34 **Abstract.** The optimal choice of the planetary boundary layer (PBL) parameterization scheme is of
35 particular interest and urgency to a wide range of scholars, especially for many works involving
36 models. At present, there have been many works to evaluate the PBL schemes. However, little
37 research has been conducted into a more comprehensive and systematic assessment of the
38 performance capability of schemes in key regions of China, especially when it comes to the
39 differences in the mechanisms of the schemes themselves, primarily because there's scarcely
40 sufficient observational data, computer resources, and storage support to complete the work. ~~In
41 addition, there are many factors that influence the selection of schemes, such as underlying surface,
42 initial and boundary conditions, near surface layer scheme, horizontal/vertical resolution, etc.~~ In
43 this Part (i.e., Part I), four typical schemes (i.e., YSU, ACM2, BL and MYJ) are selected to
44 systematically analyze and evaluate near-surface meteorological parameters, PBL vertical structure,
45 PBL height (PBLH), and turbulent diffusion ~~coefficient (TDC)~~ in five key regions (i.e., North China
46 Plain, NCP; Yangtze River Delta, YRD; Sichuan Basin, SB; Pearl River Delta, PRD and Northwest
47 Semi-arid, NS) of China in different seasons (i.e., January, April, July and October). The differences
48 in the simulated 2-m temperatures between the nonlocal closure schemes are mainly affected by the
49 downward shortwave radiation, but to compare the nonlocal closure schemes with the local closure
50 schemes, the effect of sensible heat flux needs to be further considered. ~~In terms of temporal
51 variation, the simulated results for July are better than the other three months, and the simulated
52 results for nighttime are better than daytime. In terms of regional distribution, the temperature at
53 stations with higher elevation is easily underestimated, while overestimated with lower elevation.
54 The variation of relative humidity corresponds to temperature.~~ The 10-m wind speed is under the
55 influence of factors like the momentum transfer coefficient and the integrated similarity functions
56 at night. The wind speeds are more significantly overestimated in the plains and basin, while less
57 overestimated or even underestimated in the mountains, as a result of the effect on topographic
58 smoothing in the model. Moreover, the overestimation of small wind speeds at night is attributable
59 to the inapplicability of the Monin-Obukhov similarity theory (MOST) at night. The model captures
60 the vertical structure of temperature well, while the wind speed is outstandingly overestimated
61 below 1000 m, largely because of the ~~turbulent diffusion coefficient (TDC)~~. The difference between
62 the MOST and the mixing length theory, PBLH and Prandtl number is cited as the reason for the
63 difference between the TDC of the YSU and ACM2 schemes. The TDCs of the BL and MYJ
64 schemes are affected by the mixing length scale, which of BL is calculated on the basis of the effect
65 of buoyancy, while MYJ calculates it with the consideration of the effect of the total turbulent
66 kinetic energy. The PBLH of the BL scheme is better than the other schemes because of the better
67 simulation results of temperature. ~~The difference in the PBLH by the YSU and ACM2 scheme
68 mainly comes from the Richardson number and the jagged PBLH of the MYJ scheme is due to the
69 coarse vertical resolution and the threshold value.~~

70 In general, to select the optimal scheme, it is necessary to offer different options for different regions
71 with different focuses (heat or momentum). (1) Temperature field. The BL scheme is recommended
72 for January in the NCP region, especially for Beijing, and the MYJ scheme is better for the other
73 three months. The ACM2 scheme would be a good match for the YRD region, where the simulation
74 differences between the four schemes are small. The topography of the SB region is more complex,
75 but for most of the areas in the basin, the MYJ scheme is proposed, but if more stations outside the
76 basin are involved, the BL scheme is recommended. The MYJ scheme is applied to the PRD region
77 in January and April, and the BL scheme in July and October. The MYJ scheme is counselled for
78 the NS region. (2) Wind field. The YSU scheme is recommended if the main concern is the near-
79 surface layer, and the BL scheme is suggested if focusing on the variation in the vertical direction.
80 ~~The Part II will analyse and evaluate the factors that may influence the choice of the schemes and~~
81 ~~the results of model.~~The final evaluation of the parameterization scheme and uncertainties will lay
82 the foundation for the improvement of the modules and forecasting of the GRAPES_CUACE
83 regional model developed independently in China.

84 1 Introduction

85 The planetary boundary layer (PBL) is the part of the troposphere that is directly influenced by the
86 force of the earth's surface with an hour or less timescale(R. B. Stull, 1988). Parameterization is the
87 determining factor in the predictive accuracy and skill as it determines key aspects of simulated
88 weather(Bauer et al., 2015; Williams, 2005). In numerical weather prediction, meagre
89 computational resources limit the resolution of the model. Following this reason, physical processes
90 cannot be resolved by the model in that the spatial scales are smaller than the model grid distance.
91 The physical module in the model that characterizes small scales relative to the model resolution is
92 called the sub-grid physical process parameterization scheme(Zhou et al., 2017). As a typical sub-
93 grid parameterization scheme, the spatial scale of turbulence is limited by the PBL height (PBLH)
94 and cannot be resolved by mesoscale weather prediction models and macroscale global climate
95 models with horizontal grid distances of magnitude of ~10 km and ~100 km. Therefore, the physical
96 module in the model that describes the effect of sub-grid turbulence on resolvable atmospheric
97 motion is called the PBL parameterization scheme. Even in the high resolution large-eddy
98 simulation (LES), small-scale turbulence requires parametric closure to characterize the role of sub-
99 grid turbulence(Deardorff, 1980). The PBL parameterization scheme controls the evolution of
100 momentum, heat, water vapor, and mass within the PBL, and the evolution of these parameters is
101 particularly affected by the turbulent diffusion coefficients (TDCs)(W. Jia and Zhang, 2021;
102 Nielsen-Gammon et al., 2010; Oke et al., 2017). Depending on the turbulence closure method, the
103 PBL parameterization schemes can be divided into three main categories: nonlocal closure schemes,

104 local closure schemes, and hybrid nonlocal-local closure schemes, and the above schemes have their
105 own advantages and disadvantages(Cohen et al., 2015; Hu et al., 2010; Wenxing Jia and Zhang,
106 2020; Xie et al., 2012).

107 Since the early 1980s, the vertical diffusion scheme based on local gradients of wind and potential
108 temperature (i.e., local K-theory) has been applied in the National Centers for Environmental
109 Prediction (NCEP). However, as pointed out by many scholars, this scheme has many deficiencies,
110 of which the most critical is that the mass and momentum transport within the PBL is mainly
111 accomplished by the large-scale eddies besides the local small-scale eddies(Roland B. Stull, 1984;
112 Wyngaard and Brost, 1984). Therefore, the new scheme developed later incorporates a counter-
113 gradient flux term to characterize the turbulent transport processes in large-scale eddies, such as
114 Medium-Range Forecast (MRF) scheme (i.e., nonlocal closure) (Hong and Pan, 1996; Troen and
115 Mahrt, 1986). This scheme has also been commonly used in China's self-developed
116 Global/Regional Assimilation and PrEdiction System (GRAPES) model because of its
117 computational simplicity and its ability to produce plausible results under typical atmospheric
118 conditions (Ma et al., 2021). Nevertheless, the MRF scheme has gradually shown some
119 shortcomings, the most typical being that when the wind speed is strong, the resulting mixing is too
120 strong and thus the PBLH is too high to be realistic(Mass et al., 2002; Persson et al., 2001). To
121 overcome this critical problem, one of the most commonly used and popular PBL parameterization
122 scheme has been introduced, which is the Yonsei University (YSU) scheme(Hong et al., 2006). YSU
123 scheme adds an additional entrainment term to the MRF scheme for explicitly calculating the
124 entrainment process of heat and momentum fluxes(Noh et al., 2003). It is still unclear why this
125 scheme is popular among scholars, either because it gives the best simulation results or simply
126 because the code of this scheme is 1, which is more convenient for the model setting. To be contrast,
127 a newer scheme, as a nonlocal scheme of the same series, has been developed that further considers
128 the issue of gray-zone of sub-grid scale turbulence, but this scheme has been rarely used and
129 evaluated (Hong and Shin, 2013).

130 Repairing the defects of local K-theory is possible by developing nonlocal closure schemes on the
131 one hand, and higher-order local closure method on the other hand. The most representative is the
132 higher-order closure scheme of the M-Y series proposed by Mellor and Yamada, such as Mellor-
133 Yamada-Janjic (MYJ) scheme and Mellor-Yamada Nakanishi and Niino Level 2.5/3
134 (MYNN2/MYNN3) scheme(Janjic, 1990, 1994; Mellor and Yamada, 1974, 1982; Nakanishi and
135 Niino, 2004). The higher-order closure schemes are capable of representing a well mixing PBL
136 structure, however, these schemes are computationally more expensive due to the addition of a
137 prognostic turbulent kinetic energy (TKE). In addition to the widely used local closure schemes of
138 the M-Y series, there is another local closure scheme that has been evaluated extensively. This
139 scheme is the Bougeault and Lacarrere (BL) scheme(Bougeault and Lacarrere, 1989), but there are

140 several differences between the BL and M-Y schemes. (1) In the parameterization of the turbulent
141 heat flux, an additional counter-gradient flux term is taken into account in the convective PBL, but
142 this counter-gradient term is different from that in the nonlocal closure scheme, which is a constant
143 ($= 0.7 \cdot 10^{-5} \text{ K cm}^{-1}$) in the BL scheme. (2) The turbulent diffusion coefficient in the BL scheme
144 is calculated similarly to the M-Y schemes, but the stability functions and mixing length are different
145 from M-Y schemes.

146 In addition to the typical nonlocal closure schemes and local closure schemes, there are also hybrid
147 nonlocal-local closure schemes, typically represented by the Asymmetric Convective Model version
148 2 (ACM2) scheme. ACM2 scheme operates based on the development of ACM1 that is modified
149 based upon the Blackadar convective model(Blackadar, 1962). The upward transport within the PBL
150 is mainly by buoyancy, which is transmitted upward from the lowest level to other levels, while
151 downward is transported level-by-level(Pleim, 2007). The deficiency of the ACM1 scheme is that
152 upward transport is not better represented when the vertical resolution of the model increases. In
153 response to compensating for the shortcomings of the ACM1 scheme, the ACM2 scheme adds level-
154 by-level transport to the upward level. The ACM2 scheme have the highest universality and was
155 most suitable for the study of meteorological elements in desert region(Meng Lu et al., 2018; Wang
156 et al., 2017).

157 At present, a total of 12 PBL parameterization schemes have been developed and evaluated in the
158 currently popular mesoscale Weather Research and Forecasting (WRF) model. The continuous
159 improvement of numerical simulation techniques brings opportunities for the update and
160 development of PBL parameterization schemes. Many scholars hope that by comparing the PBL
161 parameterization schemes, they can select one scheme that better reflects the changes in
162 meteorological parameters (e.g., temperature, relative humidity and wind speed/direction),
163 pollutants and the structures of the PBL. Recent review studies have shown that although many
164 studies on the evaluation and comparison of PBL parameterization schemes have been undertaken,
165 there is still no uniform conclusion on which PBL parameterization scheme performs best(Wenxing
166 Jia and Zhang, 2020). Moreover, most of the evaluation work on PBL parameterization schemes is
167 done for individual cases or a particular region(Avolio et al., 2017; Diaz et al., 2021; Falasca et al.,
168 2021; Ferrero et al., 2018; He et al., 2022; Shen et al., 2022). In spite of those, simulation results for
169 the PBL parameterization schemes are more uniform: (1) the simulation of temperature is better
170 than that of relative humidity, and the simulation of wind speed and direction is worse. (2) The
171 simulation results of the nonlocal closure scheme are better under unstable conditions, while the
172 local closure scheme for stable conditions. However, these general conclusions are open to
173 speculation and debate(Wenxing Jia and Zhang, 2020). Many previous studies have been biased
174 towards the assessment of basic meteorological parameters, of course, which is the basic work. Due
175 to the indirect output of TDC by the model, there are fewer relevant studies to investigate the impacts

176 of turbulent diffusion on meteorological parameters. Moreover, turbulent diffusion is the key factor
177 to control the vertical mixing of momentum and scalars within the PBL. Even if there is not enough
178 turbulence observation data, it can be further analyzed and discussed according to the simulation
179 results. Considering that every type of parameterization scheme should be covered, aimed at
180 remedying the current research deficiencies, this study first selects four typical boundary layer
181 parameterization schemes (nonlocal scheme: YSU, local scheme: MYJ and BL, hybrid nonlocal-
182 local scheme: ACM2) for five typical regions (NCP, YRD, SB, PRD and NS) in China, and then
183 assesses the performance capability of different PBL parameterization schemes in different regions.
184 The reasons for the differences in performance of meteorological parameters between observation
185 and simulation are illustrated in terms of temporal and regional variability. Then, the mechanistic
186 implications behind the differences are explored between schemes. In addition, we further carry out
187 the comparative analysis of the vertical structure of the PBL, turbulent diffusion and the PBLH. The
188 first part of this study (i.e., Part I) aims to be able to have a qualitative and quantitative assessment
189 of the PBL parameterization schemes in different regions for other researchers to use as a reference
190 when doing simulation studies. The second part (i.e., Part II) focuses on the analysis of some
191 uncertain factors that may affect the model simulation results, chiefly including: the influence of
192 meteorological initial and boundary conditions, underlying surface (mainly considering the impact
193 of urban and water bodies), near-surface layer (N-SL) scheme (the PBL and N-SL schemes must
194 match each other), the effect of model version update, the influence of regional horizontal and
195 vertical resolution, etc. We hope that we can dissect the effect of uncertainties from some aspects
196 that we are concerned about.

197 2 Data and methods

198 2.1 Data

199 **Hourly meteorological observation data.** The China Meteorological Administration (CMA) has
200 over 2400 automatic weather stations (AWSs), and the stations record variables such as temperature,
201 relative humidity, pressure, wind speed, wind direction and precipitation amount. In the NCP, YRD,
202 SB, PRD, NS regions, 576 stations, 455 stations, 341 stations, 128 stations, and 55 stations have
203 been selected, respectively (illustrated by gray cross in Fig. 1b-f). Observational data for four
204 months January, April, July and October 2016 have been selected and comparatively analyzed.

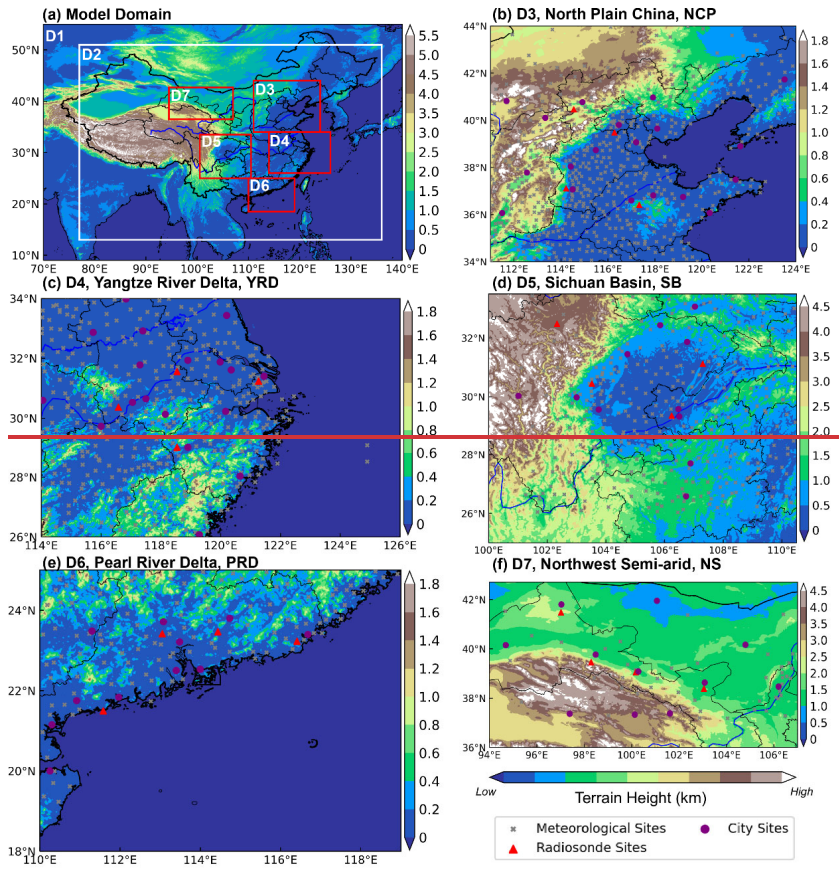

205 **L-band radiosonde observation data.** A total of 120 observation stations are equipped with L-band
206 radiosonde systems in China, which provide fine-resolution (1 Hz, and the rise rate is $\sim 6 \text{ m s}^{-1}$)
207 vertical profiles of temperature, relative humidity and wind speed and direction three times (08:00,
208 14:00 and 20:00 Beijing Time, BJT) a day (illustrated by red triangle in Fig. 1b-f). The accuracy of
209 temperature within the lower troposphere is comparable to that of GPS RS 92 radiosonde, which is

210 less than 0.1 K(Miao et al., 2018). Four sounding stations have been selected for each region,
211 including different underlying surface conditions as much as possible. In the NCP region, two plain
212 stations (Beijing: 116.28°E, 39.48°N; 31.3 m above sea level (a.s.l.) and Xingtai: 114.22°E, 37.11°
213 N; 183.0 m a.s.l.) and two mountain stations (Zhangjiakou: 114.55°E, 40.46°N; 771.0 m a.s.l. and
214 Zhangqiu: 117.33°E, 36.41°N; 121.8 m a.s.l.) have been picked. In the YRD region, one station
215 closer to the ocean (Shanghai: 121.27°E, 31.24°N; 5.5 m a.s.l.), two stations with complex
216 underlying surface (Anqing: 116.58°E, 30.37°N; 62.0 m a.s.l. and Quzhou: 118.54°E, 29.00°N; 82.0
217 m a.s.l.), and one plain station (Nanjing: 118.54°E, 31.56°N; 32.0 m a.s.l.) have been opted. In the
218 SB region, three in-basin stations (Wenjiang: 103.52°E, 30.45°N; 549.0 m a.s.l., Shapingba: 106.24°
219 E, 29.36°N; 541.1 m a.s.l. and Daxian: 107.30°E, 31.12°N; 344.0 m a.s.l.) and one out-of-basin
220 station (Hongyuan: 102.33°E, 32.48°N; 3491.6 m a.s.l., -with an altitude of 3491 m) have been
221 selected. In the PRD region, two plain stations (Qingyuan: 113.05°E, 23.42°N; 78.0 m a.s.l. and
222 Heyuan: 114.44°E, 23.47°N; 60.0 m a.s.l.) and two stations (Yangjiang: 111.58°E, 21.50°N; 85.0 m
223 a.s.l. and Shantou: 116.41°E, 23.23°N; 2.3 m a.s.l.) closer to the ocean have been singled out. In the
224 NS region, along the Qilian mountains, four stations have been chosen, Mazongshan (97.02°E,
225 41.48°N), with an altitude of 1770 m, Jiuquan (98.29°E, 39.46°N), with an altitude of 1477 m,
226 Zhangye (100.17°E, 39.05°N), with an altitude of 1460 m, and Minqin (103.05°E, 38.38°N), with
227 an altitude of 1367 m.

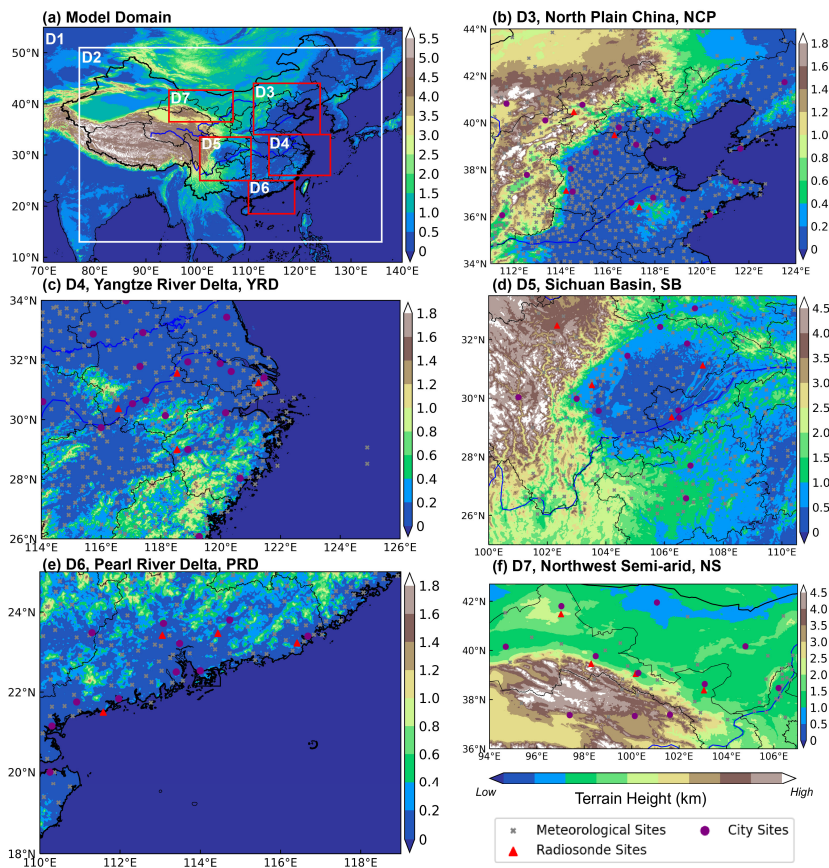

228 2.2 Model settings

229 In this study, we adopt the model WRF-ARW (Advanced Research Weather Research and
230 Forecasting) version 3.9.1 to evaluate the performance of PBL schemes. Long-term three-
231 dimensional simulation experiments are conducted in 1 month of each season of 2016 (i.e., January,
232 April, July and October). Seven nested domains (D1, D2, D3, D4, D5, D6 and D7) are defined (Fig.,
233 1a), with horizontal grid spacings of 75 km (74 × 74 grid cells, 9°N -59°N, 61°E -146°E), 15 km
234 (281 × 281 grid cells, 13°N -51°N, 77°E -136°E), 3 km (331 × 331 grid cells, 34°N -44°N, 111°E
235 -124°E), 3 km (316 × 356 grid cells, 26°N -34°N, 114°E -126°E), 3 km (331 × 331 grid cells, 25°
236 N -33.5°N, 100°E -110°E), 3 km (236 × 301 grid cells, 18°N -25°N, 110°E -119°E), and 3 km (226
237 × 351 grid cells, 36°N -42.7°N, 94°E -107°E), respectively. Along the vertical direction, 48 vertical
238 layers are configured blow the top, and the model top is set to the 50 hPa. To resolve the PBL
239 structure finely, 21 vertical layers are set below 2 km (i.e., the specific setting of vertical levels is σ
240 = 1.000, 0.997, 0.994, 0.991, 0.988, 0.985, 0.980, 0.975, 0.970, 0.960, 0.950, 0.940, 0.930, 0.920,
241 0.910, 0.895, 0.880, 0.865, 0.850, 0.825, 0.800). The initial and boundary conditions of
242 meteorological fields are set up by using the NCEP Global Forecast System (GFS) Final (FNL)
243 gridded analysis datasets, with a resolution of 1° × 1° (<https://rda.ucar.edu/datasets/ds083.2/>, last
244 access: 4 August, 2022). The Moderate Resolution Imaging Spectroradiometer (MODIS) dataset

245 includes 20 land-use categories(Broxton et al., 2014). The physical parameterization used in the
 246 present model is listed in Table 1.

