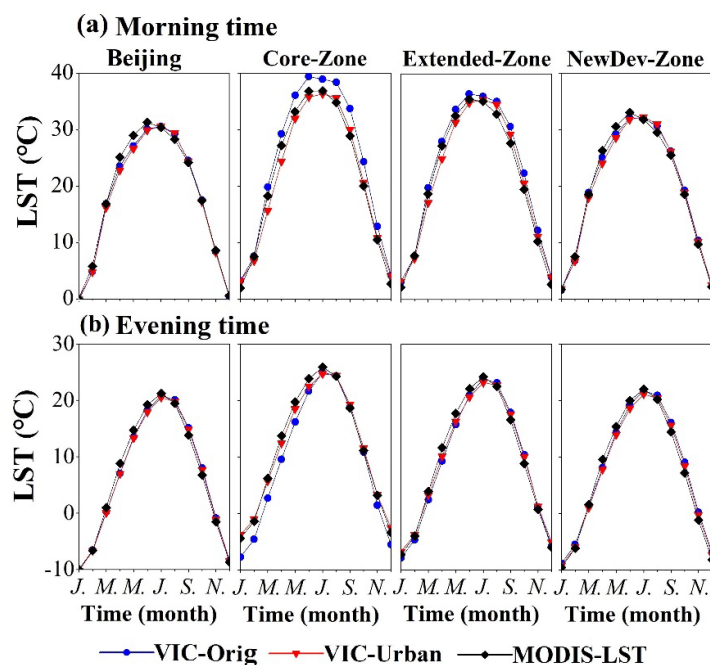

317 In terms of temporal comparison, the simulated LST exhibited a high performance in all of Beijing
318 and the three subzones (Core-Zone, Extended-Zone, and NewDev-Zone). As shown in Figures 4 and 5,
319 the simulated LST indicated similar yearly dynamics and mean monthly cycles relative to the MODIS
320 LST data. The R values were over 0.8, and the $RMSE$ and Er values were lower than 0.5°C and 2.3%
321 for the morning and evening times, respectively. These results indicated that the simulated LST values
322 closely captured the temporal variations and spatial patterns of the MODIS LST data for Beijing and the
323 three subzones.

324
 325 **Figure 3.** Spatial distribution of the simulated LST compared to the MOD11A2 product, with the average
 326 LST shown in the upper left of the figure.

327
 328 **Figure 4.** Yearly dynamics of the simulated LST compared to the MOD11A2 product for Beijing and the
 329 three functional zones (i.e., Core-Zone, Extended-Zone, and NewDev-Zone).

330

331 **Figure 5.** Mean monthly cycle of the simulated LST compared to the MOD11A2 product for Beijing and the
 332 three functional zones (Core-Zone, Extended-Zone, and NewDev-Zone).

333 In regard to station-scale comparison, the model produced satisfactory LST estimates for the annual
 334 dynamics and during the winter and summer seasons (Figure 6). Specifically, the overall *RMSE* was
 335 lower than 1.9 °C, *R* was higher than 0.9, and *Er* was lower than 7% at the annual scale. During the
 336 winter and summer seasons, the *RMSE* values were lower than 1.7 °C, the *R* values were higher than
 337 0.7, and *Er* was approximately 24.9% in winter and -0.2% in summer. The high *Er* value during the
 338 winter season could be attributed to the low average winter LST. The comparison at each site also
 339 indicated promising results (Table 3), with all *Ers* values lower than 12% and all *RMSE* values below
 340 1.8 °C. It is important to note that the stations generally provided only five available values, i.e., annual
 341 data for the 2016 to 2020 period. Nevertheless, the *R* values for all the stations consistently exceeded
 342 0.4, indicating the satisfactory performance of the VIC-urban model.

343
 344 **Figure 6.** Monthly simulated LST validated against 14 ground-based observation stations, which are marked
 345 in different colours.

346 **Table 3.**
 347 The simulated LSTs from VIC-urban and VIC-orig models are validated by 14 ground-based observations at
 348 an annual scale. The results of three indexes (*Er*, *R* and *RMSE*) are shown in the table, with the better results
 349 underlined.