247

248
 249 **Figure 1.** (a) Map of terrain height in the seven nested model domains. (b-f) Domain 3-7 correspond
 250 to the North Plain China (NCP), the Yangtze River Delta (YRD), the Sichuan Basin (SB), the Pearl
 251 River Delta (PRD) and the Northwest Semi-arid (NS), respectively. The locations of surface
 252 meteorological stations and sounding stations are marked by the gray crosses, red triangles,
 253 respectively. The purple dots indicate the major city sites that are our main focus in each region.

255 All simulations embodied a total of 16 months. The 40 h simulation is conducted beginning from
256 00:00 UTC of 1d ago for each day (i.e., 492 simulation experiments), the first 16 h of each
257 simulation is considered as the spin-up period, and results obtained from the following 24 h
258 simulations are analyzed for the present study.

259 2.3 Description of PBL parameterization schemes

260 2.3.1 YSU scheme

261 The YSU is a first-order nonlocal scheme with an explicit treatment entrainment process at the top
262 of the PBL:

$$263 \frac{\partial c}{\partial t} = \frac{\partial}{\partial z} \left[K_c \left(\frac{\partial c}{\partial z} - \gamma_c \right) - \overline{(w'c')_h} \left(\frac{z}{h} \right)^3 \right] \quad (1)$$

264 where c denotes u , v , θ , and the $\gamma_c = b \frac{\overline{(w'c')_0}}{w_{s0}h}$ is the counter-gradient flux term, which increases
265 the nonlocal effect due to the large scale turbulence. z and h are the height of a level of the model
266 and PBLH, respectively. The PBLH is defined by the bulk Richardson number method:

$$267 h = Rib_{cr} \frac{\theta_{va}|U(h)|^2}{g(\theta_v(h) - \theta_s)} \quad (2)$$

268 where g is the gravity, and Rib_{cr} is the critical bulk Richardson number, with a value of 0.25 under
269 stable conditions and 0 under unstable conditions. θ_{va} is the virtual potential temperature at the
270 lowest model level, $\theta_v(h)$ is the virtual potential temperature at h , θ_s is the appropriate
271 temperature near the surface ($\theta_s = \theta_{va} + \theta_T$, θ_T is the virtual temperature increment). Compared
272 to the predecessor of the YSU scheme, the entrainment process is additionally treated explicitly (i.e.,
273 the last term on the right side of the Eq. (1))

274 Another key variable is K_c , which is the turbulent diffusion coefficient (TDC), and can be
275 expressed based on the Monin-Obukhov similarity theory (MOST) as:

$$276 K_c = \frac{\kappa u_* z}{\phi_c} \left(1 - \frac{z}{h} \right)^2 \quad (3)$$

277 where u_* is the surface frictional velocity and ϕ_c is dimensionless function, the expressions for
278 different stability conditions are:

279 i. Unstable and neutral conditions:

设置了格式: 下标

280 $\phi_m = \left(1 - 16 \frac{0.1h}{L}\right)^{-1/4}$ (4a)

281 $\phi_h = \left(1 - 16 \frac{0.1h}{L}\right)^{-1/2}$ (4b)

282 ii. Stable condition:

283 $\phi_m = \phi_h = \left(1 + 5 \frac{0.1h}{L}\right)$ (4c)

284 The TDC of momentum (i.e., K_m) is first calculated in the model, and then the TDC of heat (i.e.,
 285 K_h) is calculated, using the Prandtl number (i.e., $Pr = \frac{K_m}{K_h}$). The TDC controls the vertical mixing
 286 process of momentum and scalars within the PBL, and it is crucial that it needs to be accurately
 287 described.

288 2.3.2 MYJ scheme

289 The MYJ scheme is a one-and-a-half order local closure scheme with a prognostic equation for
 290 turbulent kinetic energy (TKE, $TKE = e = \frac{1}{2}(u'^2 + v'^2 + w'^2)$):

291 $\frac{\partial \bar{e}}{\partial t} = -\frac{1}{\bar{\rho}} \frac{\partial}{\partial z} \overline{w'p'} - \overline{w'u'} \frac{\partial \bar{u}}{\partial z} - \overline{w'v'} \frac{\partial \bar{v}}{\partial z} - \frac{\partial}{\partial z} \overline{w'e'} + \frac{g}{\theta_v} \overline{w'\theta'_v} - \varepsilon$ (5)

292 The first term on the right side of Eq. (5) is a pressure correlation term which describes TKE is
 293 redistributed by pressure perturbations, the second and third terms is a shear production/loss term,
 294 the fourth term represents the turbulent transport of TKE, the fifth term describes the buoyant
 295 production/consumption term, and the sixth term represents viscous dissipation of TKE. To close
 296 the TKE equation, the turbulent fluxes must be parameterized. Based on the gradient transport
 297 theory (i.e., K-theory), the turbulent fluxes can be indicated as:

298 $\overline{w'u'} = -K_m \frac{\partial \bar{u}}{\partial z}$ (6a)

299 $\overline{w'v'} = -K_m \frac{\partial \bar{v}}{\partial z}$ (6b)

300 $\overline{w'\theta'_v} = -K_h \frac{\partial \bar{\theta}}{\partial z}$ (6c)

301 The TDC is proportional to the square root of TKE, and can be expressed as:

302 $K_m = S_m l e^{1/2}$ (7a)

303 $K_h = S_h l e^{1/2}$ (7b)

304 where l is mixing length and can be described as $l = \frac{l_0 \kappa z}{\kappa z + l_0}$, where $l_0 = \alpha \frac{\int_0^\infty z e^{1/2} dz}{\int_0^\infty e^{1/2} dz}$, α is an

305 empirical constant (=0.1). When z converges to a very small value, l converges to κz . However, as
 306 z converges to a very large value, l converges to l_0 .

307 To obtain the S_m and S_h in Eq. (7), G_m and G_h are defined as:

308 $G_m = \frac{l^2}{2e} \left[\left(\frac{\partial \bar{u}}{\partial z} \right)^2 + \left(\frac{\partial \bar{v}}{\partial z} \right)^2 \right] \quad (8a)$

309 $G_h = -\frac{l^2}{2e} \frac{g}{\theta_v} \frac{\partial \theta_v}{\partial z} \quad (8b)$

310 S_m and S_h are functions of G_m and G_h , and can be denoted as:

311 $S_m(6A_1A_2G_m) + S_h(1 - 3A_2B_2G_h - 12A_1A_2G_h) = A_2 \quad (9a)$

312 $A_1(1 + 6A_1^2G_m - 9A_1A_2G_h) - S_h(12A_1^2G_h + 9A_1A_2G_h) = A_1(1 - 3C_1) \quad (9b)$

313 where $[A_1, A_2, B_1, B_2, C_1] = [0.660, 0.657, 11.878, 7.227, 0.001]$.

314 The PBLH in the MYJ scheme is defined as the height at which the TKE is reduced to a critical
315 value of $0.1 \text{ m}^2 \text{ s}^{-2}$.

316 2.3.3 ACM2 scheme

317 Unlike the YSU scheme, the ACM2 scheme applies the transilient matrix to deal with the
318 contribution of nonlocal fluxes. The governing equation can be expressed as:

319 $\frac{\partial C_i}{\partial t} = f_{conv} Mu C_1 - f_{conv} Md_i C_i + f_{conv} Md_{i+1} C_{i+1} \frac{\Delta z_{i+1}}{\Delta z_i} + \frac{\partial}{\partial z} \left[K_c (1 - f_{conv}) \frac{\partial C_i}{\partial z} \right] \quad (10)$

320 The first three terms on the right side of Eq. (10) represent nonlocal mixing effect and the fourth
321 term represents local mixing effect. Where C_i is the variable at layer i , Mu is the nonlocal upward
322 convective mixing rate, Md_i is the downward mixing rate from layer i to layer $i-1$, Δz_i is the
323 thickness of layer i , and C_l represents the variable at the lowest layer in the model. f_{conv} is the
324 weighting factor for the nonlocal and local effects (i.e., $f_{conv} = \frac{K_h \gamma_h}{K_h \gamma_h - K_h \bar{\alpha}}$), where the value of f_{conv}

325 ranges from 0 to 1, a larger f_{conv} indicates stronger nonlocal mixing.

326 There are two methods to calculate the TDC, and the first method is the same as the YSU scheme,
327 i.e., Eq. (3), but there is also a very stable condition in the ACM2 scheme. In this case, the
328 dimensionless function can be expressed as $\phi_m = \phi_h = \left(5 + \frac{0.1h}{L} \right)$.

329 The second calculation principle is based on the mixing length theory, which uses mixing length
330 and stability function to calculate TDC:

331 $K_h = 0.01 + l^2 \sqrt{ss} f_h(Ri) \quad (11)$

332 where l is similar to the MYJ scheme, but l_0 is a constant ($=80$), ss is the wind shear ($ss =$
333 $(\partial \bar{u} / \partial z)^2 + (\partial \bar{v} / \partial z)^2$), 0.01 denotes the minimum value of the TDC in the model, and $f_h(Ri)$ is
334 the empirical stability functions of gradient Richardson number of heat.

335 i. when $Ri \geq 0$:

336 $f_h(Ri) = (1 - 25Ri)^{1/2} \quad (12a)$

337 ii. when $Ri < 0$:

338 $f_h(Ri) = \frac{1}{1 + 10Ri + 50Ri^2 + 5000Ri^4} + 0.0012 \quad (12b)$

339 Similarly, the empirical stability functions of momentum can be indicated as:

340 i. _____ when $Ri \geq 0$:

341 $K_{m\alpha} = Pr \cdot K_{h\alpha}$ (13a)

342 $f_m(Ri) = Pr \cdot f_h(Ri) + 0.00104$ (13a)

343 $K_{m\alpha} = 0.01 + l^2 \sqrt{ss f_m(Ri)}$ (13b)

344 ii. _____ when $Ri < 0$:

345 $K_{m\alpha} = Pr \cdot K_{h\alpha}$ (13c)

346 $f_m(Ri) = Pr \cdot f_h(Ri) + 0.00104$ (13b)

347 $K_m = 0.01 + l^2 \sqrt{ss f_m(Ri)}$ (13c)

348 The ACM2 scheme has a range setting for the TDC in the model with a minimum value of 0.01 m²
349 s⁻² and a maximum value that cannot exceed 1000 m² s⁻².

350 The PBLH discrimination in the ACM2 scheme is similar to the YSU scheme, and is defined with
351 the bulk Richardson number method. The difference is that the entrainment region at the top of the
352 PBL is considered in the ACM2 scheme, and turbulence still exists due to the wind shear and thermal
353 penetration. Therefore, special processing of the PBLH is required under unstable and stable
354 conditions.

355 2.3.4 BL scheme

356 The BL scheme is also a one-and-a-half order local closure scheme, and the TDC is calculated in a
357 similar way to Eq. (7) of the MYJ scheme. Nevertheless, the function S_m and mixing length (i.e., l)
358 are different from the MYJ scheme. In the BL scheme, S_m is a constant 0.4 and the l is divided into
359 upward and downward mixing length (i.e., l_{up} and l_{down}), which are defined as:

360 $\int_z^{z+l_{up}} \beta[\theta(z) - \theta(z')] dz' = e(z)$ (14a)

361 $\int_z^{z-l_{down}} \beta[\theta(z') - \theta(z)] dz' = e(z)$ (14b)

362 where, β is the buoyancy coefficient and the l is equal to the minimum of l_{up} and l_{down} (i.e., $l =$
363 $\min(l_{up}, l_{down})$). It is worth noting that in the BL scheme the TDC of heat is equal to the TDC of
364 momentum (i.e., $K_h = K_m$). In addition, the PBLH of the BL scheme is defined as the height at which
365 the virtual potential temperature of a layer is greater than that of the first layer by 0.5 K.

366 To accommodate different methods of calculating PBLH for different schemes and to evaluate the
367 simulation performance of PBLH, two methods are employed to calculate PBLH using observed
368 data in this study, the first being the bulk Richardson number method, and the detailed calculation
369 principle is as follows (Miao et al., 2018):

370 $Ri(z) = \frac{(g/\theta_s)(\theta_z - \theta_s)(z - z_s)}{(u_z - u_s)^2 + (v_z - v_s)^2 + bu_s^2}$ (15)

371 here z is the height, g is the gravity, θ is the virtual potential temperature, u and v are the components
372 of the horizontal wind, b is a constant, and u_* is the friction velocity. The subscript "s" indicates

带格式的: 正文, 无项目符号或编号

373 the near-surface. Since the friction velocity is much smaller in magnitude than the wind shear, the
 374 b is set to 0, ignoring the effect of surface friction (Vogelezang and Holtslag, 1996; Seidel et al.,
 375 2012). The PBLH is estimated as the lowest layer height when Ri reaches a critical value of 0.25.
 376 The second method adopts the same calculation method as the BL scheme, i.e., the virtual potential
 377 temperature method:
 378 $\Delta\theta_{v|PBLH} = \theta_{v1} + 0.5$ (16)
 379 The PBLH is the height when the virtual potential temperature exceeds the virtual potential
 380 temperature of the first level by 0.5 K.

381 2.4 Evaluation of the model

382 To evaluate the PBL schemes and the performance of the model for estimating meteorological
 383 variables, the statistical parameters used in this statistical analysis are defined as follows(Emery et
 384 al., 2017):

385 Index of agreement (IOA):

$$386 \quad IOA = 1 - \frac{[\sum_{i=1}^n |X_{sim,i} - X_{obs,i}|^2]}{[\sum_{i=1}^n (|X_{sim,i} - \bar{X}_{obs}| + |X_{obs,i} - \bar{X}_{obs}|)^2]} \quad (17)$$

387 Mean bias (MB):

$$388 \quad MB = \frac{1}{n} \sum_{i=1}^n (X_{sim,i} - X_{obs,i}) \quad (18)$$

389 Root mean square error (RMSE):

$$390 \quad RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^n (X_{sim,i} - X_{obs,i})^2} \quad (19)$$

391 Normalized standard deviations (NSD):

$$392 \quad NSD = \frac{\sqrt{\frac{1}{n-1} \sum_{i=1}^n (X_{sim,i} - \bar{X}_{sim})^2}}{\sqrt{\frac{1}{n-1} \sum_{i=1}^n (X_{obs,i} - \bar{X}_{obs})^2}} \quad (20)$$

393 Relative bias (RB):

$$394 \quad RB = \frac{\bar{X}_{sim} - \bar{X}_{obs}}{\bar{X}_{obs}} \times 100\% \quad (21)$$

395 Where $X_{sim,i}$ and $X_{obs,i}$ represent the value of simulation and observation, respectively, i refers
 396 to time and n is the total number of time series. \bar{X}_{sim} and \bar{X}_{obs} represent the average simulation
 397 and observation.

398 The Taylor diagram is a compact tool that displays simultaneously the values of four statistical
 399 parameters: IOA, NSD, RB, and RMSE. In particular, in these diagrams the perfect match of a
 400 model with the observations would be the point with IOA=1, NSD=1, RB=0 and RMSE=0.

401 3 Results and discussion

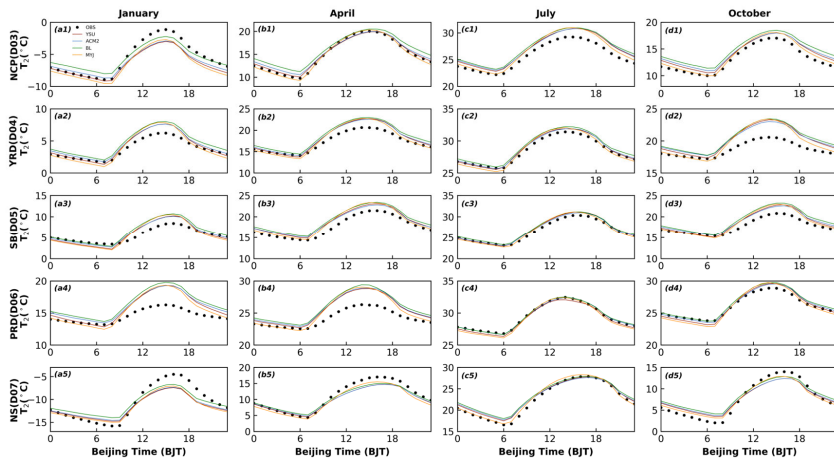

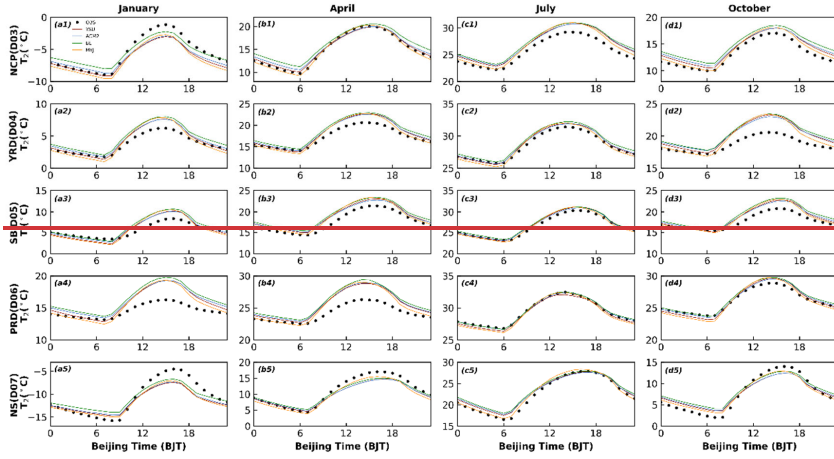

402 In section 3.1, the mechanistic analysis of the PBL schemes for the simulation of near-surface

403 meteorological parameters, including 2-m temperature, 2-m relative humidity, 10-m wind speed and
404 direction. Section 3.2 gives an in-depth analysis of different schemes for PBL vertical structures. In
405 section 3.3, the PBLH was evaluated for different schemes. In section 3.4, the reason for the
406 differences in turbulent diffusion are interrogated from the calculation principle of the schemes.
407 Section 3.5 summarizes the performance and expressiveness of different PBL schemes in different
408 regions, and recommends the optimal choice of PBL scheme.

409 3.1 surface meteorological variables

410 3.1.1 2-m temperature and relative humidity

411 To better analyze the variation of the time series, we selected representative stations in different
412 regions. Figure 2 shows the diurnal variation of 2-m temperature (i.e., T_2) for four months (i.e.,
413 January, April, July and October 2016) at representative sites (indicated in the orange-purple dots in
414 Fig. 1) in the five regions. The model basically captures the daily variation characteristics of T_2 , but
415 there are significant differences between different regions and seasons. The simulated results for
416 July are closest to the observed values (Fig. 2 c1-c5), anywhere. Overall, the mean biases (MBs) of
417 the diurnal variation of T_2 predicted in July for the NCP, YRD, SB, PRD and NS regions are
418 0.61~1.19, -0.02~-0.56, -0.32~-0.60, -0.38~-0.69, and 0.28~0.81 °C, respectively. However, a
419 smaller value of the mean bias does not mean that the simulated value of the model is closer to the
420 observed value. For example, if one overestimation and the other underestimation occur during the
421 day and night, the average results will cancel each other out, resulting in a small mean bias.
422 Accordingly, more statistical parameters are needed to further evaluate the optimal scheme. In the
423 other three months (January, April, and October), the simulated results of T_2 are overestimated to
424 varying degrees during daytime in the YRD, SB and PRD regions, while in the NS region, T_2 are
425 underestimated to varying degrees (Fig. 2 a2-b5, d2-d5 and Table 1). In the NCP regions, T_2 presents
426 underestimation in January by the model with the YSU, ACM2, BL and MYJ schemes are -1.33, -
427 1.21, -0.52 and -1.18 °C, respectively, while overestimation arises in the other three months (Table
428 1). In the five regions, the simulation results of the nighttime T_2 outperform those of the daytime T_2
429 for almost four months. At night, the MYJ scheme shows a significant underestimation of T_2 for all
430 months in five regions compared to the other three schemes (Fig. 2 and Table 1). The simulation
431 results of Hu et al. (2010) and Xie et al. (2012) have also obtained the lowest temperature for the
432 MYJ scheme during the nighttime.