Station	<i>Er</i> (%)		<i>R</i>		<i>RMSE</i>	
	VIC-urban	VIC-orig	VIC-urban	VIC-orig	VIC-urban	VIC-orig

350 **4.2 Runoff**

351 The model was further calibrated using the streamflow data for the QXZH and BYCH watersheds
 352 and validated against the streamflow data for the WY, QXZH, and BYCH watersheds (Figure 7). During
 353 the calibration period, the *NSE* and *R* values for the QXZH and BYCH watersheds were approximately
 354 0.5 and 0.8, respectively, and the *Er* and *RMSE* values were below 10% and 4 mm/month, respectively,
 355 for both watersheds. During the validation period, the simulated runoff showed a high correlation with
 356 the observed data of the three watersheds, with *R* ranging from 0.8 to 0.9 and *NSE* ranging from 0.6 to
 357 0.8. The *RMSE* reached approximately 4 mm/month at QXZH, 5 mm/month at BYCH, and 42 mm/yr

358 at WY. The Er values were approximately 12% (QXZH), 29% (BYCH), and -9.5% (WY), respectively.

359 The overestimations at QXZH and BYCH and the underestimation at WY could likely be attributed
 360 to the limitations of the VIC-urban model in considering human activities. Specifically, the model did
 361 not consider water allocation for industrial use in the upstream region of the city (QXZH and BYCH)
 362 or the impact of industrial and domestic wastewater at the city centre (WY). Er of the WY watershed
 363 showed an increasing trend, particularly after 2013, which could be attributed to the increasing
 364 wastewater discharge. Despite these limitations, the VIC-urban model demonstrated an acceptable
 365 performance in simulating runoff.

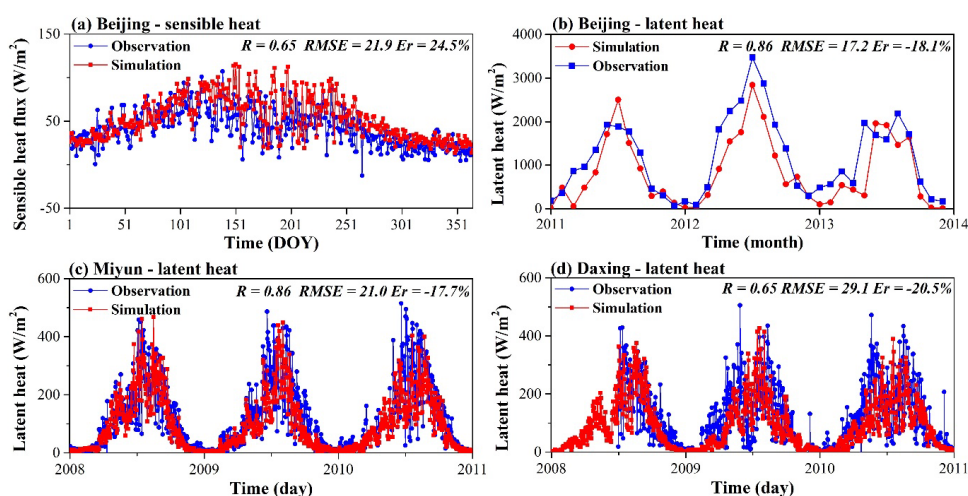

366
 367 **Figure 7.** Evaluation of the simulated runoff. (a) QXZH; (b) BYCH; and (c) WY. The dark dotted line
 368 divides the data into the calibration period (before) and validation period (after).

369 **4.3 Turbulent heat fluxes**

370 The VIC-urban model was evaluated regarding the sensible and latent heat using the observed

371 data of three stations: Beijing, Miyun, and Daxing. As shown in Figure 8a, the simulated sensible heat
372 flux agrees well with the observed value at the Beijing station. R is approximately 0.65, and the $RMSE$
373 and Er are below 22 W/m^2 and 25%, respectively. Regarding the latent heat (Figure 8b, c, d), the
374 simulated values exhibit high correlations (R s) with the observed data at the Beijing and Miyun
375 stations (~ 0.86), and R at the Daxing station is approximately 0.65. Additionally, the $RMSE$ values
376 are below 30 W/m^2 for all stations, and the Er values vary between -21% and -17% .

377
378 **Figure 8.** Evaluation of the sensible and latent heat flux simulations. (a) Sensible heat flux at the Beijing
379 flux tower; (b) latent heat flux at the Beijing flux tower; (c) latent heat flux at the Miyun flux tower; (d) latent
380 heat flux at the Daxing flux tower.

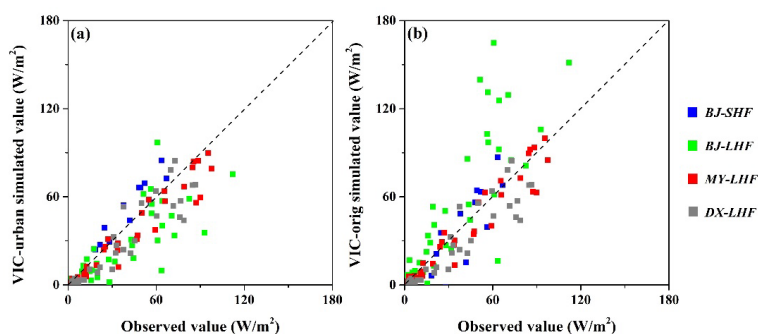

381 4.4 Comparison with the original VIC

382 The performance of the VIC-urban model and the original VIC model (VIC-orig) were compared
383 in terms of the simulated turbulent heat fluxes, LST, and runoff. As shown in Figure 9, the simulation
384 results of the VIC-urban and VIC-orig models showed similar patterns at the Miyun and Daxing stations.
385 However, at the Beijing station, with a high degree of urbanization, the VIC-urban model provided a
386 better performance for both the latent heat and sensible heat fluxes. Specifically, the VIC-urban model
387 yielded a smaller $RMSE$ ($\sim 21.2 \text{ W/m}^2$) for the latent heat flux than that of the VIC-orig model (~ 35.4

388 W/m^2) and attained a higher correlation with the observed sensible heat flux (R of 0.92) than the VIC-
389 orig model (R of 0.81) at the Beijing site.

390 In terms of the LST, the VIC-urban model simulations show a lower discrepancy from the MODIS
391 product, especially at the city centre, and the average LST difference is less than $0.5\text{ }^\circ\text{C}$ for both the
392 morning and evening times (Figure 10). However, the average LST difference is larger than $1.8\text{ }^\circ\text{C}$ when
393 using the VIC-orig model. Regarding temporal comparison (Figures 3 and 4), the VIC-urban model
394 simulations show similar patterns to those in the MODIS data, while the VIC-orig model simulations
395 tend to overestimate the LST at the morning time and underestimate the LST at the evening time in
396 Extended-Zone. The VIC-urban model also outperforms the VIC-orig model at the station scale, as
397 indicated by the higher R and lower Er and $RMSE$ values (Table 3).

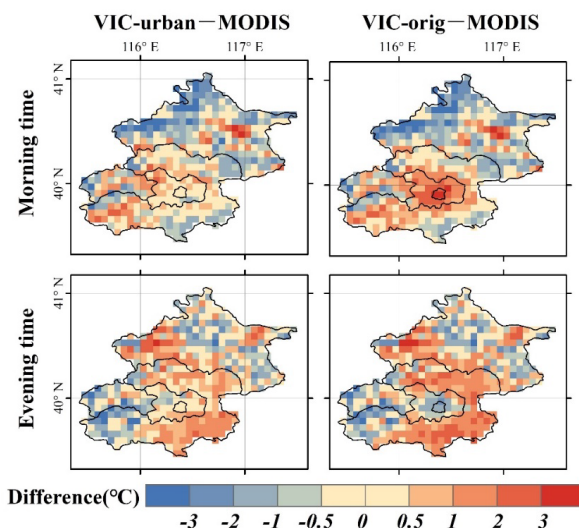

398 **Figure 9.** Simulated yearly turbulence heat fluxes of the VIC-urban and VIC-orig models compared to the
399 observed data. The blue points denote the comparison of the sensible heat flux at the Beijing station, and the
400 green, red and grey points denote the comparisons of the latent heat flux at the Beijing, Miyun, and Daxing
401 stations, respectively.
402

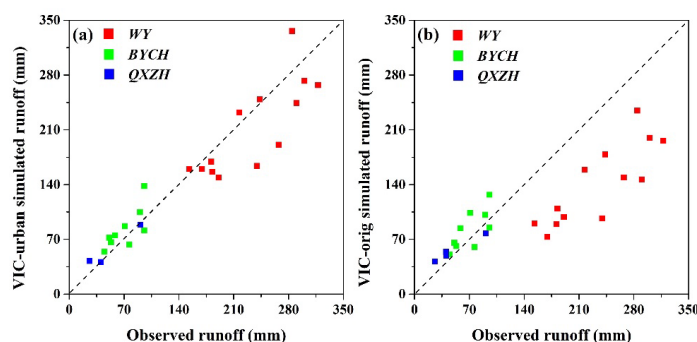

403 Regarding runoff (Figure 11), the VIC-urban and VIC-orig models exhibit similar performance
404 levels for both the BYCH and QXZH watersheds. However, the VIC-orig model obviously
405 underestimates runoff in the WY watershed, which has a high urban coverage. The $RMSE$ values of the
406 VIC-orig and VIC-urban model simulations for WY are 98.3 and 41.8 mm/yr, respectively. Based on
407 the comparisons above, it is evident that the VIC-urban model outperforms the original VIC model in