433

434

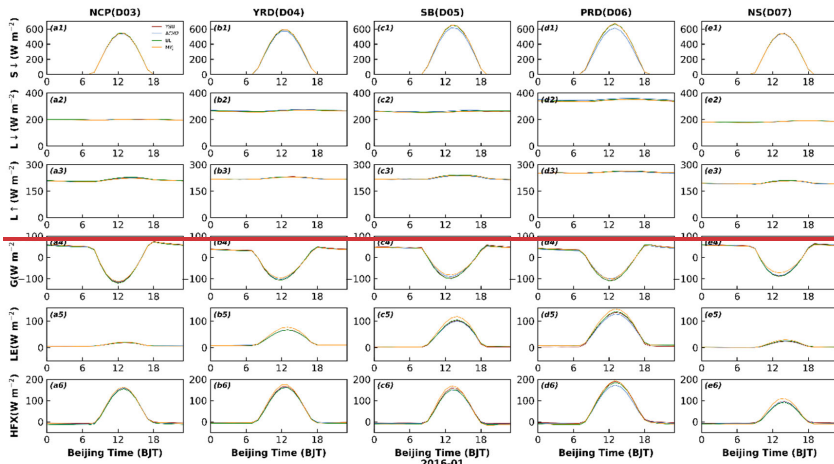

435 **Figure 2. Time series of diurnal variation of observed and simulated 2-m temperature in five**
 436 **regions for four seasons.**

437 The 2-m temperature does not actually represent the air temperature at a height of 2 m, but it is a
 438 diagnostic variable of the near-surface temperature. It is calculated from the surface temperature
 439 (T_s), the sensible heat flux (HFX) and the heat transfer coefficient (C_h). The T_s is a prognostic
 440 variable, which is obtained in the model through the energy balance equation:

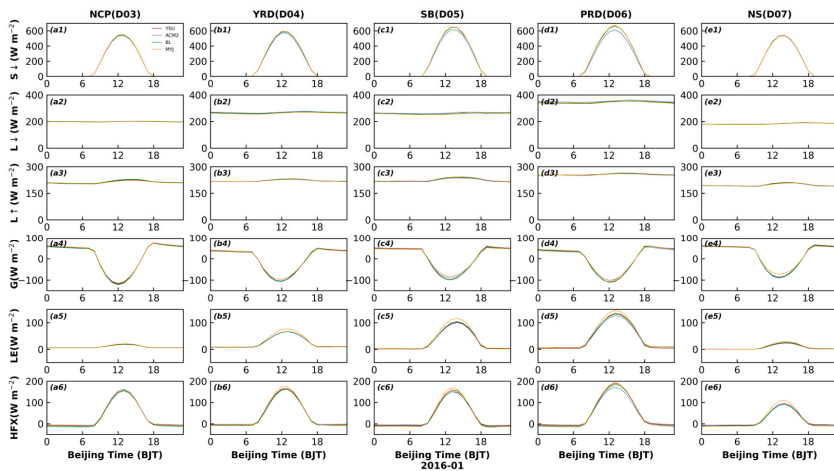

441
$$(1 - \alpha)S \downarrow + L \downarrow - L \uparrow + G - HFX - LH = 0 \quad (22)$$

442 where α is the albedo of the underlying surface, $S \downarrow$ represents the downward of the shortwave
 443 radiation, $L \downarrow$ is the downward of the longwave radiation emitted by the cloud and atmosphere,
 444 $L \uparrow$ is the upward of the longwave emitted by the ground surface, G is the ground heat flux, and it
 445 is positive when heat transfers from the soil to the near surface, HFX is the sensible heat flux and

446 LH is the latent heat flux.
447 We compare the effects of the six variables mentioned above on T_s with the expectation that we can
448 further examine the reasons for the differences in T_2 variation between different schemes. The YSU
449 scheme is used as a control and analyzed in comparison with each of the schemes.
450 The nonlocal closure scheme (YSU) and the local closure scheme (MYJ) are compared first.
451 Theoretically, the greater the downward shortwave radiation ($S \downarrow$) becomes, the more energy reaches
452 the ground, and the higher the surface temperature (T_s) is. After comparing the YSU and MYJ
453 schemes, the surface temperature does not show a proportional change with the downward
454 shortwave radiation, and the $S \downarrow$ of the MYJ scheme is almost the same as that of the YSU scheme
455 (Fig. 3 a1-e1), but the T_s of the MYJ scheme is the lowest (Fig. 4 a1-e1). Therefore, the $S \downarrow$ is not
456 the main factor that causes the difference in T_s between the two schemes. There is no significant
457 difference in the upward/downward longwave radiation between these two schemes (Fig. 3 a2-e3),
458 so the effect of longwave radiation on the T_s can also be excluded. During the daytime, the MYJ
459 scheme transfers less heat from the surface to the soil than the YSU scheme (Fig. 3 a4-e4), and the
460 T_s of the MYJ scheme should be higher than that of the YSU scheme. But that's not how it has
461 turned out (Fig. 4 a1-e1). Thus, the ground heat flux (G) is also not a key factor that directly affects
462 the T_s . The latent heat flux (LH) is mainly related to water vapor (or relative humidity), so further
463 attention is paid to the effect of sensible heat flux (HFX) on T_s (Fig. 3 a5-e6). The HFX is determined
464 by the difference between the surface temperature and the 2-m temperature ($T_s - T_2$), and the heat
465 transfer coefficient (C_h) ($HFX = \rho C_h u_1 (T_s - T_2)$, here, ρ is the air density, u_1 is the wind
466 speed at the first level of the model). MYJ has the largest HFX, and transfers more heat from the
467 surface to the atmosphere, resulting in the largest energy loss at the surface, which should
468 correspond to the smallest T_s (Fig. 3 a6-e6, 4 a1-e1). The smallest difference between the two
469 temperatures indicates a smaller temperature gradient and more uniform mixing, symbolizing the
470 largest C_h , which is also true (Fig. 4 a2-e3). A larger C_h would lead to higher T_2 during the day.
471 Although the T_s of the MYJ scheme is significantly lower than YSU scheme, it makes the T_2 higher
472 due to the large C_h . During the daytime, the less heat is transferred from the surface to the soil in
473 the MYJ scheme, which results in lower soil temperature. During the nighttime, the difference in
474 HFX and temperature gradient between the two schemes decreases, and the lower soil temperature
475 results in lower T_s and T_2 .

476

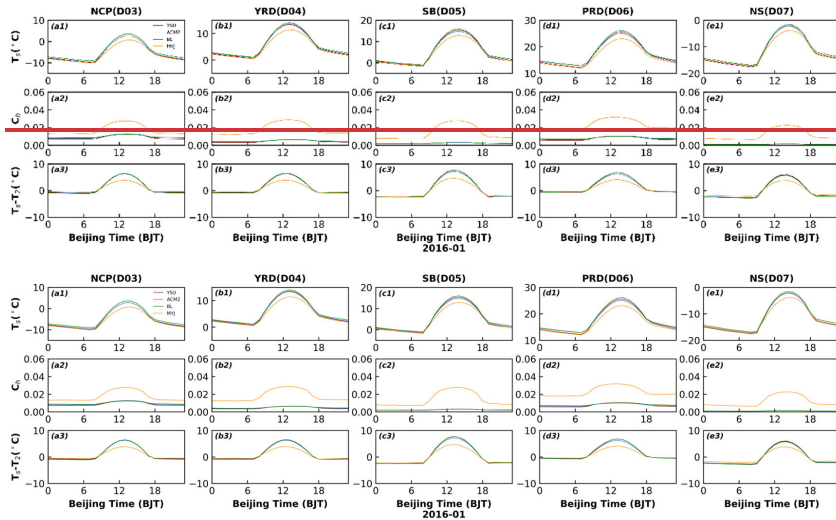

477

478 **Figure 3.** Time series of diurnal variation of (a1-e1) downward shortwave radiation ($S \downarrow$), (a2-e2)
 479 downward longwave radiation ($L \downarrow$), (a3-e3) upward longwave radiation ($L \uparrow$), (a4-e4) ground heat
 480 flux (G), (a5-e5) latent heat flux (LH), and (a6-e6) sensible heat flux (HFX) by four PBL schemes
 481 in five regions in January.

482 The differences between the YSU scheme and the ACM2 scheme are further explored. Except for
 483 the NCP and NS regions, the $S \downarrow$ of the ACM2 scheme is smaller than that of the YSU scheme in
 484 the other three regions (i.e., YRD, SB and PRD) (Fig. 3 b1-d1). The HFX of the ACM2 scheme
 485 is smaller than that of the YSU scheme (Fig. 3 b6-d6), the heat loss from the surface of the ACM2
 486 scheme is less, and the T_s of the ACM2 scheme should be higher. However, the T_s corresponding to
 487 the ACM2 scheme is lower than that of the YSU scheme (Fig. 4 b1-d1), reflecting that the $S \downarrow$

488 varies proportionally with the T_s , and it is the main factor controlling the T_s variation. In the ideal
 489 case, assuming the same temperature gradient for the nonlocal schemes, the T_2 of the YSU scheme
 490 should also be higher than that of the ACM2 scheme when the T_s of the YSU scheme is higher than
 491 that of the ACM2 scheme with the same C_h . But in fact, it can be seen that the C_h of the ACM2
 492 scheme and YSU scheme are the same (Fig. 4 b2-d2), and the temperature gradient of the YSU
 493 scheme is greater than that of ACM2 scheme (Fig. 4 b3-d3). The T_2 of the ACM2 scheme should be
 494 slightly higher than the ideal case, closer to the T_2 of the YSU scheme, and even may also exceed
 495 T_2 of the YSU scheme. At night, the T_s of the YSU scheme is lower than that of the ACM2 scheme,
 496 and the C_h of the YSU scheme is smaller than that of the ACM2 scheme (Fig. 4 a1-e2). Meanwhile,
 497 the difference in HFX between the two schemes is not obvious at night, contributing to lower T_2 of
 498 the YSU scheme. In both NCP and NS regions, there is no significant difference in downward
 499 shortwave radiation between two schemes, and no noticeable difference between T_2 and T_s .

500

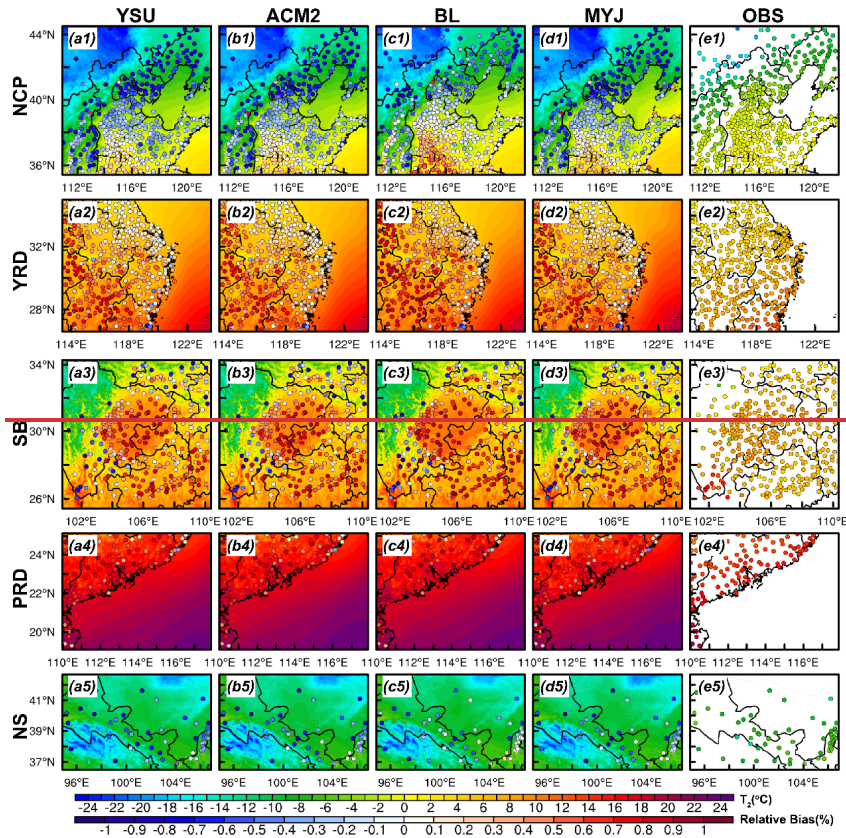

501

502 **Figure 4. Time series of diurnal variation of (a1-e1) surface temperature (T_s), (a2-e2) heat transfer**
 503 **coefficient (C_h) and (a3-e3) the difference between the surface temperature and the 2-m**
 504 **temperature ($T_s - T_2$) by four PBL schemes in five regions in January (Winter).**

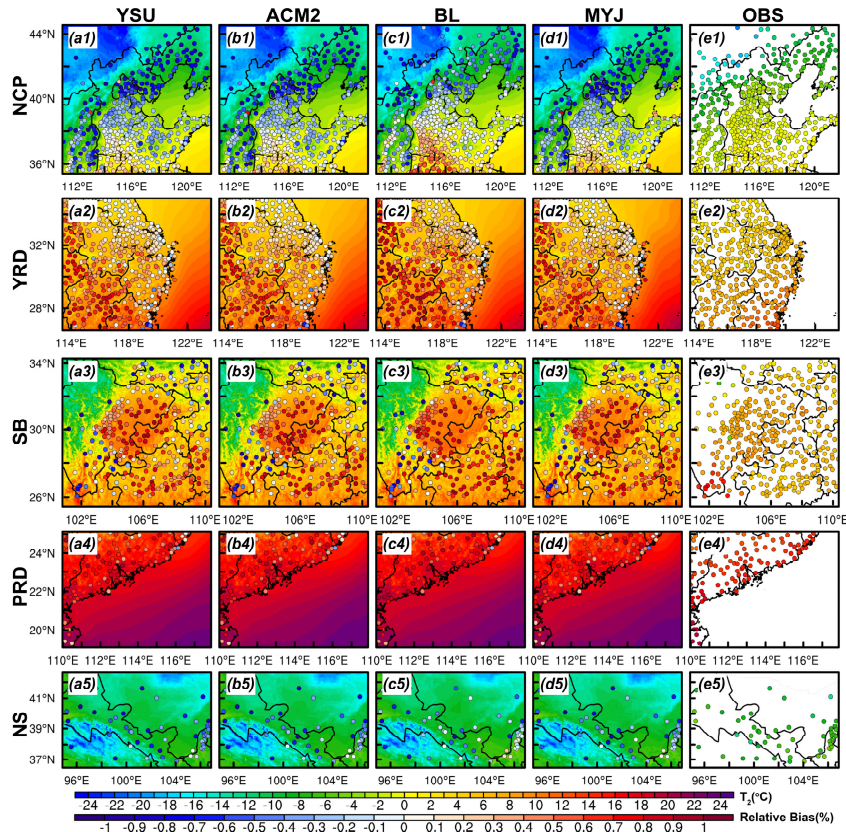

505 Then, the reasons for the simulated temperature difference between the YSU scheme and the BL
 506 scheme are demonstrated. During the daytime, the $S \downarrow$ of both schemes are the same (Fig. 3 a1-e1),
 507 but the HFX of the BL scheme is smaller than that of the YSU scheme (Fig. 3 a6-e6), less heat is
 508 loss at the surface, hence the T_s should be higher than that of the YSU scheme (Fig. 4 a1-e1). The
 509 C_h of both schemes are the same, thus, the BL scheme has a higher T_2 (Fig. 2, 4a1-e2). At night, the
 510 HFX of BL scheme is larger than that of YSU scheme, and more heat is transferred from atmosphere
 511 to the surface, and the larger C_h resulting in higher T_2 (Fig. 3 a6-e6, 4 a1-e2).

512 Finally, we can also uncover the reasons for the difference between the local closure schemes (MYJ
 513 and BL). The larger HFX of the MYJ scheme leads to a lower T_s in the daytime, while the
 514 temperature gradient of MYJ scheme is smaller than that of the BL scheme, and C_h is larger than
 515 BL scheme (Fig. 3 a6-e6, 4). Therefore, the difference in T_2 between the two schemes is smaller
 516 than that in T_s . The T_2 of the MYJ scheme is closer to that of the BL scheme.
 517 In conclusion, the causes of temperature differences simulated by the nonlocal closure schemes
 518 should first focus on the effect of the downward shortwave radiation ($S \downarrow$), and when it comes to the
 519 local closure scheme, the effect of HFX should be further concerned. All of the above results have
 520 been analyzed for January 2016, and the results for the other three months are similar (Figs. S1-S6).
 521 The results for the months of January, April and October differ slightly from those of July. In terms
 522 of regional distribution differences, T_2 in the northern and near mountainous regions of the NCP
 523 region is significantly underestimated in the daytime for January, April and October, while T_2 in
 524 other areas of the NCP region regions shows an overestimation (Fig. 5, S7, S8 a1-e1). The range of
 525 overestimated areas is smaller than the underestimated in January, only in a small part of the area
 526 south of Hebei and Shandong pProvinces (Fig. 5 a1-e1). The relative bias (RB) of the
 527 underestimated (overestimated) T_2 with the YSU, ACM2, BL and MYJ schemes are -0.60% (0.15%),
 528 -0.57% (0.17%), -0.43% (0.26%) and -0.60% (0.20%), respectively in January. Also in these three
 529 months, temperature is overestimated at almost all stations in the YRD region (RB=0.38%~0.50%
 530 in January, RB=0.49%~0.65% in April and RB=0.58%~0.70% in October) and underestimated at
 531 some stations along the coast (RB=-0.13%~-0.24% in January, RB=-0.32%~-0.37% in April and
 532 RB=-0.23%~-0.28% in October) (Fig. 5, S7, S8 a2-e2). The results show an overestimation of T_2
 533 simulated in those stations in the basin for the SB region as well as the simulation results of the
 534 stations in the plain for the NCP region, while for the stations in the hilltop areas, the T_2 shows an
 535 underestimation (Fig. 5, S7, S8 a3-e3). In the PRD region, the entire region exhibits an
 536 overestimation of T_2 , with the simulation results in October (RB=0.06%~0.15%) being significantly
 537 better than those in January (RB=0.59%~0.81%) and April (RB=0.56%~0.67%), with a lower
 538 degree of T_2 overestimation (Fig. 5, S7, S8 a4-e4). The BL scheme simulates a higher T_2 and a large
 539 range of overestimated areas (about 167, 378, 252 and 100 stations in NCP, YRD, SB and PRD
 540 regions). The NS region has a more complex topography and higher elevation, and the T_2 is
 541 underestimated at almost all stations, with best simulation results in October (RB=-0.04%~-0.21%)
 542 and worst in April (RB=-0.49%~-0.64%).
 543 For July, when the temperature is higher, the simulation results are significantly different from the
 544 other three months. The relative bias of T_2 simulated with the YSU, ACM2, BL and MYJ schemes
 545 are 0.47%, 0.46%, 0.53% and 0.46%, respectively, in the NCP region. The overestimation results
 546 are similar to daytime, with the most pronounced overestimation for the BL scheme. For the
 547 southern region of the NCP, the T_2 is consistently overestimated regardless of the season (Fig. S9

548 a1-e1). The T_2 at most stations are underestimated in the YRD region, which is different from the
 549 other three months (Fig. S9 a2-e2). In summer, the temperature of the ocean, affected by the
 550 subtropical high (prevailing southeasterly winds), is lower than that of the land, and the transport of
 551 momentum is accompanied by the transport of heat from the sea to the land, causing the temperature
 552 of the land to decrease. The T_2 of the basin area in the SB region is well reproduced, and no
 553 significant overestimation occurs (Fig. S9 a3-e3). There is an underestimation of the T_2 at most
 554 stations in the PRD region, but to a lesser extent (Fig. S9 a4-e4). In contrast, for the NS region, the
 555 temperature is overestimated for areas at lower elevations, while underestimated (or better
 556 reproduced) for areas at higher elevations (Fig. S9 a5-e5).

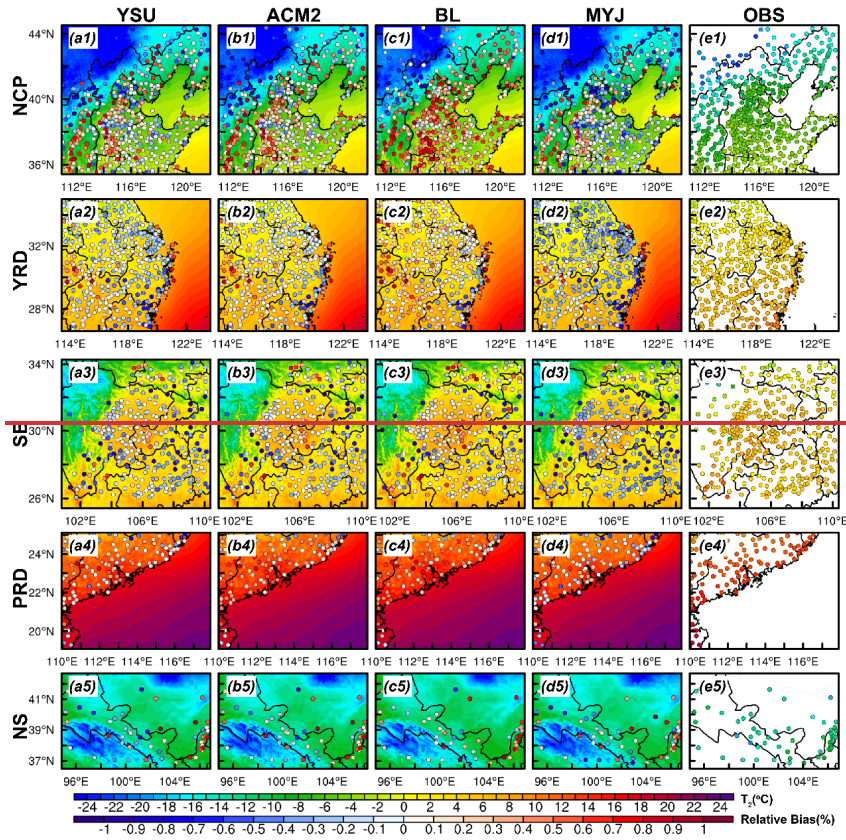

557

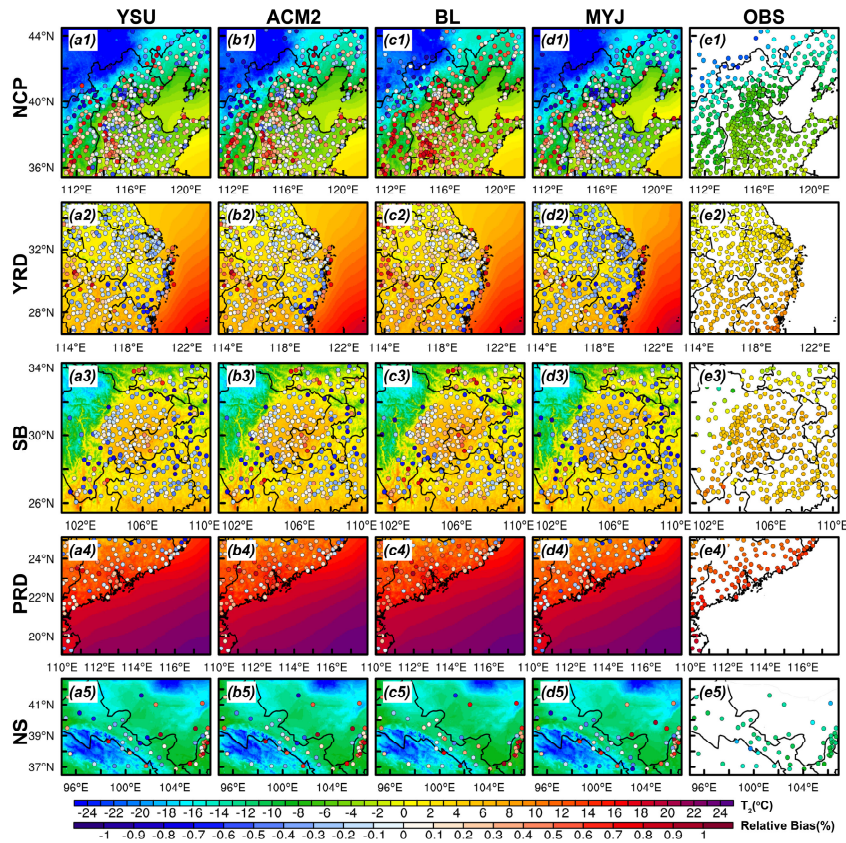

558
 559 **Figure 5.** Regional distribution of 2-m temperature simulated by (a-d) four PBL schemes in five
 560 regions during the daytime in January (Winter), (e1-e5) distribution of observation in five regions,
 561 and (a1-d5) distribution of relative bias between simulations and observations is denoted by
 562 scatters.