408 analysing urban-related processes and can capture more realistic hydrological and thermal processes in
 409 cities.

410
 411 **Figure 10.** Spatial distribution of the LST differences between the MODIS LST and the simulated LST of
 412 the VIC-urban model (left), and between MODIS LST and the simulated LST of the VIC-orig model.

413
 414 **Figure 11.** Simulated yearly runoff of the VIC-urban and VIC-orig models compared to the observed data.
 415 The red, green, and blue points denote the comparisons in the WY, BYCH, and QXZH watersheds,
 416 respectively.

417 4.5 Sensitivity analysis

418 We further calculated the sensitivity of the hydrothermal process-related urban input parameters,
 419 that is, we calculated the impact on four indicators (i.e., roof temperature and evaporation and canyon
 420 temperature and evaporation). Regarding the roof (Figure 12 a, b), Emissivity_R and Albedo_R

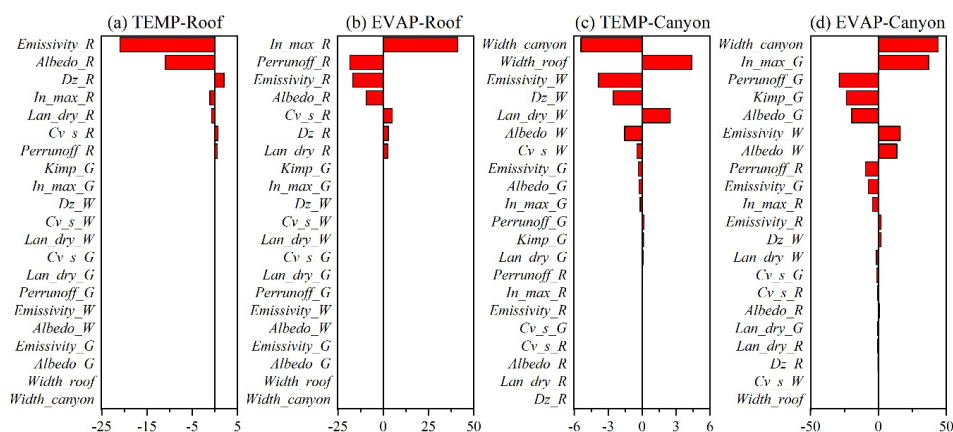

421 generally exhibited high sensitivity to the roof temperature, with sensitivity coefficients of -21% and
422 -11% , respectively. The changes in `In_max_R`, `Perrunoff_R`, `Emissivity_R` and `Albedo_R` exerted
423 obvious impacts on roof evaporation, with values of 41% , -19% , -10% , and -8% , respectively.

424 Regarding the sensitivity of the canyon environment (Figure 12 c, d), `Width_canyon` (-5%) and
425 `Width_roof` (4%) imposed the greatest impact on the canyon temperature, followed by `Emissivity_W`
426 (-4%), `Dz_W` (-3%), `Lan_dry_W` (3%), and `Albedo_W` (-2%). In terms of canyon evaporation,
427 `Width_canyon` (44%) and `In_max_G` (37%) yielded the highest impact, followed by `Perrunoff_G`
428 (-29%), `Kimp_G` (-23%), `Albedo_G` (-20%), `Emissivity_W` (16%) and `Albedo_W` (14%). An
429 interesting finding is that the wall parameters (e.g., `Emissivity_W`, `Albedo_W`) generally imposed a
430 greater influence on the canyon temperature, while the ground parameters exerted a higher influence on
431 canyon evaporation. The sensitivity coefficients of all parameters are listed in Supplementary Table 2.