563 The relative deviation of the nighttime T_2 simulations is less than that of the daytime, regardless of
 564 the region and month (Fig. 6, S10-S12). The differences between the four schemes are more striking
 565 at night compared to the daytime. The BL scheme simulates the highest T_2 and the MYJ scheme
 566 simulates the lowest T_2 in the whole region (Fig. 6, S10-S12). Compared to the observed values, the
 567 MYJ scheme is the best when all schemes overestimate the simulated temperature, but if there is an
 568 underestimation, the MYJ scheme is no longer the best scheme. Later, a comprehensive statistical
 569 evaluation of the schemes will be presented. For the NCP region, the overestimation and
 570 underestimation in the whole region do not show a north-south divide (or a mountain-plain divide)
 571 as in the daytime (Fig. 5, 6 a1-e1). In the YRD region, the temperature along the coastal area still
 572 shows a significant underestimation (Fig. 6, S10-S12 a2-e2). Similar to the daytime, the temperature

573 at stations in the hill top areas of the SB region still presents an underestimation (Fig. 6, S10-S12
 574 a3-e3). Most stations show the underestimation of T_2 in July and October in the PRD region (Fig.
 575 S11-S12 a4-e4). In the NS region, the relative deviation of temperature simulations in October is
 576 greater than that in daytime (RB=0.17%~0.56%) (Fig. 5, S12 a5-e5).

577

578

579 **Figure 6. Similar as Figure 5, but at night.**

580

In summary, the simulation results of T_2 have the following main characteristics. From the

581

perspective of differences between observations and simulations, (1) the simulation results for July

582

are better compared to the other three months. (2) The simulation results at night are better than

583

those at daytime, with less relative deviation, especially in winter (i.e., January and October). (3)

584

The temperature is easily underestimated at higher altitudes while overestimated in plains and basin

585

areas. From the perspective of the differences between the different schemes, (1) the differences in

586

the performance of the four schemes are more noticeable at night. (2) The difference in the

587

simulation of temperature in the nonlocal closure schemes is mainly attributed to the difference in

588

downward shortwave radiation ($S \downarrow$), and the difference in the variation of sensible heat flux (HFX)

589

needs to be further analyzed when the local closure schemes are involved. (3) The BL scheme

590

simulates the highest temperature and the MYJ scheme for the lowest temperature.

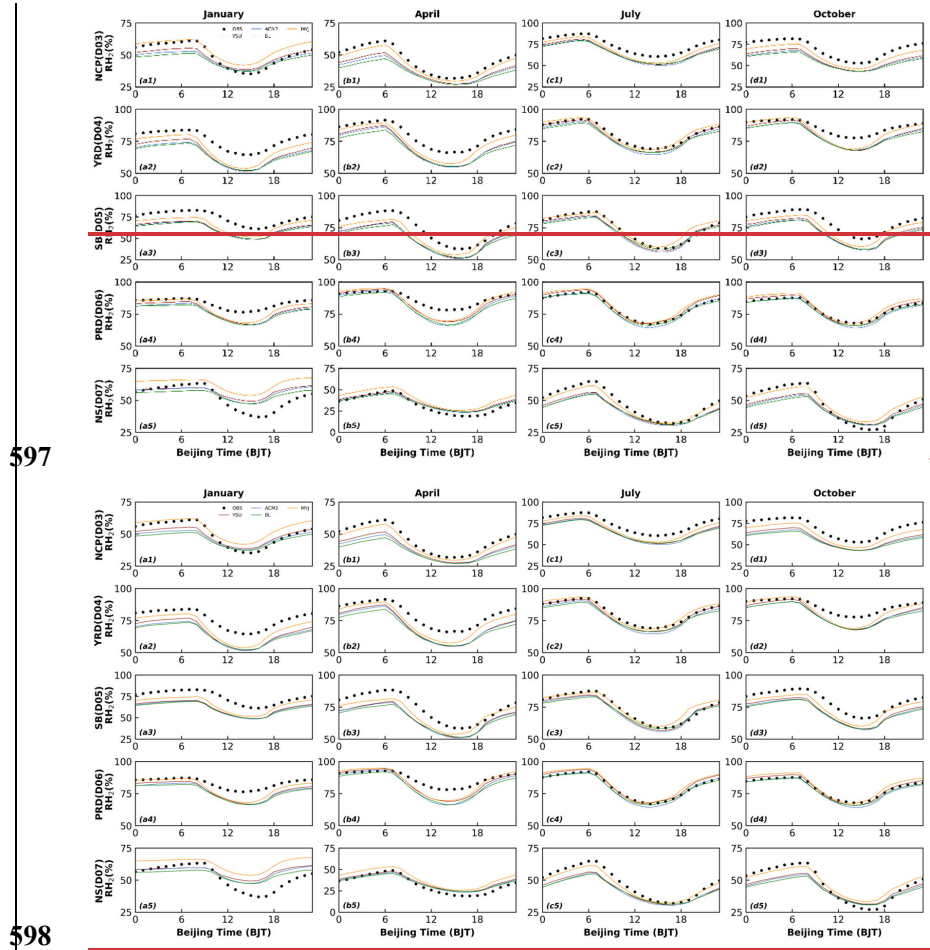

591

The results for 2-m relative humidity (RH_2) and T_2 correspond to each other, and the overestimation

592

of T_2 corresponds to the underestimation of RH_2 . The simulation of RH_2 still shows the best results

593 in July, with the highest simulated values for the MYJ scheme and the lowest for the BL scheme.
 594 Except for the NS region, the simulated RH₂ of the other four regions is almost underestimated.
 595 This uniform trend in relative humidity may be due to errors in the initial field, which will be
 596 discussed in Part II. Too much will not be repeated here (Figs. 2, 7).

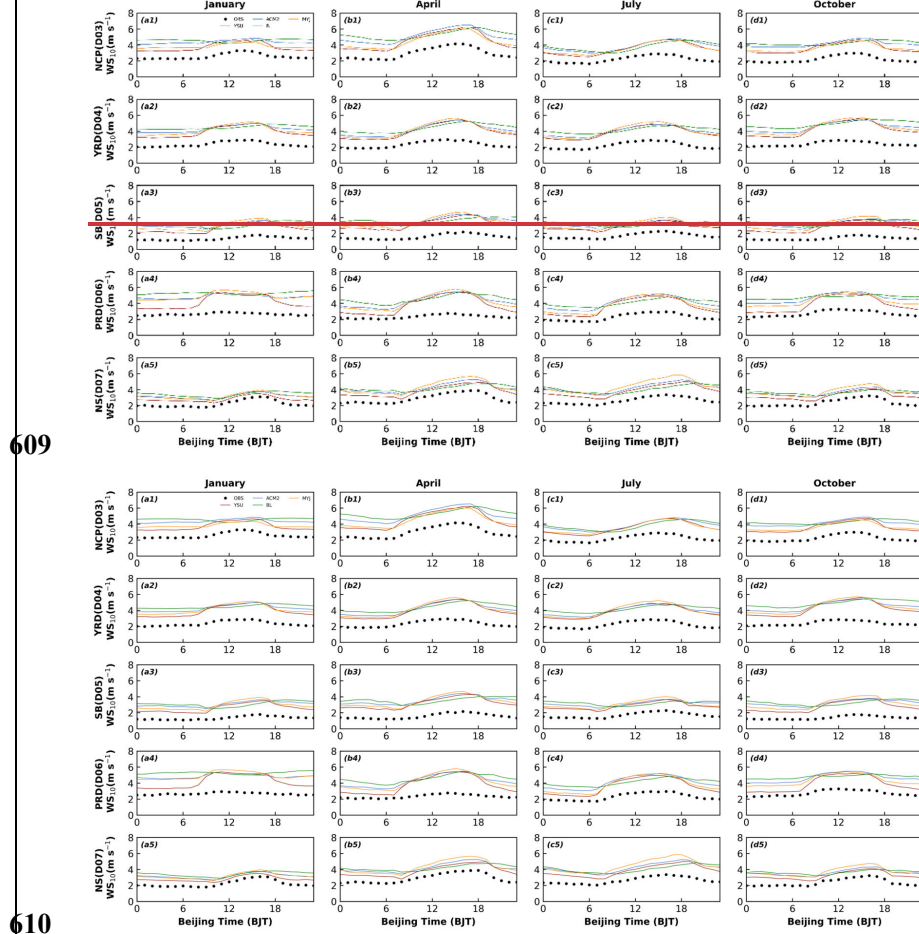

598 Figure 7. Similar as Figure 2, but for 2-m relative humidity.

600 3.1.2 10-m wind speed and direction

601 Although the model simulates the diurnal cycle of wind speed, the wind speed shows different
 602 degrees of overestimation, and the mean bias is in the range of 0.86 m s⁻¹~2.74 m s⁻¹ (Fig. 8, Table
 603 2). This is also the conclusion reached in many previous studies and it is more widely accepted by
 604 the public (Cohen et al., 2015; Wenxing Jia and Zhang, 2020; W. Jia and Zhang, 2021; Jiménez and

605 Dudhia, 2012). Except for the NCP region where the MYJ scheme has the largest mean bias (MB)
 606 value during the day (YSU: MB=1.6 m s⁻¹, ACM2: MB=1.8 m s⁻¹, BL: MB=1.7 m s⁻¹, MYJ: MB=2.1
 607 m s⁻¹), while the BL scheme has the largest MB value at night regardless of the region (YSU:
 608 MB=1.3 m s⁻¹, ACM2: MB=1.8 m s⁻¹, BL: MB=2.2 m s⁻¹, MYJ: MB=1.7 m s⁻¹) (Fig. 8, Table 2).

610
 611 Figure 8. Similar as Figure 2, but for 10-m wind speed.

612 Table 2. Mean bias of 2-m temperature, 2-m relative humidity and 10-m wind speed during daytime
 613 and nighttime by four PBL schemes in five regions and four seasons.

614

615 Similar to T₂, 10-m wind speed (i.e., WS₁₀) is also a diagnostic variable of the near-surface wind
616 speed. For the YSU, ACM2 and BL schemes, in the revised MM5 surface layer scheme, WS₁₀ is
617 calculated based on the Monin-Obukhov (M-O) similarity theory (Monin and Obukhov, 1954). The
618 dimensionless profile function of momentum is denoted as:

619
$$\phi_m \left(\frac{z}{L} \right) = \frac{\kappa z}{u_*} \frac{\partial u}{\partial z} \quad (23)$$

620 where κ is the von Karman constant, u_* is the friction velocity, z is the height, L is the Obukhov
621 length, integrating the Eq. (23) with respect to height z :

622
$$du = \frac{u_*}{\kappa} \left[\frac{dz}{z} - \frac{1 - \phi_m \left(\frac{z}{L} \right)}{\frac{z}{L}} d \left(\frac{z}{L} \right) \right] \quad (24)$$

623 integrate Eq. (24):

624
$$\int_0^u du = \frac{u_*}{\kappa} \left\{ \int_{z_0}^z \frac{dz}{z} - \int_{\frac{z_0}{L}}^{\frac{z}{L}} \left[1 - \phi_m \left(\frac{z}{L} \right) \right] d \ln \left(\frac{z}{L} \right) \right\} \quad (25)$$

625 here, let $\psi_m \left(\frac{z}{L} \right) = \int_0^{\frac{z}{L}} \left[1 - \phi_m \left(\frac{z}{L} \right) \right] d \ln \left(\frac{z}{L} \right)$, where $\psi_m \left(\frac{z}{L} \right)$ is the integrated similarity function

626 for momentum.

627 Therefore, Eq. (25) can be indicated as $u = \frac{u_*}{\kappa} \left[\ln \left(\frac{z}{z_0} \right) - \psi_m \left(\frac{z}{L} \right) + \psi_m \left(\frac{z_0}{L} \right) \right]$, where z_0 is the

628 roughness length.

629 Based on the bulk transfer method, the momentum flux can be represented as $\tau = \rho u_*^2 = \rho C_m u^2$,

630 where τ is the momentum flux, C_m is the bulk transfer coefficient for momentum:

631
$$C_m = \frac{u_*^2}{u^2} = \frac{\kappa^2}{\left[\ln \left(\frac{z}{z_0} \right) - \psi_m \left(\frac{z}{L} \right) + \psi_m \left(\frac{z_0}{L} \right) \right]^2} \quad (26)$$

632 Thus, the wind speed at 10 m divided by the wind speed at a certain height can be written as:

633
$$u_{10} = \frac{u_*}{\kappa} \left[\ln \left(\frac{z}{z_0} \right) - \psi_m \left(\frac{z}{L} \right) + \psi_m \left(\frac{z_0}{L} \right) \right] \cdot \frac{\left[\ln \left(\frac{10}{z_0} \right) - \psi_m \left(\frac{10}{L} \right) + \psi_m \left(\frac{z_0}{L} \right) \right]}{\left[\ln \left(\frac{z}{z_0} \right) - \psi_m \left(\frac{z}{L} \right) + \psi_m \left(\frac{z_0}{L} \right) \right]} = \frac{u_*}{\kappa} \left[\ln \left(\frac{z}{z_0} \right) - \psi_m \left(\frac{z}{L} \right) + \right.$$

634
$$\left. \psi_m \left(\frac{z_0}{L} \right) \right] \cdot \left(\frac{C_m}{C_{m10}} \right)^{1/2} \quad (27)$$

635 where C_{m10} is the transfer coefficient for momentum at 10 m height:

636
$$C_{m10} = \frac{\kappa^2}{\left[\ln \left(\frac{10}{z_0} \right) - \psi_m \left(\frac{10}{L} \right) + \psi_m \left(\frac{z_0}{L} \right) \right]^2} \quad (28)$$

637 Comparing the C_m of the three schemes (i.e., YSU, ACM2 and BL schemes) at night, C_m is the

638 largest for the BL scheme, the second largest for the ACM2 scheme, and the smallest for the YSU

639 scheme (Fig. 9). Correspondingly, the BL scheme simulates the largest WS_{10} , ACM2 the second

640 largest, and the YSU the smallest (Fig. 8). The larger C_m corresponds to the stronger mixing, which

641 transports more momentum from the upper to the lower layers, making WS_{10} increase. Therefore,

642 the bulk transfer coefficient C_m controls the variation of WS_{10} at night. During the daytime, the C_m

643 of the BL scheme is smaller than that of the other two schemes, and the corresponding WS_{10} decrease

644 (Fig. 8, 9). However, the difference among the three schemes is smaller in daytime than that in

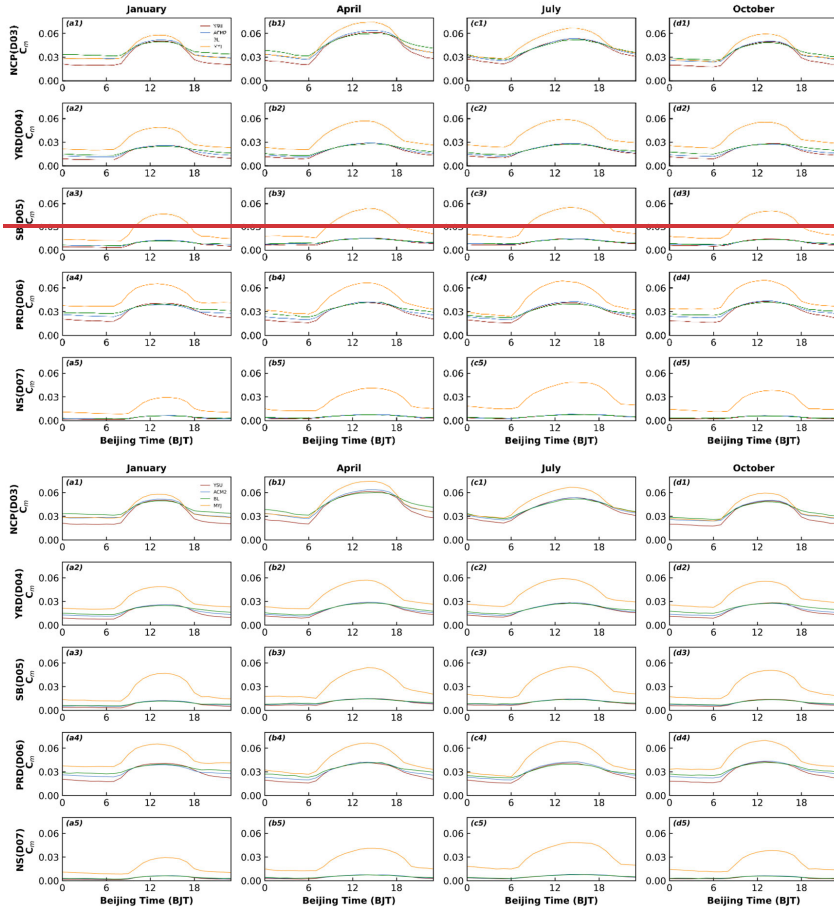

645 nighttime. The reason why the results of C_m and WS_{10} differ with the same calculation method is

646 because of the vertical variation of heat and momentum within the boundary layer involved in the

647 calculation. This will correlate to the vertical diffusion coefficients within the boundary layer that

648 will be discussed further in a later section.

649

650

651 **Figure 9.** Similar as **Figure 2**, but for momentum transfer coefficient (C_m).

652 For the near surface scheme of the MYJ scheme, WS_{10} is calculated according to the near surface
 653 flux profile relationship proposed by Liu et al. (1979):

654
$$u_0 - u_s = D_1 \left[1 - \exp\left(-\frac{z_u u_*}{D_1 \nu}\right) \right] \left(\frac{F_u}{u_*} \right) \quad (29)$$

655 where 0 represents the value at height z above the surface where the molecular diffusivity still plays
 656 a dominant role, s denotes the surface value, D_1 denotes a near surface parameter, u_* is the friction
 657 velocity, ν is the molecular diffusivity for momentum ($=1 \times 10^{-5}$), and F_u is the momentum flux.

658 Since $1 - \exp\left(-\frac{z_u u_*}{D_1 \nu}\right) \approx \frac{z_u u_*}{D_1 \nu}$, $u_0 - u_s = \left(\frac{z_u}{\nu}\right) F_u$.

659 The momentum flux in the surface layer above the viscous sublayer is represented by $F_u =$

660 $\left(\frac{C_m}{\Delta z_e}\right) (u_{low} - u_0)$, here, the subscript *low* denotes the variables at the lowest model level, Δz_e is

661 either the equivalent height of the lowest model level that considers the presence of the “dynamical
 662 turbulence layer” at the bottom of the surface layer (Janjić, 1990). C_m is the bulk transfer coefficient,
 663 defined as:

$$664 \quad C_m = \frac{\kappa u_*}{\ln\left(\frac{z_0+z}{z_0}\right) + \psi_m\left(\frac{z_0+z}{L}\right) - \psi_m\left(\frac{z_0}{L}\right)} \quad (30)$$

665 In Eq. (29), z_u is still an unknown, such that $\frac{z_u u_*}{D_1 v} = \xi$, where ξ is a smaller constant (equal to
 666 0.35 in the model). Here, the near surface parameter D_1 is further defined as $D_1 = C \cdot$

667 $\left(\frac{z_0 u_*}{v}\right)^{1/4}$, where C is a constant ($=30$), the roughness length z_0 as a function of u_* ($z_0 = \frac{0.11v}{u_*} +$

668 $\frac{0.018u_*^2}{g}$), substituting D_1 and z_u to Eq. (29):

$$669 \quad u_0 = \frac{\xi \left[C \left(\frac{z_0 u_*}{v} \right)^{1/4} \right] \left(\frac{C_m}{\Delta z_e} \right) u_{low} + u_s}{1 + \frac{\xi}{u_*} \left[C \left(\frac{z_0 u_*}{v} \right)^{1/4} \right] \left(\frac{C_m}{\Delta z_e} \right)} \quad (31)$$

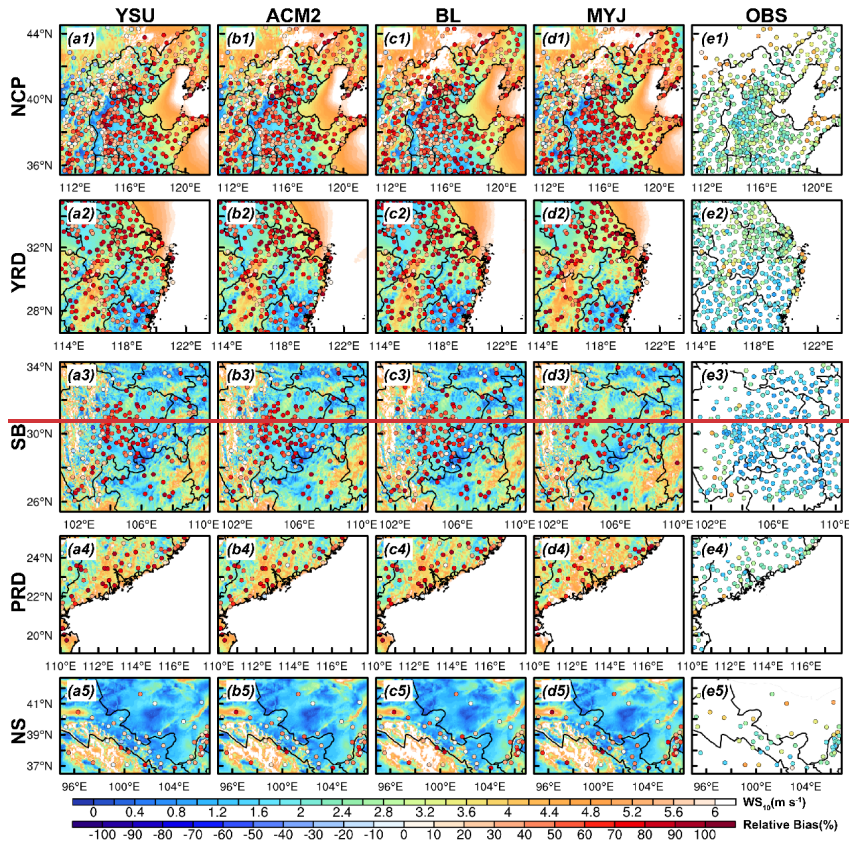

670 The wind speed at a height of 10 m can be expressed as:

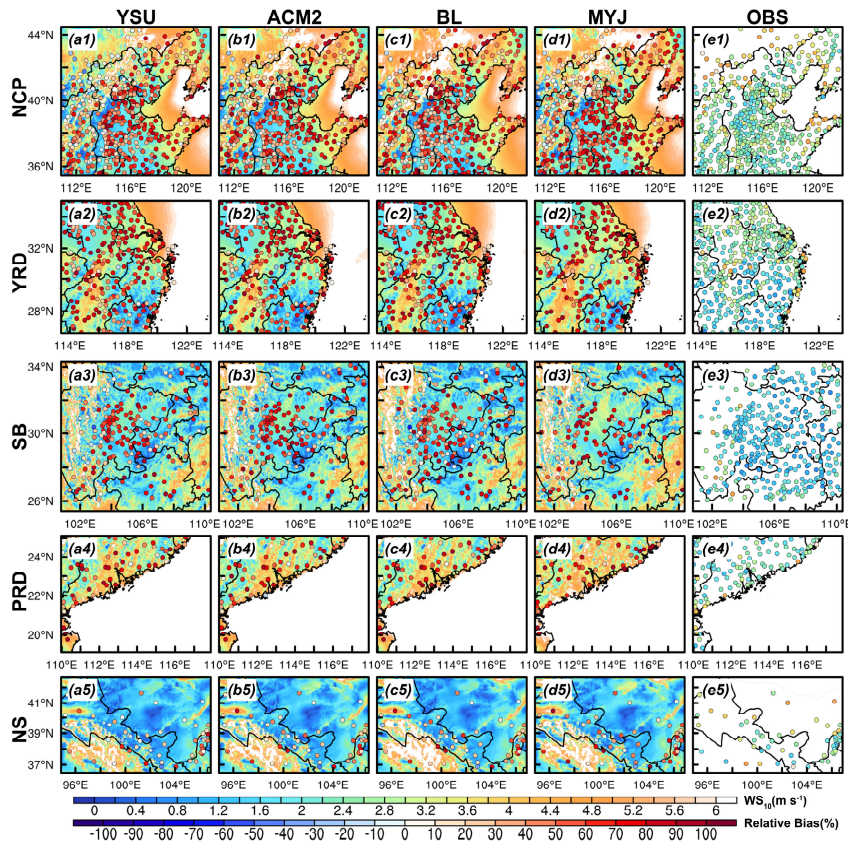

$$671 \quad u_{10} = \frac{F_u \Delta z_e}{C_{m10}} + u_0 = \frac{C_m (u_{low} - u_0)}{C_{m10}} + u_0 \quad (32)$$

672 where C_{m10} is the transfer coefficient for momentum at 10 m height:

$$673 \quad C_{m10} = \frac{\kappa u_*}{\ln\left(\frac{z_0+10}{z_0}\right) + \psi_m\left(\frac{z_0+10}{L}\right) - \psi_m\left(\frac{z_0}{L}\right)} \quad (33)$$

674 Therefore, the C_m of the MYJ scheme is significantly different from the other three schemes. Except
 675 for the NCP region, although the C_m of the MYJ scheme is larger than the other three schemes at all
 676 times of the day, the WS_{10} presents the maximum only during the daytime. This suggests that at
 677 night, the wind speed simulated by the MYJ scheme also be influenced by other factors. For example,
 678 the calculation method of the integrated similarity functions (ψ_m) in the MYJ scheme is different
 679 from the other three schemes. In the other three schemes, the ψ_m is calculated according to four
 680 stability regimes defined in terms of the bulk Richardson number (Zhang and Anthes, 1982). In the
 681 MYJ scheme, the ψ_m is calculated based on two stability regimes by the z/L (Paulson, 1970).

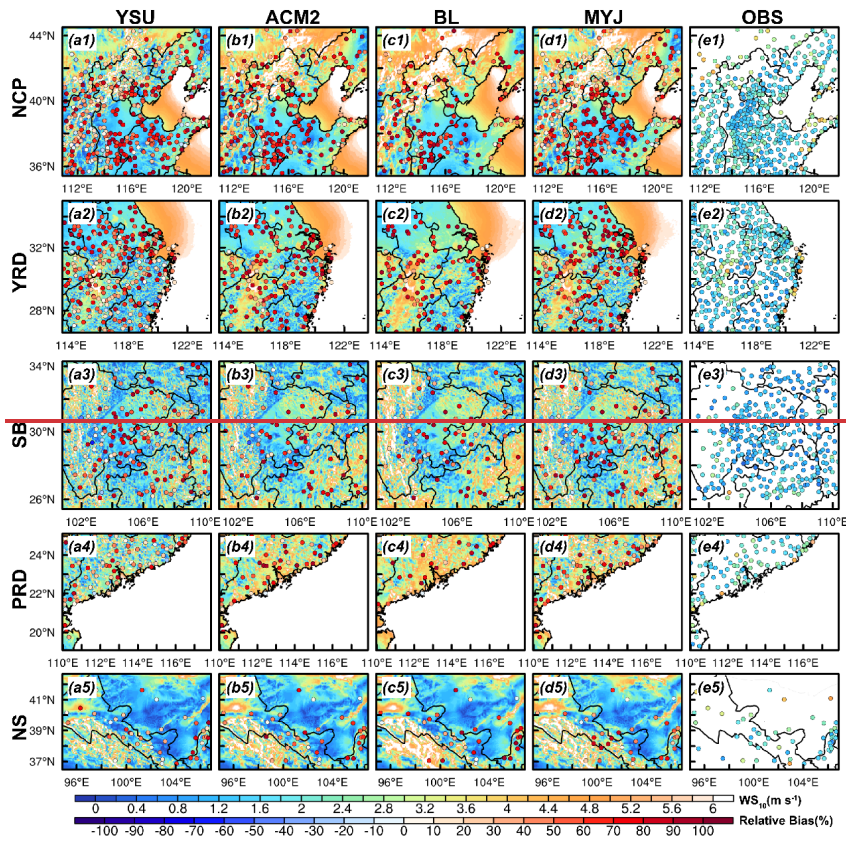

683

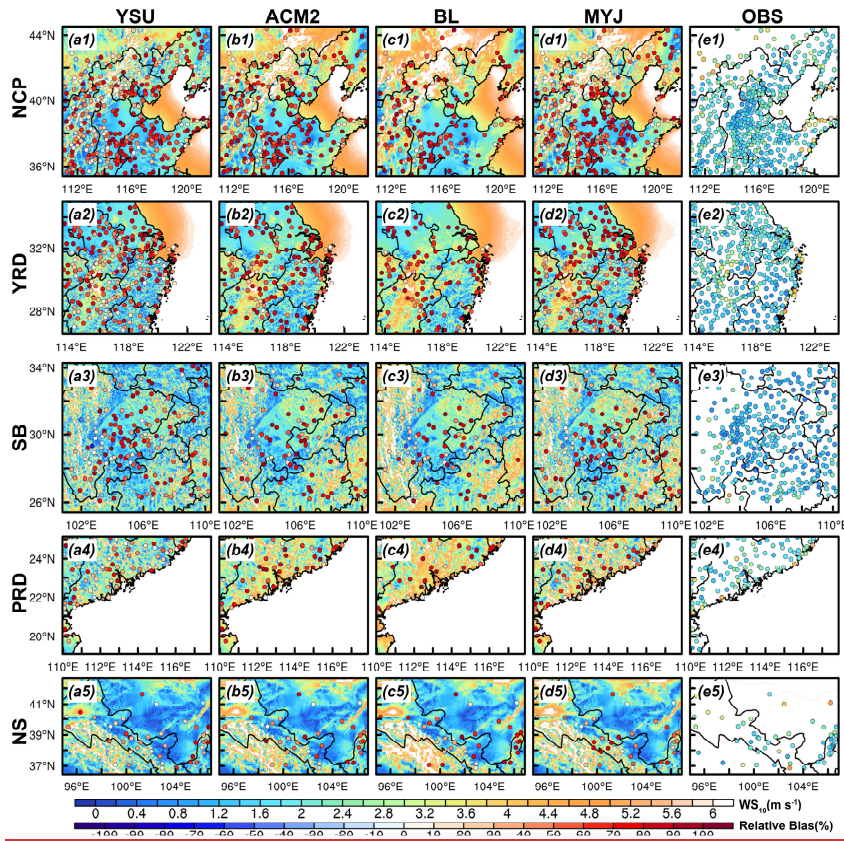

684 **Figure 10. Similar as Figure 5, but for 10-m wind speed.**

685 The reasons for the differences in WS₁₀ simulation are further analyzed in terms of regional
 686 distribution. During the daytime, wind speed is significantly overestimated at most sites throughout
 687 the NCP region, which are centered in the plains and valleys, but is less overestimated and even
 688 underestimated at some sites on the mountain tops (Fig. 10, S13-S15 a1-e1). Wind speed is
 689 overestimated at almost all stations throughout the YRD and PRD regions (Fig. 10, S13-S15 a2-e2,
 690 a4-e4). The WS₁₀ in the basin is importantly overestimated in the SB region, while less
 691 overestimated at hilltop stations on the eastern side of the basin, with higher wind speed being more
 692 pronounced in January (Fig. 10, S13-S15 a3-e3). In the NS region, wind speed is overestimated to
 693 a lesser extent than in other regions, but for regions with lower wind speed, the relative bias (RB)
 694 is larger, especially in July (Jan: RB=29.3%~49.1%, Apr: RB=32.0%~55.6%, Jul:
 695 RB=44.2%~78.7%, Oct: RB=42.7%~65.7%). Comparing the simulation results of the four schemes,
 696 the MYJ scheme simulates the most significantly overestimated wind speed and the least
 697 overestimated for the YSU scheme (Fig. 10, S13-S15). In comparison with the four months, it is

698 found that the RB of the simulation is the largest for the month with slower wind speed (i.e., July).
699 At night, the wind speed is overestimated at almost all stations in the whole region of NCP, and the
700 overestimation is greater at the hilltop stations than during the day (Fig. 11, S16-S18). The other
701 four regions are more similar to the daytime (Fig. 11, S16-S18). However, by comparing the four
702 schemes, we find that the BL scheme has the most obvious overestimation, different from the
703 daytime, while the YSU scheme still has the lowest overestimation, the same as the daytime. In
704 general, wind speed is smaller at night, and the four schemes overestimate wind speed much more
705 than during the day. Averaging the RB of wind speed over the five regions and four months, the
706 daytime (nighttime) values for the YSU, ACM2, BL and MYJ schemes are 77.7% (92.4%), 85.6%
707 (123.6%), 80.2% (146.0%), and 100.8% (117.4%), respectively. This simulated misestimation of
708 low winds at night may mainly originate from the inapplicability of the M-O similarity theory. The
709 strong stable boundary layer usually occurs on nights with low winds (Monahan and Abraham, 2019;
710 Vignon et al., 2017). In this strong stable boundary layer, turbulence occurs weakly and
711 intermittently, the turbulence intensity is disproportionate to the mean gradient, and the M-O
712 similarity theory is no longer applicable (Acevedo et al., 2015; Sun et al., 2012). Ultimately, these
713 inapplicable functions affect the calculation of the bulk transfer coefficient and can further lead to
714 large deviations in the simulation of wind speed.

715

716

717 **Figure 11. Similar as Figure 6, but for 10-m wind speed.**

718

719

720

721

722

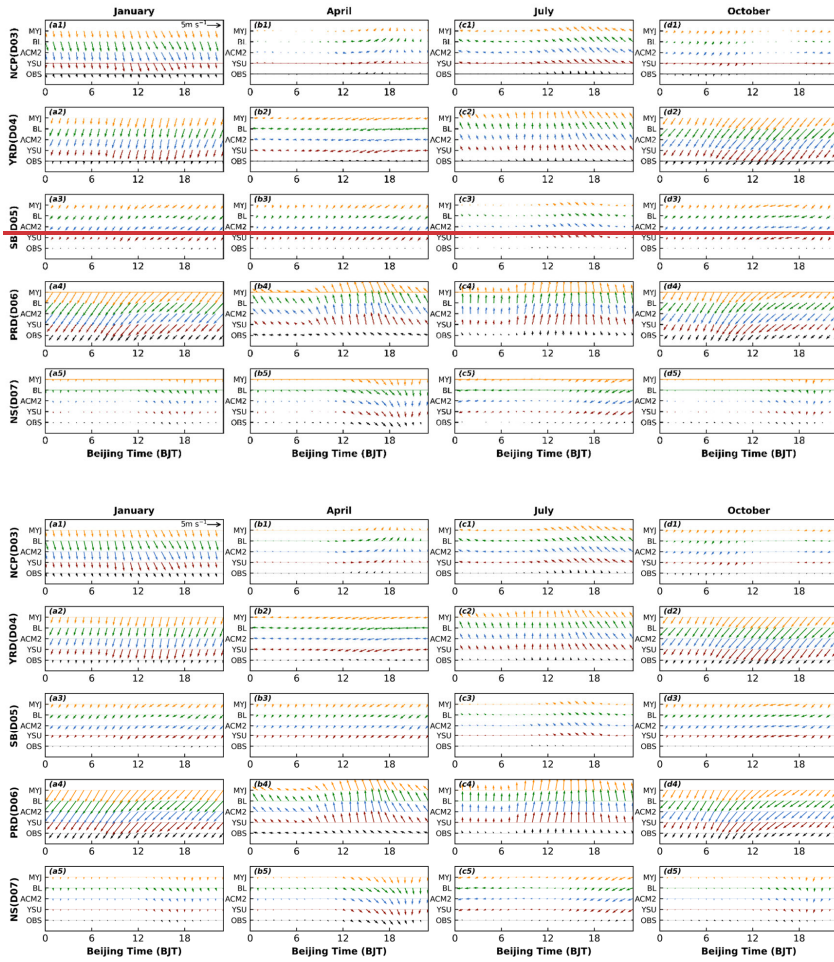

723

724

725

726

We further re-analyze the effect of topography on wind speed. The wind speed is overestimated for plains and valleys and better reproduced/underestimated for mountain tops, mainly because of the smoother topography in the model. This is rather because coastal stations in the plains, many of which also have high wind speeds, are not well reproduced and still show significant overestimation (Fig. 10), than the high wind speeds at the top of the mountains, which are better simulated. It is assumed that the wind speed should be small in plain areas with complex underlying surface, but it increases after the model has smoothed the terrain. The wind speed increases gradually with height, and when the terrain at the top of the mountain is smoothed, the originally larger wind speed decreases, and the wind speed will be closer to the observed value.

727

728

729

Figure 12. Similar as Figure 2, but for 10-m wind direction.

730

The model can basically simulate the changes of wind direction in the five regions, well capturing

731

the overall wind direction in each region (Fig. 12). In the NCP region, the simulation of wind

732

direction is poor in January compared to the other three months, with a high frequency of

733

northwesterly-northerly winds, overestimated by about 6.6% (Fig. 13 a1-d1). In addition, coupled

734

with larger wind speed, it causes the effect of advective transport to be amplified, thus affecting the

735

variation of pollutant concentrations(W. Jia and Zhang, 2021). The frequency of simulated

736

northeasterly winds in the YRD region is higher than that observed in January (~6.9%), April

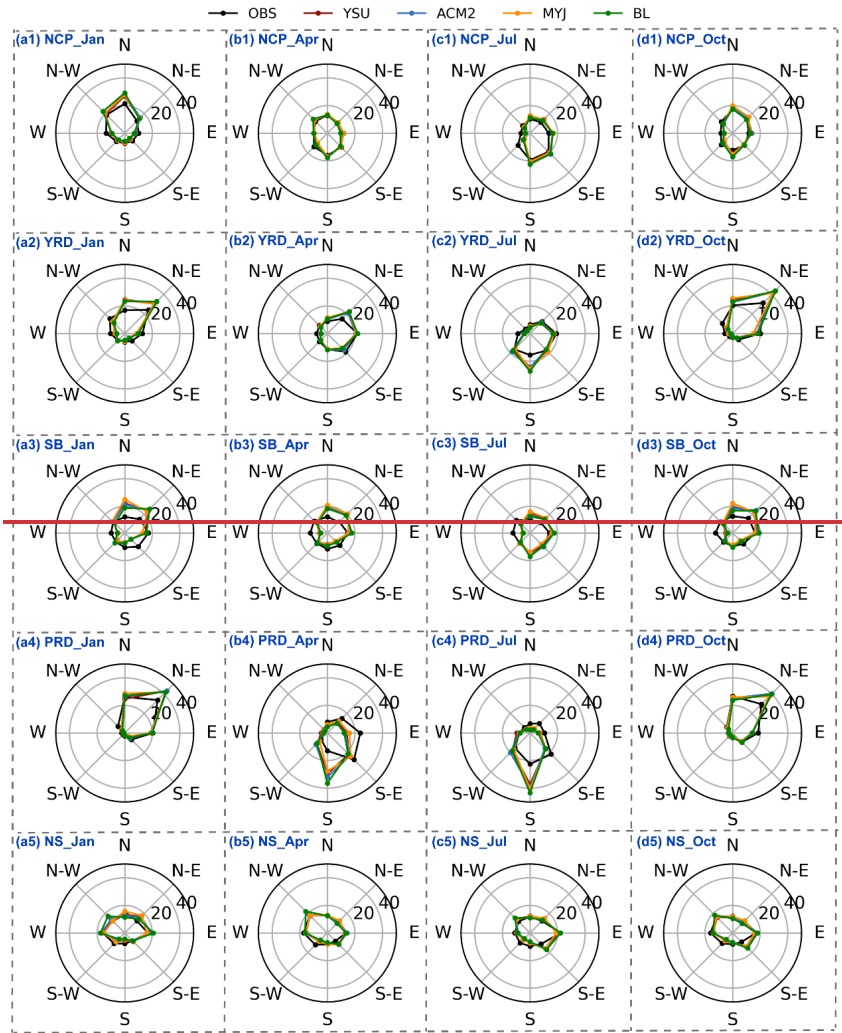

737

(~6.9%) and October (~11.2%), while the frequency of southerly winds is higher in July (~10.0%)

738

(Fig. 13 a2-d2). The wind direction of SB region is poorly simulated since the topography is too

739 complicated in the SB region, with a basin in the middle and high topographic mountains all around
740 (Fig. 13 a3-d3). The low wind state in the middle of the basin is difficult to be captured. The
741 percentage of northeasterly winds simulated by the model in January, April, July and October are
742 22.9%~25.6%, 19.2%~20.6%, 14.9%~16.4%, 22.4%~24.2%, respectively, and the percentage of
743 observations are 15.1%, 12.0%, 10.9%, 16.1%, respectively. Similarly, the percentage of westerly
744 winds simulated by the model in January, April, July and October are 4.7%~5.1%, 4.7%~5.7%,
745 4.8%~5.5%, 3.8%~5.1%, respectively, and the percentages of observations are 9.9%, 12.4%, 12.4%,
746 12.3%, respectively. The model simulates a large proportion of northeasterly winds and a smaller
747 proportion of westerly winds (Fig. 13 a3-d3). In the PRD region, the frequency of northeasterly
748 wind occurrences in January and October is significantly overestimated by about 8.8% and 9.5%,
749 while the frequency of southerly winds is overestimated in April and July by about 14.5% and 17.3%,
750 and the frequency of southeasterly winds is underestimated (Fig. 13 a4-d4). The wind direction is
751 better simulated in the NS region, not significantly influenced by the complex terrain (Fig. 13 a5-
752 d5).

754

755 Figure 13. Wind-rose plots in five regions for four seasons are (a1-d1) NCP region, (a2-d2) YRD
 756 region, (a3-d3) SB region, (a4-d4) PRD region and (a5-d5) NS region, respectively.