432 Supplementary Figures 1 and 2 show the urban environment (roof and canyon temperature and
433 evaporation) changes with increasing parameter value during the summer and winter seasons. The urban
434 environment exhibited diverse patterns under parameter increase, rather than simply following linear
435 trajectories. An interesting discovery is that the `Dz_R` and `Lan_dry_R` parameters showed opposite
436 impacts on the roof temperature during the summer and winter seasons. This inconsistency could be
437 attributed to their role in regulating heat transfer between indoor and outdoor environments. Specifically,
438 indoor temperatures are higher than outdoor temperatures in winter and lower in summer. A higher
439 thermal conductivity (i.e., higher `Lan_dry_R` and lower `Dz_R` values) will increase the outdoor surface
440 temperature in winter and decrease it in summer. Similarly, the parameters related to heat conduction
441 (e.g., `Dz_W` and `Lan_dry_G`) in canyon exerted contrasting impacts on the canyon environment during
442 the summer and winter seasons. Moreover, parameters such as albedo and emissivity directly exerted

443 negative impacts on both the roof and canyon temperatures and evaporation levels. Their effects on roofs
 444 are generally similar between winter and summer, and their impact on canyons is more pronounced in
 445 summer than in winter.

446
 447 **Figure 12.** Sensitivity coefficients of the parameters to the urban environment: (a) Roof temperature; (b) roof
 448 evaporation; (c) canyon temperature; and (d) canyon evaporation.

449 5. Discussion

450 5.1. Enhanced performance of VIC-urban in urban systems

451 The urban module described above is among the first attempts to establish a systematic urban
 452 environment in the solution of the energy and water budget in the VIC model. The VIC-urban model
 453 incorporates detailed representations of urban canyons, urban geometry, and human influences. The
 454 model therefore provides favourable estimates of various components of the energy and water balance
 455 (e.g., surface runoff, evaporation, and LST) of each urban surface (i.e., roof, canyon, ground, and sunlit
 456 and shaded walls).

457 In each urban tile, the VIC-urban model calculates the incoming radiation of each surface based on
 458 geographic information, solar time, and geometric parameters. It then estimates energy budgets using
 459 an iterative approach that considers radiative interactions and energy balance principles (Meili et al.,

460 2020). In water balance calculation, the model simulates the hydrological processes of the ground and
461 roof individually and assumes that roof runoff contributes to the groundwater input. Additionally, given
462 the distinct characteristics of urban areas, where excess water on a given surface tends to remain in place
463 rather than immediately exiting the system (e.g., flat roofs and ground), the model includes a runoff
464 component to more comprehensively represent water movement in urban environments.

465 The VIC-urban model was assessed based on the data of multiple gauge stations and MODIS LST
466 data and compared to the original VIC model in Beijing urban areas. The results indicated that the VIC-
467 urban model achieves excellent performance, with *RMSE* values below 0.5 and 1.8 °C relative to the
468 MODIS LST and gauge station data, respectively, and lower than 30 W/m² and 6 mm/month in turbulent
469 heat and runoff evaluation, respectively. Importantly, the VIC-urban model outperforms the original VIC
470 model in urban areas. It largely reduces the discrepancy between the simulated and observed values,
471 successfully capturing higher LST and runoff values at the urban center. These findings suggest that the
472 VIC-urban model is a valuable tool for reliable analysis of urban areas.

473 **5.2 Advantages of the VIC-urban model**

474 The development of the VIC-urban model provides a new urban modelling option. It employs the
475 canyon concept, which has been widely used in UCMs and coupled models (Oleson and Feddema, 2020;
476 Li et al., 2016a; Sun and Grimmond, 2019). Compared to UCMs, which often neglect heterogeneity
477 within urban areas (Kusaka et al., 2001; Meili et al., 2020). The VIC-urban model offers high
478 customizability with urban configurations and simulates hydrothermal processes at the grid cell scale.
479 It can merge hydrothermal inputs at the subcity scale to enhance its potential for accurately predicting
480 the water and energy balance in complex urban systems.

481 Large-scale urban models provide advantages in detecting hydrothermal dynamics in urban

482 environments due to their consideration of surface heterogeneity within a city. For instance, the CLMU
483 model incorporates a building energy model that considers convection and longwave radiation exchange
484 with interior building surfaces (Oleson and Feddema, 2020). The LM3-UCM model can simulate carbon
485 exchange and considers dynamic transitions between urban, agricultural, and unmanaged tiles (Li et al.,
486 2016a). However, these models often use constant land cover and radiation parameters over time. The
487 VIC-urban model can continuously capture land cover and radiation dynamics by integrating remote
488 sensing products. Furthermore, it incorporates a comprehensive thermally conductive framework that
489 considers three distinct layers (i.e., outdoor environment, interior building, and indoor environment) and
490 two vertical wall layers. These features are crucial for identifying long-term urban-induced
491 environmental changes and providing a comprehensive understanding of the urban environment.