757

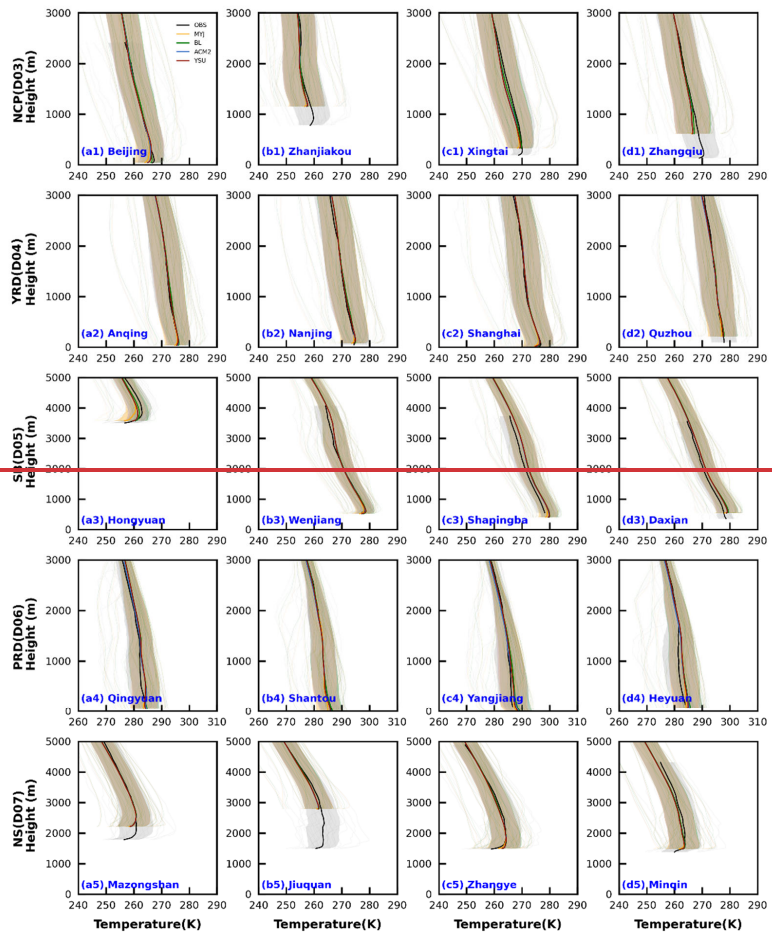

758 3.2 Vertical structures

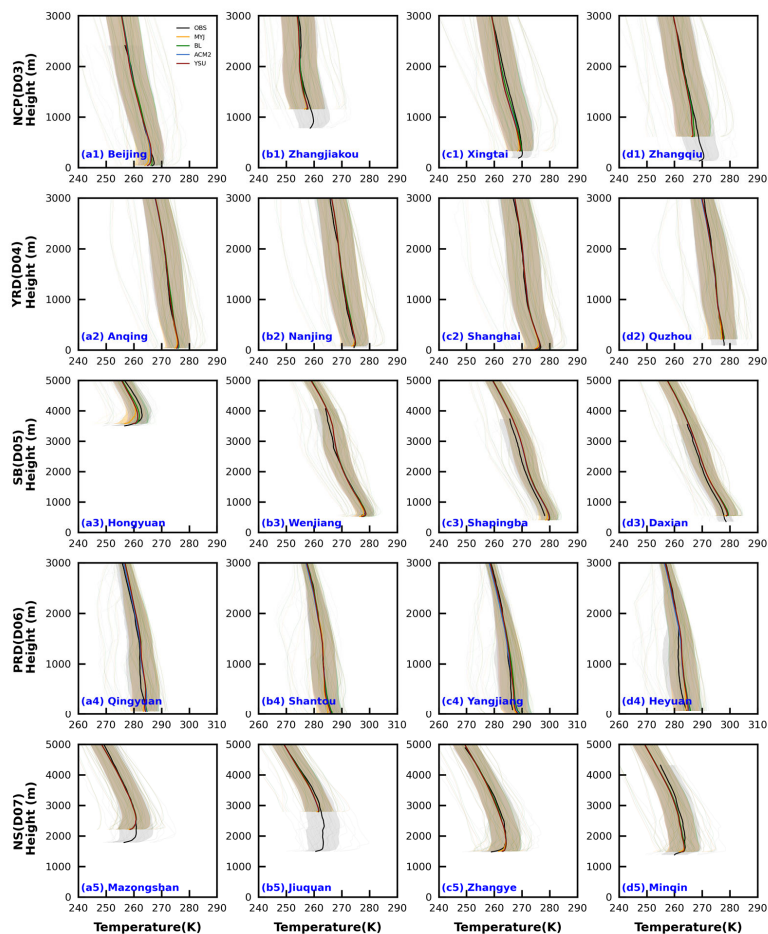

759 To better understand the performance of model in simulating PBL structure under different
 760 underlying surface, four representative stations have been selected in each region, with stations in
 761 plain areas, stations in mountains areas with high elevation, and stations near the sea.

762 3.2.1 temperature

763 Accurate simulation of the vertical structure of the PBL is very important for the evolution of
764 pollution, precipitation and typhoons. In the vertical direction, four typical sounding stations are
765 selected for each region at 08:00 to better reflect the simulation of the vertical structure of the PBL
766 under different underlying surface conditions. Overall, the model captures the vertical structures of
767 the temperature. From the simulation results in January, the best reproduction of the temperature
768 simulation is found in the YRD region, in which the temperature is closer to the observed values
769 (Fig. 14 a2-d2). In addition to the NCP, SB and NS regions, a temperature inversion layer appears
770 in the lower layers at 08:00, and the NS region has the most significant temperature inversion (Fig.
771 14 a1-d1, a3-d3, a5-d5). The model does not simulate the temperature variation of the inversion
772 layer well, and shows significant differences from the observations. When there is a difference in
773 topography between the observed and simulated stations, the bias in the temperature is more
774 pronounced. These stations usually exist in complex topographic conditions, such as Zhangjiakou
775 and Zhangqiu stations in the NCP region, Shapingba in the SB region, and Mazongshan and Jiuquan
776 in the NS region (Fig. 14 b1, d1, c3, a5, b5). The topographic discrepancy caused by the lack of
777 high resolution may, on the one hand, account for it, resulting in more complex topography in the
778 grid points closest to the observation stations. On the other hand, there is also an urgent need for
779 finer underlying surface data to respond more closely to the observed real topography. The effect of
780 resolution and underlying surface will be discussed in detail in the Part II. Although the elevation
781 of the Hongyuan station in the SB region is higher, the difference in topographic height obtained
782 from observations and simulations are close to each other (Fig. 14 a3).

784
 785 **Figure 14.** Average vertical profiles of observed and simulated temperature at 08:00 and 20:00 BJT
 786 at four sounding stations for each region in January (Winter). The unobtrusive gray lines indicate
 787 the simulated lines for all time periods, and the lines with shading indicate the average values and
 788 shaded areas show the uncertainty range (the mean ± 1 standard deviation).

789 There is an underestimation of temperature at stations with higher topography and overestimation
 790 for lower topography, which is more consistent with the conclusions drawn from 2-m temperature
 791 (Fig. 5, 14). However, the underestimation of temperature is not present throughout the vertical, but
 792 is more pronounced in the lower layers, which are more influenced by the underlying surface. From
 793 the differences of the four schemes, the MYJ scheme simulates the lowest temperature and largest
 794 temperature gradient. Since the MYJ scheme simulates a weak turbulent diffusion of heat, a well
 795 vertical exchange process cannot occur, bringing into a large temperature gradient (Fig. S19). The

796 differences of the four schemes gradually decrease with the increase of the height. The BL scheme,
797 which is also a local closure scheme, with a smaller vertical gradient in temperature, mainly because
798 this scheme adds a counter-gradient correction term to the heat flux, which is mainly applicable to
799 the convective PBL(Bougeault and Lacarrere, 1989). The presence of this term leads to an increase
800 in turbulent diffusion and a decrease in temperature gradient. However, it is worth noting that there
801 are still slightly stable stratifications at 08:00, and this term generates upward heat flux and reduces
802 the temperature gradient, which is closer to the results of the nonlocal closure schemes (YSU and
803 ACM2 schemes). The simulation results for the other three months are not as good as January, but
804 the simulation characteristics are similar to January (Figures not shown). The results at 20:00 are
805 similar to those at 08:00, and thus will not be repeated here (Figures not shown).

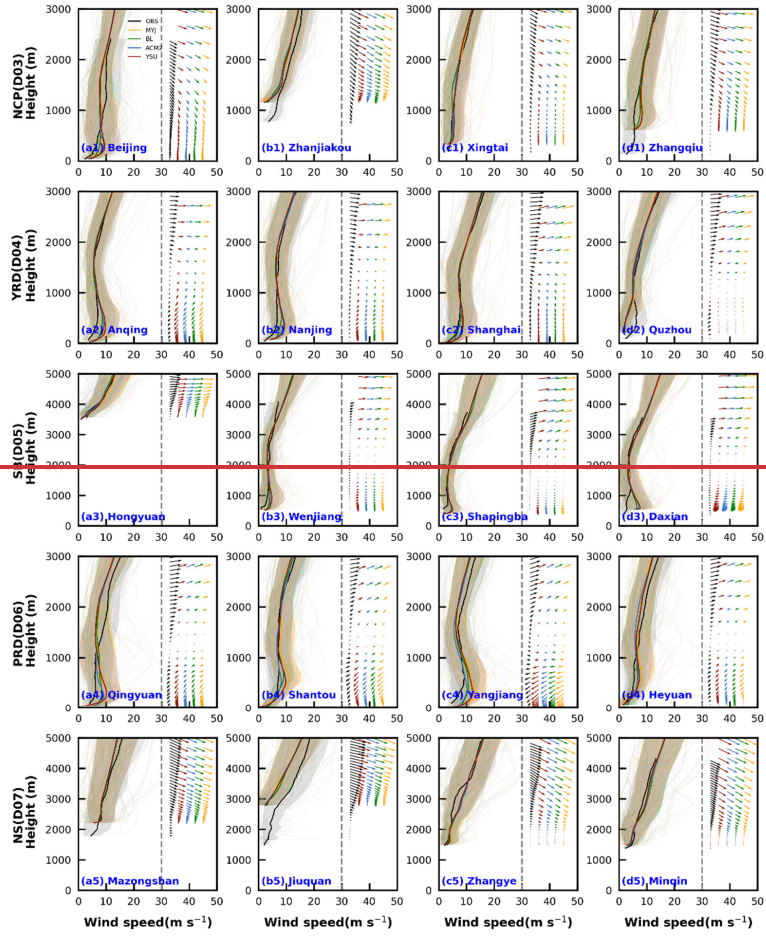

806 3.2.2 wind speed and direction

807 The simulation of wind speed vertical structure is much worse in comparison to temperature (Fig.
808 14, 15). The simulated results of wind speed in the vertical direction and 10-m wind speed are still
809 quite different. In the four months, the wind speed is almost overestimated at the lower altitude
810 stations below 1000 m in all the four regions except the NS region, and wind speed is less
811 overestimated in July than in the other three months (Fig. 15, S20-S22 a1-d4). However, for the NS
812 region, the wind speed is almost better simulated, or underestimated, and is significantly different
813 from the other four regions (Fig. 15, S20-S22 a5-d6). We can compare the Zhangjiakou station in
814 the NCP region with the Hongyuan station in the SB region, and find that the wind speeds at these
815 stations are almost not overestimated (Fig. 15 b1, a3). The effect of the model on terrain smoothing
816 contributes to it. Because the wind speed itself increases with the increase of height, and it decreases
817 when the model smooths over the terrain.

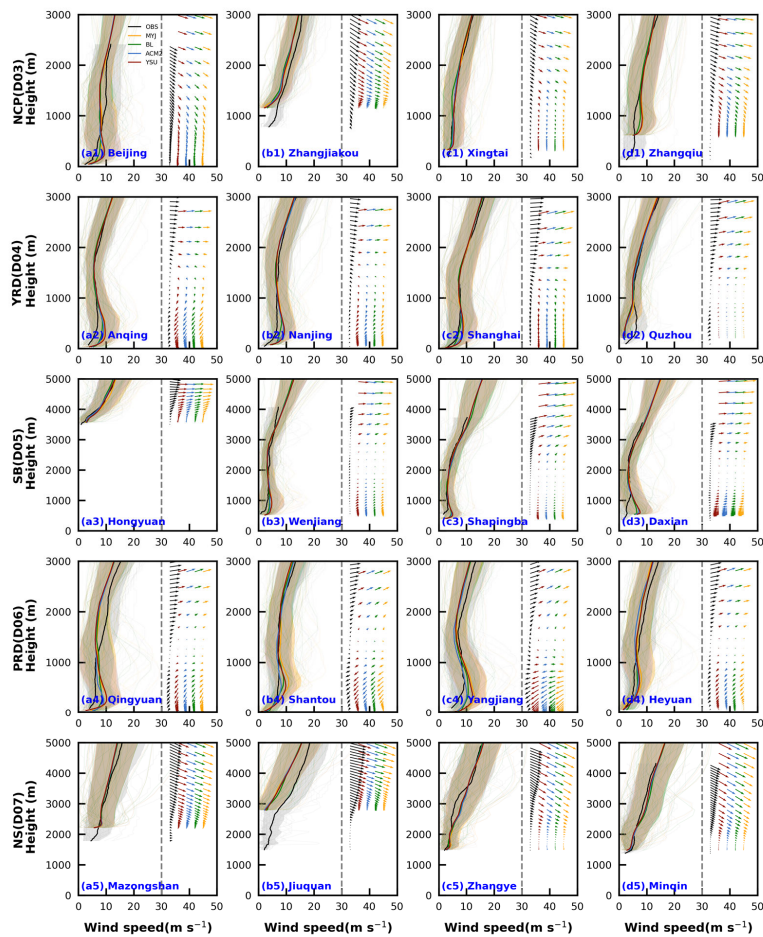

818 Unlike the 10-m wind speed, the simulation results of the 10-m wind speed have the smallest bias
819 for the YSU scheme, which is closer to the observed value (Table 2, Figs. 8, 10-11). Of course, this
820 phenomenon can also be found from the evolution of the wind speed in the vertical direction (Fig.
821 15, S20-S22). However, as the height increases, the bias of the YSU scheme gradually increases and
822 is greater than the other three schemes (Fig. 15, S20-S22). Such a large vertical gradient of wind
823 speed in the YSU scheme indicates a weak mixing in this scheme. From the turbulent diffusion
824 coefficients of the momentum at 08:00 in January, it is true that the YSU scheme simulates the
825 smallest turbulent diffusion coefficient below 1000 m (Fig. S23). While the BL scheme simulates a
826 smallest vertical gradient of wind speed, which corresponds to the largest turbulent diffusion
827 coefficient of momentum (Fig. S23). The time variation characteristics of the turbulent diffusion
828 coefficient will be deliberated and analyzed in detail later.

829 The simulation results of wind direction notes that the model can capture the characteristics of wind
830 direction well, and it also simulates well for the stations with more complicated topography and

831 higher altitude (Figs. 15, S20-S22).

832

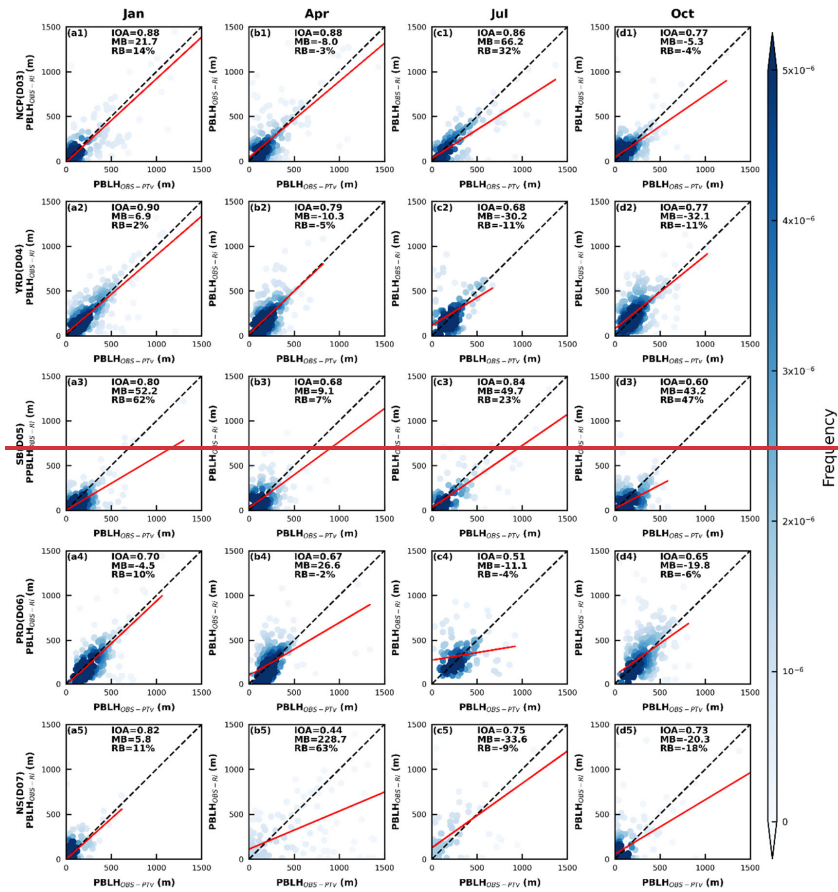

833
834
835

Figure 15. Similar as Figure 14, but for 10-m the vertical profile of wind speed and direction.

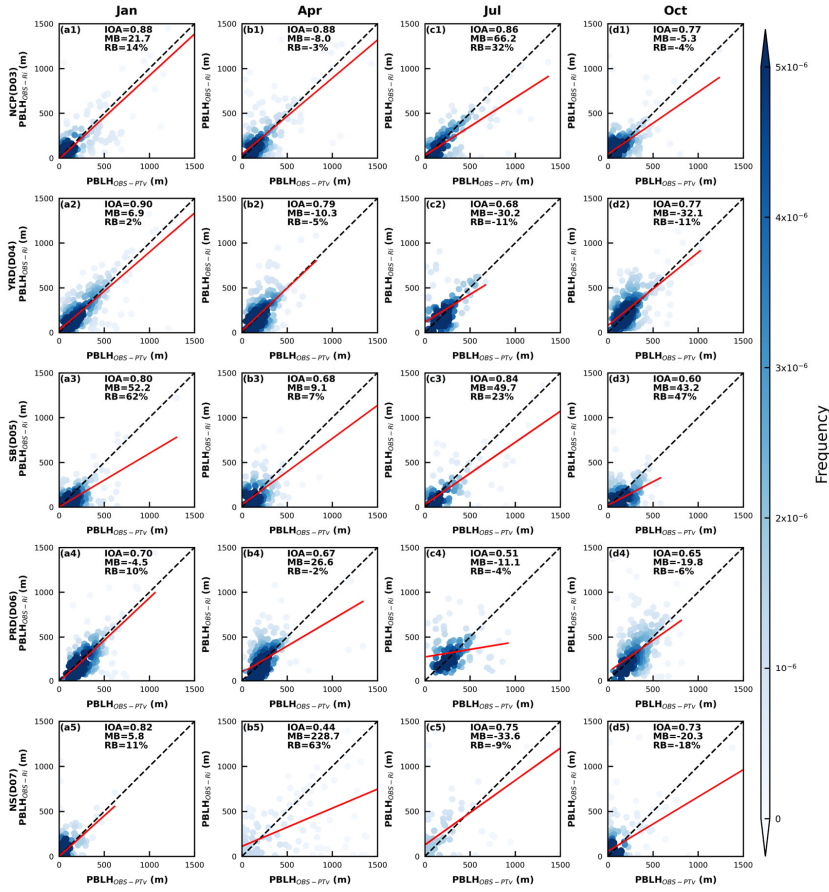

836 3.3 PBLH

837 Since the observations are only available at 08:00 and 20:00 (Beijing Time, BJT), the comparison
 838 of the PBLH are all the results of these two moments. Based on the observed data, comparing the
 839 PBLH calculated by the two methods, it is found that the results are mixed for two methods (Fig.
 840 16). The results for January (IOA=0.70~0.90) are better than the other three months
 841 (IOA=0.44~0.88 in April, IOA=0.51~0.86 in July, IOA=0.60~0.77 in October), and the results in
 842 the NCP region are better than the other four regions (Fig. 16). The PBLH in the NS region are more
 843 scattered, unlike the other regions where most of the PBLH are concentrated below 500 m,

844 especially in April and July (Fig. 16 b5-c5). On the whole, the difference in PBLH calculated by the
 845 two methods is more obvious in the NS region with more complex topography, which is especially
 846 noted when calculating in this type of underlying surface region.