492 **5.3 Limitations**

493 The current version of the VIC-urban model still has certain limitations. First, the model lacks the
494 water and energy balance related to snow melting, as well as certain anthropogenic disturbances (e.g.,
495 drainage systems, air conditioning, and car exhaust) (Liu et al., 2021). These factors may impose a
496 significant impact on the urban environment and need to be further studied and incorporated into the
497 model. Second, the model does not consider horizontal interactions between land cover types and water
498 and energy transfer in the subsoil beneath impervious surfaces due to impermeable characteristics.

499 Third, the module does not explicitly formulate the type of urban vegetation (i.e., vegetation or
500 trees in cities), which may play an important role in the hydrology and energy cycle of cities (Meili et
501 al., 2020; Wang et al., 2018). Nevertheless, the VIC-urban model divides the study area of interest into
502 grids and categorises urban vegetation as forests and/or grasslands, thus estimating the water and energy
503 balance. Moreover, the VIC-urban model introduces new parameters (Table 1) that should be estimated

504 or calibrated before the simulation, and these parameters may cause substantial uncertainties. Notably,
505 parameters such as `In_max_R` (maximum infiltration rate) and height-to-width ratio are influential on
506 estimating urban temperature and evaporation patterns, as illustrated in Subsection 4.5. Cities worldwide
507 exhibit diverse configurations and various human influences, leading to differing empirical parameters
508 of influence. The VIC-urban model therefore requires more evaluations in cities with diverse urban
509 environments.

510 **6. Conclusion**

511 In this study, we developed a new urban module in the VIC model, demonstrated its reliability and
512 estimated the sensitivity of the model parameters. Adopting Beijing as an evaluation site, the VIC-urban
513 model showed promising performance regarding the simulation of sensible heat, latent heat, runoff, and
514 LST. Moreover, the VIC-urban model could better capture the LST and runoff patterns at the city centre
515 than the original VIC model. The sensitivity analysis revealed that the parameters of emissivity (i.e.,
516 `Emissivity_R`) and maximum interception capacity of the roof (i.e., `In_max_R`) generally exert the
517 greatest impacts on the roof temperature and evaporation, respectively, and the height-to-width ratio
518 imposed the highest impact on the canyon temperature and evaporation.

519 The current version of the VIC-urban model still holds substantial uncertainties due to its
520 parameters and related processes and the lack of consideration of human disturbances such as horizontal
521 interactions, air-conditioning systems and snow dynamics. However, our work is among the first
522 attempts to establish a systematic urban estimation within the VIC model, and the model is suitably
523 formulated with detailed subcity configurations, human influences, and radiative balance and
524 interactions. By considering the unique characteristics of urban areas and land cover and radiation
525 dynamics, the VIC-urban model provides a more realistic representation of urban hydrology and thermal

526 dynamics. Therefore, the model can be a valuable tool for detecting and understanding water and energy
527 processes in urban areas, and for improving the prediction of hydrothermal fluxes and states of the urban
528 environment.

529 **Code and data availability**

530 The codes of the VIC-urban, and example file for urban parameters are available at
531 <https://doi.org/10.5281/zenodo.10258321>. The original VIC model is available at
532 <https://vic.readthedocs.io/en/master/Overview/ModelOverview/>, and the urban module refers to
533 <https://doi.org/10.5194/gmd-13-335-2020> (Meili et al., 2020). The MODerate-resolution Imaging
534 Spectroradiometer (MODIS) datasets used in this study are available at <https://modis.gsfc.nasa.gov/>. The
535 Global LAnd Surface Satellite (GLASS) products are available at www.glass.umd.edu.

536 **Author contributions**

537 Yibing Wang designed and implemented the model, performed the analysis, and wrote the manuscript.
538 Xianhong Xie proposed and supervised the study, wrote and revised the manuscript. Bowen Zhu, Arken
539 Tursun, Fuxiao Jiang created the figures and wrote Supplementary Section 1. Yao Liu, Dawei Peng, Buyun
540 Zheng wrote Supplementary Section 2. All authors gave comments and discussions to the study.

541 **Competing interests**

542 The contact author has declared that neither of the authors has any competing interests.