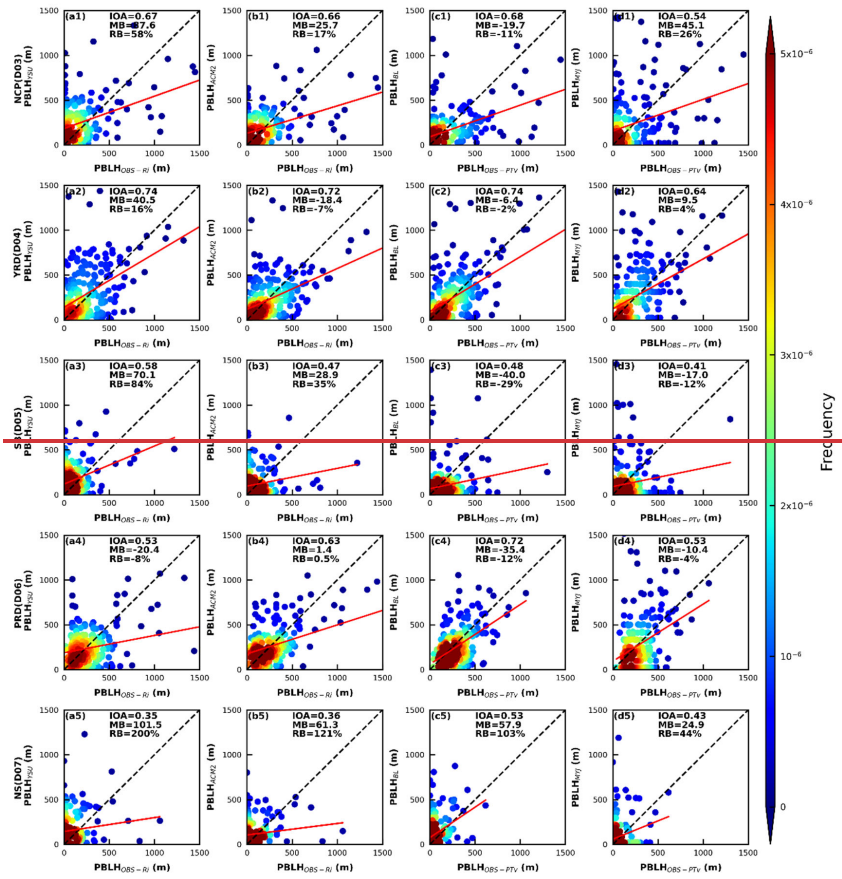

847

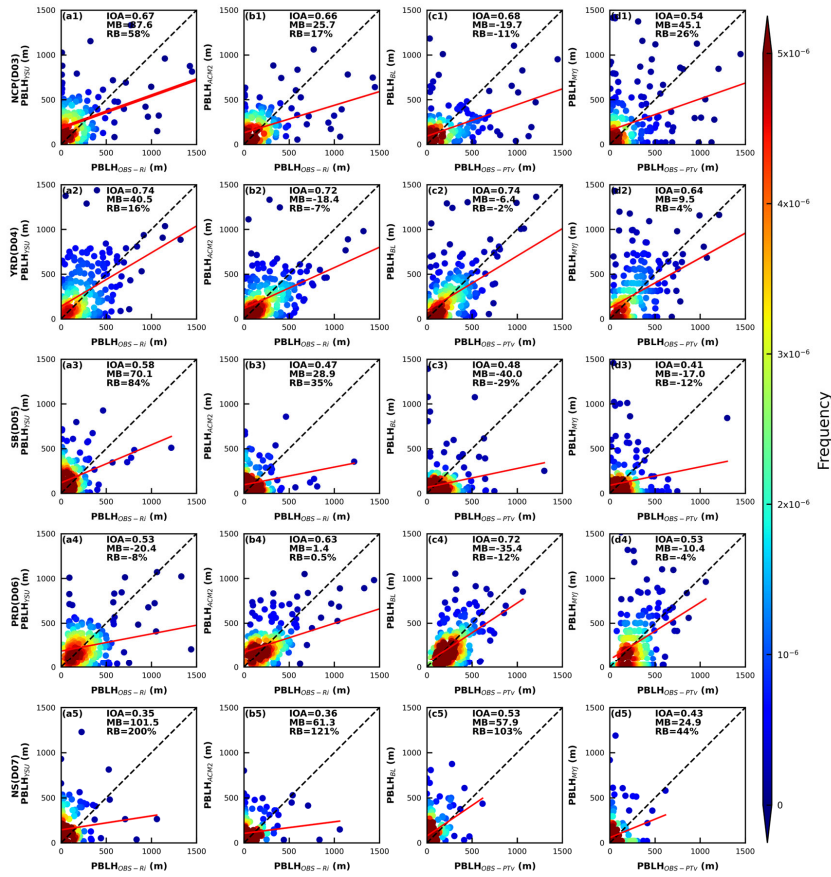

848
 849 Figure 16. Density scatterplots of the PBLH at 08:00 and 20:00 (Beijing Time, BJT) by the two
 850 methods in five regions for four seasons. The horizontal and vertical coordinates represent the
 851 PBLH calculated based on the observed data using the virtual temperature method and the
 852 Richardson number method, respectively, and IOA, MB, and RB represent the index of agreement,
 853 mean bias, and relative bias, respectively.

854 Further, the mechanism of understanding the PBLH differences based on different stations from
 855 different regions. The planetary boundary layer height (PBLH) for the YSU and ACM2 schemes is
 856 calculated by the Richardson number method, and the PBLH for the BL scheme is obtained by
 857 the virtual potential temperature method (see Section 2 for details). The same two methods are also used
 858 to calculate the PBLH with sounding data for comparison (Eqs. 1529 and 1630). First, we compare
 859 the PBLH calculated based on the observed data using Richardson number (Ri) with the PBLH
 860 simulated by YSU and ACM2 schemes. The Ri is determined by both buoyancy term and the shear

861 term together (Eq. 1529). The difference between simulated and observed temperature gradient is
862 smaller than the wind speed gradient within the PBL (Figs. 14-15). Therefore, the difference in Ri
863 mainly comes from the variation in the shear term. The wind speed gradient simulated in both
864 schemes are greater than the observed values (Fig. 15), except for individual stations, which would
865 result in small values of Ri. Thus, the height of Ri up to 0.25 would be high and the PBLH would
866 be high. Consequently, the PBLH simulated by the YSU and ACM2 schemes are higher than the
867 observed values at most stations. For example, in the case of the Quzhou station in the YRD region,
868 the simulated wind speed gradient at this station is much smaller than the observed value in January,
869 thus, the simulated PBLH is correspondingly smaller than PBLH calculated from observations (Figs.
870 15, S24 d2). Comparing the results of the other three months, we can also find similar conclusions
871 (Figures not shown). The wind speed gradient simulated by the YSU scheme is larger than that of
872 the ACM2 scheme, and therefore the PBLH is larger than that of the ACM2 scheme, except for the
873 Shanghai station in the YRD region, Shantou and Yangjiang stations in the PRD region (Fig. S24).
874 For the ocean, the PBLH simulated by the ACM2 scheme is higher than that of the YSU scheme,
875 while for most areas adjacent to the ocean, the PBLH simulated by the ACM2 scheme is on the high
876 side in the YRD and PRD regions (Fig. S25). The simulated PBLH of the BL scheme is in better
877 agreement with the PBLH calculated by the virtual potential temperature method, which is
878 substantially better than the other three schemes. The PBLH simulated by the MYJ scheme is mixed
879 (Fig. 17).

881

882 Figure 17. Density scatterplots of observed and simulated PBLH at 08:00 and 20:00 (BJT) by four
 883 PBL schemes in five regions in January (Winter). The horizontal and vertical subscripts YSU,
 884 ACM2, BL, and MYJ indicate the four schemes, and OBS-Ri and OBS-PTv indicate the
 885 Richardson number method and virtual potential temperature method, respectively.

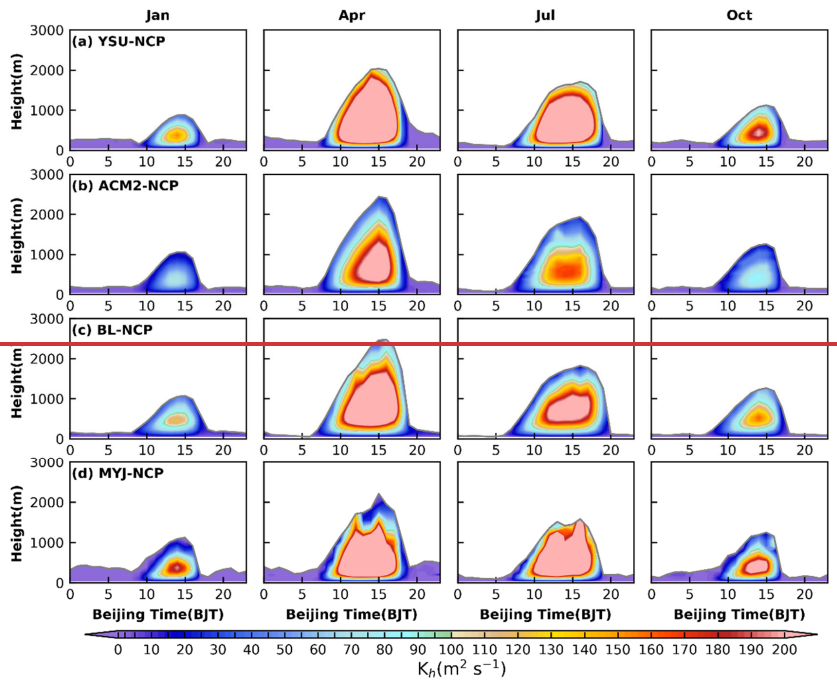

886 From the differences of regional distributions, the region with the best PBLH simulation results is
 887 the YRD region in January, (IOA=0.64~0.74; MB=-6.4~40.5 m; RB=-2%~16%), followed by the
 888 PRD region (IOA=0.53~0.72; MB=-35.4~1.4 m; RB=-12%~0.5%), and the worst simulation results
 889 for the PBLH in the NS region (IOA=0.35~0.53; MB=24.9~101.5 m; RB=44%~200%) (Fig. 17).
 890 Also, the PBLH simulation in the SB region is poorer and slightly better than that in the NS region,
 891 noting that there is still much potential for the model to improve the reproduction of the PBLH in
 892 complex terrain. From the simulation results of the four schemes, the PBLH simulated by the BL
 893 scheme is the closest to the observed value, followed by the YSU and ACM2 schemes, and the

894 PBLH simulated by the MYJ scheme is the worst. However, it is worth noting here that the method
895 for calculating the PBLH in the MYJ scheme is the TKE, and there is still some uncertainty in the
896 comparison using the virtual potential temperature method. The simulation results of temperature
897 are better than other meteorological parameters, therefore, the PBLH calculated in the model using
898 the virtual potential temperature method is more consistent with the observed results.~~in that the~~
899 ~~simulation results of temperature are better compared with other meteorological factors, so the~~
900 ~~method of judging the PBLH using the virtual potential temperature will be more consistent with~~
901 ~~the observed values.~~ While as the YSU and ACM2 schemes using Richardson number method will
902 involve the wind speed gradient, and the vertical gradient of wind speed is poorly simulated below
903 1000 m. That's why it will affect the judgment of the PBLH. If the simulation results of vertical
904 gradient of wind speed can be improved subsequently, then the simulation results of PBLH of these
905 two schemes will be improved to some extent. There are not enough observations to calculate the
906 PBLH using TKE, so there will be some differences with the PBLH simulated by the MYJ scheme.
907 The mean bias of the simulation increased in April and July when the PBLH is higher compared to
908 January, with mean bias of -29.6~361.8 m (6.5~603.9 m), -12.6~410.6 m (41.6~603.2 m), -
909 34.1~301.1 m (3.2~683.9 m) and -14.5~96.3 m (-11.3~523.6 m) for the YSU, ACM2, BL and MYJ
910 schemes in April (July), respectively. Similar to January, the best simulation results have been
911 obtained for the YRD (MB=7.8~72.4 m in April, MB=28.5~66.5 m in July) and PRD (MB=-34.1~
912 12.6 m in April, MB=-11.3~54.8 m in July) regions, and the worst for the NS region
913 (MB=61.8~410.6 m in April, MB=523.6~683.9 m in July). The results for October are more similar
914 to those for January, with lower PBLH and better simulations than those for April and July (Figures
915 not shown).

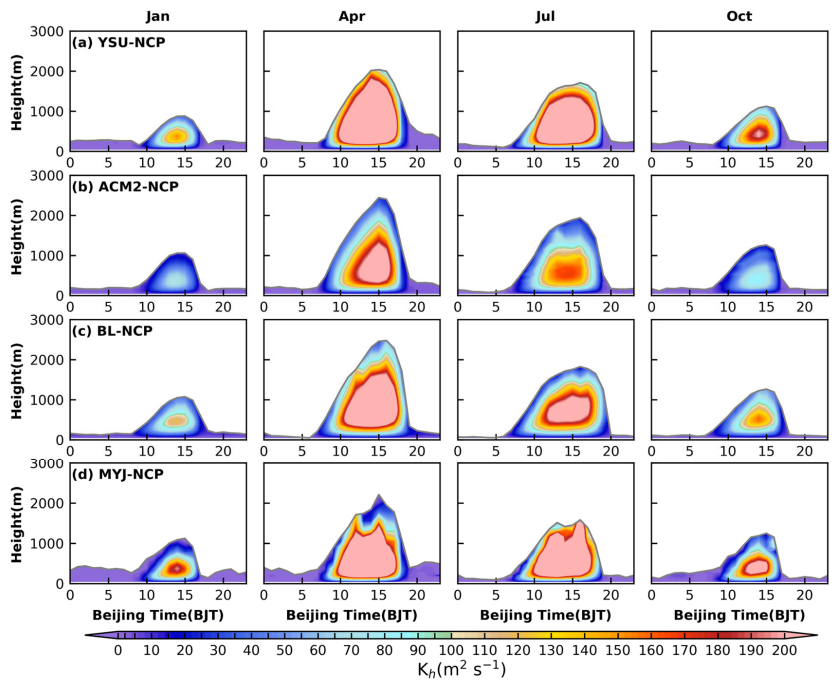

916 3.4 turbulent diffusion coefficient

917 Since the model itself does not directly output turbulent diffusion coefficients for all schemes, there
918 is relatively little direct comparison and analysis of this parameter. As seen in section 3.2.2 above,
919 the ~~turbulent diffusion coefficient (TDC)~~ plays a crucial role in the momentum vertical transport
920 within the PBL and also has an impact on the diffusion of other parameters, such as heat, water
921 vapor and pollutants (Ding et al., 2021; R. B. Stull, 1988). The accurate portrayal of the TDC directly
922 affects the evolution of the PBL structures. Based on the contents of section 2.3, the momentum
923 TDC is not equal to the heat TDC under unstable and neutral conditions for the YSU scheme, and
924 the momentum TDC is equal to the heat TDC under stable conditions. The ACM2 scheme uses the
925 MOST method to calculate the TDC as the YSU scheme, but also considers the TDC calculated by
926 the mixing length theory. The momentum TDC is not equal to the heat TDC in the MYJ scheme,
927 while the momentum TDC is equal to the heat TDC in the BL scheme. Because of the difference in
928 altitude of different stations, Beijing station in the NCP region, Nanjing station in the YRD region,

929 Daxian station in the SB region, Qingyuan station in the PRD region and Zhangye station in the NS
930 region were selected as representative stations to analyze the turbulent diffusion characteristics.
931 Here, the TDC of heat is taken as an example, the following basic characteristics have been found.
932 (1) the YSU and MYJ schemes have the largest TDC during the day, followed by the BL scheme,
933 and the ACM2 scheme has the smallest TDC (Fig. 18). (2) The TDC is largest in April and July, and
934 smallest in January and October (Fig. 18). (3) There are significant seasonal differences in the PBLH
935 for the NCP, SB and NS regions, while for the YRD and PRD regions (Figures not shown). The
936 difference in the PBLH affects the variation of the turbulent diffusion, especially for the YSU and
937 ACM2 schemes, where the PBLH is used during the calculation of the turbulent diffusion. In the
938 YSU scheme, the TDC of momentum is calculated first, and then the TDC of heat is calculated with
939 the Prandtl number (Pr). Thus, the variation of the PBLH is proportional to the TDC (Fig. 18a).
940 While in the ACM2 scheme, the TDC of heat is calculated directly based on the dimensionless
941 function of heat. Moreover, the Pr in the YSU scheme varies with height, while the Pr in the ACM2
942 scheme is a constant (=0.8). It is also worth noting that in the ACM2 scheme, another TDC is
943 calculated using the mixing length theory, and the change of the empirical stability function in the
944 mixing length method changes the TDC. Therefore, the YSU scheme calculates a large TDC of
945 momentum, which also leads to a large TDC of heat. The TDC of heat in the ACM2 scheme, on the
946 other hand, will be affected by the mixing length method, and differs from the calculation principle
947 of the YSU scheme.

948

949

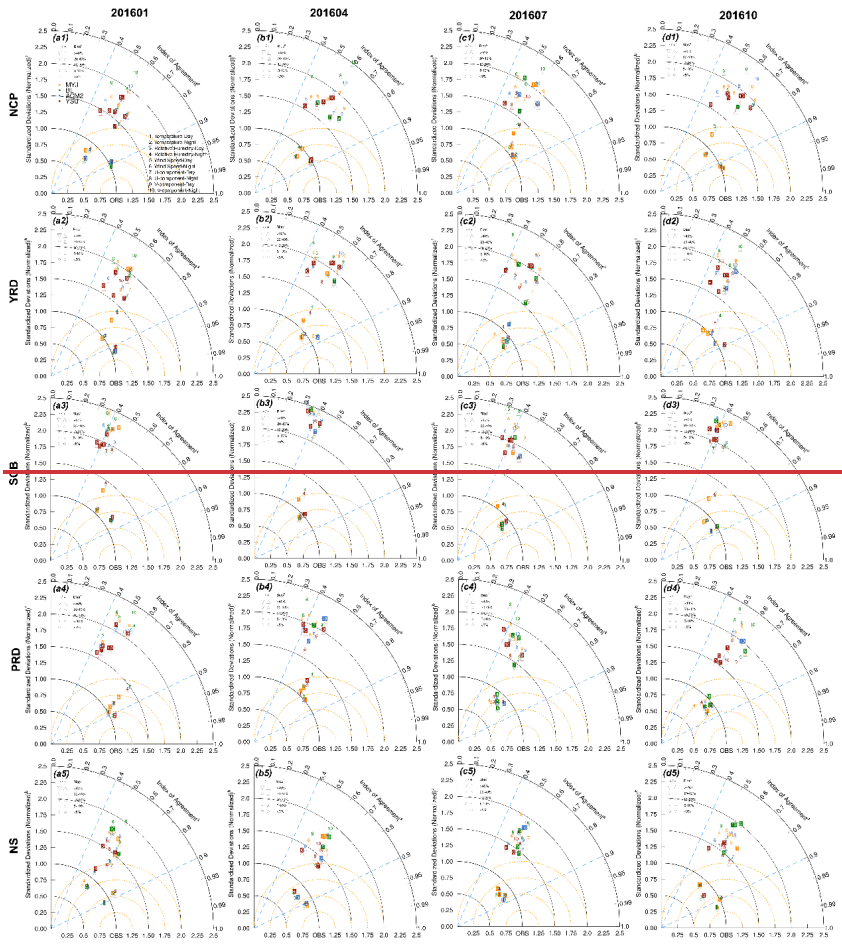

950 **Figure 18. Time-height cross sections of heat turbulent diffusion coefficient simulated by (a) YSU**
951 **scheme, (b) ACM2 scheme, (c) BL scheme and (d) MYJ scheme for four seasons in the NCP region.**

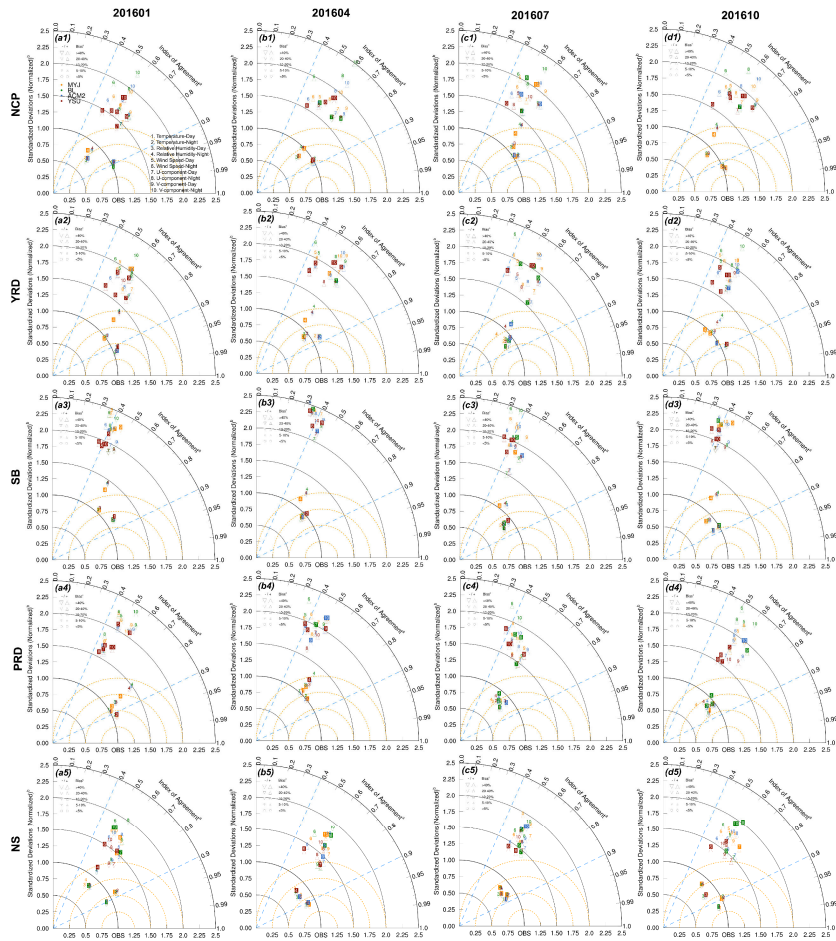

952 **The gray line indicates the PBLH.**

953 From the section 3.2.2 above, it is clear that the BL scheme has the strongest turbulent diffusion at
954 08:00, making the vertical gradient smaller, especially the wind speed is large. Similarly, this
955 phenomenon can be found in the daily variation of turbulent diffusion, and not only at 08:00, but
956 almost throughout the night (Fig. 18). The difference between MYJ and BL schemes is mainly
957 reflected in the calculation principle of mixing length, which is not directly related to the PBLH. In
958 the BL scheme, mixing length scale can be relative to the distance that a parcel originating from this
959 layer, can travel upward and downward before being stopped by buoyancy effects (Eq. 14).
960 Therefore, the vertical height below the temperature inversion layer at night, with the surface as the
961 lower boundary, is the length scale of turbulence, i.e., mixing length scale. While in the MYJ scheme,
962 the mixing length scale is equal to z minus the integral depth scale, which is equal to the height of
963 the equal-area rectangle under the profile. It is worth noting that the mixing length scale in the BL
964 scheme mainly considers the effect of thermal and takes temperature gradient as the criterion, while
965 the turbulent length scale in the MYJ scheme is mainly determined based on the TKE. TKE is further
966 divided into horizontal TKE and vertical TKE. Horizontal TKE is mainly influenced by wind shear
967 and the turbulent eddy scale can reach 1.5~3 times the PBLH on the horizontal, and even reach 6
968 times the PBLH (Atkinson and Zhang, 1996). The vertical depth of an unstable layer capped by an
969 inversion is automatically selected as the length scale for turbulence in the BL scheme during the
970 daytime. Moreover, in the BL scheme, there is a counter-gradient correction term in the convective
971 PBL, which leads to a downward transport of dry and cool air, making the thermal reach a lower
972 height and a smaller length scale for turbulence (Bougeault and Lacarrere, 1989). We also find that
973 the PBLH of the MYJ scheme exhibits a “sawtooth”, and is more pronounced at night. This is mainly
974 because the turbulence is weaker at night, and presents intermittent characteristics, which, together
975 with the judgment method of PBLH and the coarse vertical resolution, can cause such variation of
976 the PBLH. Although the improvement of PBLH in the MYJ scheme cannot have a substantial effect
977 on turbulent diffusion, the threshold value of its determination method is open to question.

978 **3.5 Discussion of optimal PBL schemes**

979 To better understand the simulation performance of different PBL parameterization schemes for
980 different parameters in each region, this section will discuss the expressiveness of different PBL
981 schemes through the statistical approach. Figure 19 shows the Taylor statistics for the analysis of
982 near-surface meteorological parameters in four months in five regions.

984
 985 **Figure 19. Taylor diagram of observation and simulation in five regions for four seasons. XY axes**
 986 **and arc represent the normalized standardized deviations (NSDs; $NSD =$**
 987 **$\frac{\sqrt{\frac{1}{N-1} \sum_{i=1}^n (X_{sim,i} - \bar{X}_{sim})^2}}{\sqrt{\frac{1}{N-1} \sum_{i=1}^n (X_{obs,i} - \bar{X}_{obs})^2}}$, \bar{X}_{sim} and \bar{X}_{obs} represent the average value of simulation and observation,**
 988 **respectively) and index of agreement (IOA; $IOA = 1 - \frac{\sum_{i=1}^n |X_{sim,i} - X_{obs,i}|^2}{\sum_{i=1}^n (|X_{sim,i} - \bar{X}_{obs}| + |X_{obs,i} - \bar{X}_{obs}|)^2}$, $X_{sim,i}$ and**
 989 **$X_{obs,i}$ represent the value of simulated and observed, respectively; i refers to time, and n is the**
 990 **total number of time series), respectively. Four schemes are shown in different colors, and different**
 991 **numbers represent different parameters. The root mean square is denoted by orange dashed line**
 992 **and the relative bias (RB; $RB = \frac{\bar{X}_{sim} - \bar{X}_{obs}}{\bar{X}_{obs}} \times 100\%$) is shown by different symbols.**

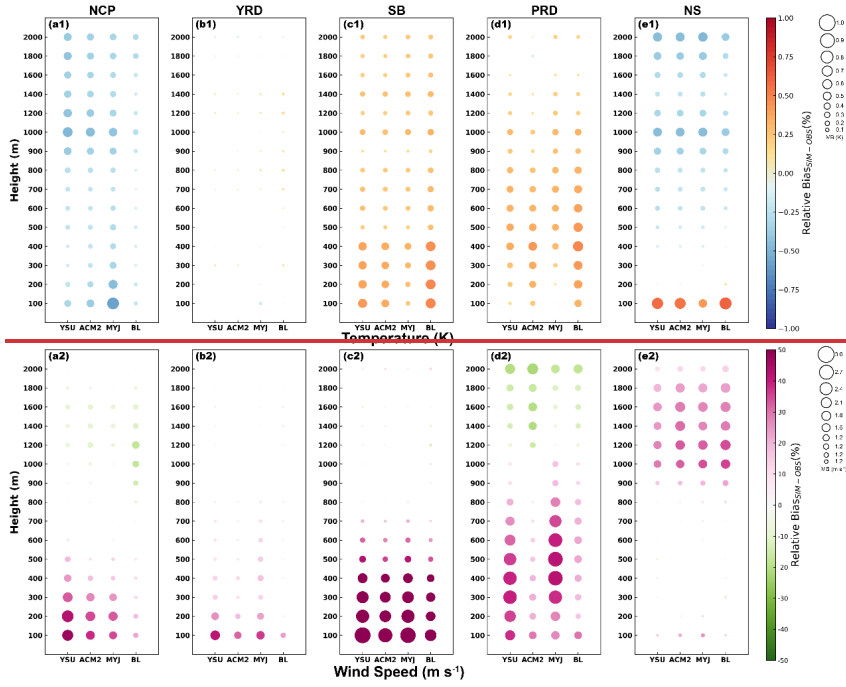

993 For the NCP region, the 2-m temperatures are underestimated during the daytime in January (Fig.
994 2), while the BL scheme simulates the highest temperature, so the BL scheme performs optimally.
995 Although the temperatures are somewhat overestimated at night, the overestimated period is shorter.
996 The IOA of the four schemes is similar, with the ACM2 scheme having a slightly smaller bias (Fig.
997 19 a1). Combined with the regional distribution of all stations in the NCP region, the BL scheme is
998 recommended if the study area is mainly for Beijing, while the ACM2 and YSU schemes are
999 recommended for the south of the NCP in January, such as Shandong Peninsula and southern Hebei
1000 province. For the other three months, temperatures are overestimated to varying degrees, both
1001 during the day and at night (Fig. 2). The MYJ scheme performs best in all statistical parameters at
1002 night (Fig. 19 b1-d1), while during the daytime, it slightly underperforms the YSU and ACM2
1003 schemes in relative bias in January and April, but the difference is not very distinct. Therefore, for
1004 the simulation of 2-m temperature in other three months, the MYJ scheme would be more
1005 recommended. In the YRD region, the 2-m temperatures are overestimated during the daytime, the
1006 BL schemes show overestimation at night, the MYJ scheme show underestimation, and the YSU
1007 and ACM2 schemes perform optimally (Fig. 2 a2-d2). According to the Taylor statistical parameters,
1008 it can be seen that the ACM2 scheme performs better than the YSU scheme in the four months, and
1009 based on that, the ACM2 scheme is recommended (Fig. 19 a2-d2). The 2-m temperature in the SB
1010 region during the daytime is the same as in the YRD region, and the ACM2 scheme performs
1011 optimally (Fig. 19 a3-d3). However, the BL scheme performs optimally during the nighttime, except
1012 in April (Fig. 19 b3). The PRD region differs from the other regions in that the temperature
1013 simulation is significantly higher in January and April, and the MYJ scheme performs best in both
1014 daytime and nighttime (Fig. 19 a4-b4). In contrast, the temperature simulation bias less in July and
1015 October, and the BL scheme performs best (Fig. 19 c4-d4). The 2-m temperature are almost
1016 underestimated during the daytime and overestimated for the nighttime in the NS region, and the
1017 MYJ scheme outperforms other schemes on account of its large diurnal temperature range (Fig. 19
1018 a5-d5). Of course, the BL scheme presents a slight advantage in the relative bias during the daytime
1019 in January (Fig. 19 a5).

1020 The results of 2-m relative humidity are relatively uniform, and the MYJ scheme shows optimal
1021 simulation performance in almost all months in all regions. Except for July in the YRD region, July
1022 and October in the PRD region, and January and April in the NS region (Fig. 19 c2, c4-d4, a5-b5).

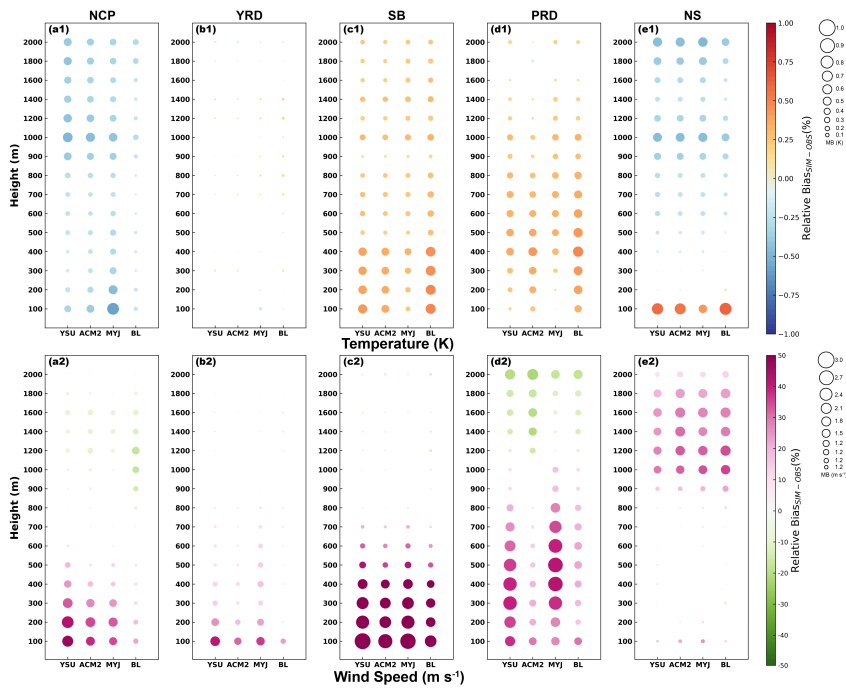

1023 For the simulation of 10-m wind speed and direction, the YSU scheme shows a very clear advantage,
1024 which is outstanding in all regions and all months (Fig. 19).

1025 Several sounding stations with large differences between the observed and simulated altitudes are
1026 removed. Then, the stations in each region are averaged to induce the variation characteristics from
1027 100 m to 2000 m in vertical.

1028

1029

1030 Figure 20. Statistics of temperature and wind speed in different layers at vertical height in January
1031 (Winter), with circle size indicating the mean bias between simulations and observations, and
1032 circles filled with color denoting the relative bias.

1033 The BL scheme has the smallest simulation bias for the temperature in the vertical direction in
1034 January for the NCP region, and performs optimally, which is associated with the discussion of the
1035 optimal scheme for the 2-m temperature (Fig. 20 a1) to some degree. While in all the other three
1036 months, the MYJ scheme has the smallest bias and is consistent with the conclusion of the 2-m
1037 temperature (Fig. S26-S28 a1). In the YRD region, there is no clear difference between the four
1038 schemes for the simulation of temperature in the vertical direction, and the deviation of the
1039 simulation in January is less than 0.1 K (Fig. 20 b1). The optimal scheme for 2-m temperature can
1040 be considered as a representative choice. The MYJ scheme has a better simulation of the vertical
1041 profile of the temperature that is somewhat different from the most preferred scheme of 2-m
1042 temperature in the SB region (Fig. 20, S26-S28 c1). This is mainly because the selected sounding
1043 stations are basically located in the basin area with low elevation, and the temperatures are
1044 overestimated, as is the 2-m temperature (Fig. 5). If the stations around the basin are not considered,
1045 the simulation of 2-m temperature will also be overestimated and the MYJ scheme also perform
1046 optimally. There is no complex topography in the PRD region, the results from the sounding stations
1047 and surface layer can be well echoed. In the vertical direction, the MYJ simulates the vertical profile
1048 of temperature better, particularly in January and April (Fig. 20, S30, d1). While in July and October,
1049 the simulation results of the four schemes have little difference, especially in the lower level, which
1050 can be represented by the optimal scheme of 2-m temperature (Fig. S27-S28, d1). For the NS region,
1051 there is an overestimation in the lower levels and an underestimation in the upper levels for each
1052 month. The height of overestimation is lower in January and April, around 200 m, while it can reach
1053 around 500 m in July and October (Fig. 20, S26-S28, e1). The positive deviation decreases as the
1054 height increases, but after reaching a certain height, the negative deviation increases again. In the
1055 process of decreasing the positive deviation with height, the MYJ scheme performs the best, which
1056 is consistent with the 2-m temperature. While the BL scheme performs slightly better when the
1057 negative deviation gradually increases with height.

1058 For wind speed, the YSU scheme is optimal for 10-m wind speed for all regions and months.
1059 However, the quite different in terms of the variation of vertical wind speed. Throughout all regions
1060 and months, the simulation bias of the BL scheme is the smallest and closer to the observation,
1061 which is also the results obtained from the section 3.2.2 (Fig. 20, S26-S28 a2-e2). The stronger
1062 turbulent diffusion of the BL scheme at 08:00 makes the wind speed more uniformly mixed in the
1063 vertical direction. And the vertical variation characteristics at 08:00 can be extended to the whole
1064 night. But during the daytime, the result may not be the same, after all, the vertical mixing of the
1065 YSU scheme is stronger, and does not produce such a large wind speed gradient.

1066 In general, in the selection process of the PBL scheme, if the focus is on temperature variation, such
1067 as temperature inversion, the optimal scheme for both 2-m temperature and vertical temperature can
1068 be considered, and there is basically no significant difference. However, if the focus is on the
1069 variation of wind speed, wind energy, then the vertical wind speed and in the surface layer need to
1070 be evaluated and selected with comprehensive consideration.

1071 4 Conclusion

1072 The ~~planetary-boundary-layer~~PBL serves as a bridge between the ground and the free atmosphere,
1073 and its role cannot be ignored. Turbulence, as the primary motion within the PBL, controls the
1074 vertical mixing of heat, water vapor, momentum, and pollutants. Turbulence as a sub-grid-scale
1075 motion is usually parameterized in the model, i.e., PBL parameterization scheme. The most widely
1076 used mesoscale model (i.e., WRF), which has developed 12 schemes, includes nonlocal closure
1077 scheme, local closure scheme and hybrid nonlocal-local closure scheme. Across the world, there
1078 have been many evaluation studies for PBL parameterization schemes (reference Fig. 1 in Jia and
1079 Zhang, 2020). However, most of the studies have been conducted for individual stations in a small
1080 region with special individual cases for research and analysis, which are not well represented and
1081 applied. Meanwhile, there is a deficiency in understanding the mechanism of the scheme itself. In
1082 response, aiming at the current research deficiencies, four typical schemes (YSU, ACM2, BL and
1083 MYJ, covering each type scheme) are selected in this study to evaluate and analyze the near-surface
1084 meteorological parameters, vertical structure of the PBL, PBLH and turbulence diffusion in four
1085 months (i.e., January, April, July and October) in five typical regions of China (i.e., NCP, YRD, SB,
1086 PRD and NS regions).

1087 *a. 2-m temperature.* (1) In terms of time series and diurnal, the simulation results for July are better
1088 than the other three months, and better at night than daytime, with less deviation between simulation
1089 and observation. (2) in terms of regional distribution, temperatures at stations with higher elevations
1090 are easily underestimated (e.g., mountainous areas in the NCP region, areas around the SB basin,
1091 and the NS region), while overestimated at plains and basin (e.g., YRD, PRD and the SB basin
1092 regions), and the overestimation/underestimation is more significant during the daytime. (3) In
1093 terms of mechanism differences between schemes, the differences in the simulated temperatures of
1094 the four schemes are more pronounced at night. The differences in simulated temperatures between
1095 the nonlocal scheme mainly originate from downward shortwave radiation, while the effects of
1096 sensible heat flux (HFX) need to be further ruminated when comparing with the local closure
1097 scheme. when analyzing the HFX, the gradient of 2-m temperature and surface temperature, the
1098 variation of heat transfer coefficient need to be discussed in detail.

1099 *b. 2-m relative humidity.* The changes in relative humidity and temperature correspond to each other,
1100 and again the best simulation results are obtained in July. Except for the NS region, the relative

1101 humidity of the other regions is underestimated.

1102 *c. 10-m wind speed.* (1) The simulation bias is the largest for the MYJ scheme during the daytime
1103 (except for the NCP region), and the BL scheme presents the largest deviation at night in all regions,
1104 and the difference is not significant in the four months. The variation of 10-m wind speed is
1105 influenced by the momentum transfer coefficient, where a larger C_m produces stronger mixing and
1106 transports more momentum from the upper layers to the lower layers. For the YSU, ACM2 and BL
1107 schemes, the C_m and 10-m wind speed vary proportionally. In contrast, the MYJ scheme calculate
1108 principle of for MYJ scheme is different from the other schemes, and the C_m is larger than other
1109 months almost all day. However, the wind speed simulated by the MYJ scheme is maximum only
1110 during the daytime, which indicates that it is influenced by integrated similarity functions. (2) In
1111 terms of regional distribution, the wind speed is more overestimated in plains and basins, and less
1112 overestimated or even underestimated in mountainous areas. This is chiefly due to the influence of
1113 the model on terrain smoothing. (3) The overestimation of smaller wind speed at night is more
1114 obvious in the four schemes, primarily owing to the non-application of the MOST. At night, the
1115 turbulence intensity is disproportionate to the mean gradient, and the M-O similarity theory is no
1116 longer applicable.

1117 *d. 10-m wind direction.* The simulation of wind direction in January for the NCP region worse than
1118 the other three months, and the frequency of simulated northwest-north winds is overestimated by
1119 about 6.6%. For the YRD region, the frequency of northeasterly winds is overestimated. The
1120 simulation of wind direction in the SB region is not as good as other regions due to the complex
1121 topography. The frequency of northeasterly winds is overestimated in January and October in the
1122 PRD region, and that of southerly winds is overestimated in April and July. The wind direction is
1123 better simulated for the NS region, and the difference is not very obvious.

1124 *e. ~~vertical distribution of PBL~~ vertical structures.* The model can reproduce the vertical structure
1125 of temperature well, but the inversion temperature at the lower levels of many stations in complex
1126 terrain cannot be simulated well, mainly because there is a certain difference in the terrain height
1127 between observation and simulation. At 08:00, the MYJ scheme simulates the lowest temperature
1128 and the BL scheme for the highest temperature, and the difference is more conspicuous at the lower
1129 levels. The vertical structure of the wind speed is clearly not as good as the temperature. The wind
1130 speed is almost always overestimated below 1000 m, except for the NS region. Unlike the 10-m
1131 wind speed, YSU has the smallest deviation from the 10-m wind speed, while the BL scheme has
1132 the smallest bias in the vertical direction. The BL scheme has the largest turbulent diffusion and the
1133 strongest mixing at 08:00.

1134 *f. PBLH.* The PBLH calculated based on the observed data using the two methods are better in
1135 January than in the other three months, and in the NCP region than in the other four regions. The
1136 wind speed gradient simulated by the YSU scheme is large, resulting in a small Richardson number

1137 (Ri), making the height higher when Ri reaches 0.25, and the PBLH is higher than that of the ACM2
1138 scheme. The PBLH simulated by the BL scheme is closer to the observation because the temperature
1139 gradient is best simulated. The MYJ scheme results in a jagged variation of the PBLH due to the
1140 determination of the threshold and the vertical resolution, and this phenomenon is especially
1141 obvious at night. In terms of regional distribution, the PBLH is best simulated in the YRD region,
1142 followed by the PRD region and worst in the NS region. The results are similar in January and
1143 October, when the PBLH is lower and the simulations are better than those in April and July.

1144 *g. turbulent diffusion coefficient.* (1) The TDC simulated by the YSU and MYJ schemes is the
1145 largest during the daytime, followed by the BL scheme, and the smallest by the ACM2 scheme. The
1146 TDC simulated by the BL scheme is the largest at night, and the other three schemes are about the
1147 same. (2) The TDC is maximum in April and July, and minimum in January and October. (3) The
1148 obvious difference in PBLH affects the turbulent diffusion of the YSU and ACM2 schemes. It is
1149 worth noting that the YSU scheme calculates the TDC of momentum first, and then uses Prandtl
1150 number (Pr) to calculate the TDC of heat, while the ACM2 scheme calculates the TDC of both
1151 momentum and heat. (4) The difference between the BL and MYJ schemes is mainly reflected in
1152 the calculation principle of mixing length. The buoyancy effect mainly affects the mixing length
1153 scale in the BL scheme, and the mixing length scale of MYJ scheme is influenced by the TKE.

1154 For the discussion of the optimal scheme, different schemes need to be proposed for different
1155 parameters. (1) Temperature. The BL scheme is recommended for January in the NCP region,
1156 especially for the Beijing, and the MYJ scheme is recommended for the other three months. The
1157 simulation difference between the four schemes is small in the YRD region, and the ACM2 scheme
1158 is recommended. The topography is more complex in the SB region, but the MYJ scheme is
1159 recommended for most areas within the basin, and the BL scheme is recommended for the SB region
1160 if more around basin is involved. The MYJ scheme is recommended for the PRD region in January
1161 and April, and the BL scheme is recommended for July and October. In the NS region, the MYJ
1162 scheme is recommended. (2) Relative humidity. The MYJ scheme is recommended for all regions
1163 in four months. (3) Wind speed. The YSU scheme is recommended if the main concern is the surface
1164 layer, and the BL scheme is recommended if the focus on the variation of wind speed in the vertical
1165 direction.

1166 The PBL parameterization scheme, as the most critical parameterization process within the PBL in
1167 the model, has been well proposed and developed by previous generations, but the development has
1168 been slower in recent years, few new theories have been proposed and almost no new schemes have
1169 been put into the model or the existing schemes have rarely been improved. Most of the previous
1170 studies have evaluated the PBL parameterization scheme, but many of them focus on a particular
1171 case in a certain region and lack of universality. This study makes up for this deficiency and provides
1172 a comprehensive discussion on the evaluation and uncertainty analysis of the PBL parameterization

1173 [scheme, hoping to give some reference to the model users. The future development of the PBL](#)
1174 [parameterization scheme needs to start from the theoretical mechanism, go deeper into the PBL](#)
1175 [parameterization scheme, and have a deeper understanding of the PBL parameterization, even if it](#)
1176 [is only for one scheme, or the improvement of one parameter. And for China's self-developed](#)
1177 [GRAPES model, the introduction and improvement of PBL parameterization schemes need to be](#)
1178 [selected, rather than a brain to write all the schemes, in fact, many schemes are almost not measured](#)
1179 [and used.](#)

1181 Code and data availability

1182 The source code of WRF version 3.9.1 can be found on the following website:
1183 <https://www2.mmm.ucar.edu/wrf/users/download/>, and the model settings file is named
1184 “3.9.1_namelist.input”, which can be found in the Supplement. In addition, the hourly
1185 meteorological observation data and L-band radiosonde observation data provided by the Chinese
1186 Academy of Meteorological Sciences, are available at <https://doi.org/10.5281/zenodo.7792241> (Jia
1187 et al., 2023).

1188 Author contributions

1189 Development of the ideas and concepts behind this work was performed by all the authors. Model
1190 execution, data analysis and paper preparation were performed by WJ. XZ and HW provide
1191 computing resources, and offer advice and feedback. YW, DW, and JZ support the data. WZ, LZ,
1192 LG, YL, JW, YY, and YL provides suggestions. All authors contributed to the manuscript.

1193 Competing interests

1194 The authors declare that they have no conflict of interest.

1195 Acknowledgements.

1196 The work was carried out at the National Supercomputer Center in Tianjin, and the calculations
1197 were performed on TianHe-1 (A).

1198 Financial support

1199 This research is supported by NSFC Major Project (42090031), NSFC Project (U19A2044), [Basic](#)
1200 [Research Fund of CAMS \(2023Y003\)](#).
