10 **Abstract.** A key challenge in paleoseismology is constraining the timing and occurrence of past earthquakes to create an earthquake history along faults that can be used for testing or building fault-based seismic hazard assessments. We present a new methodological approach and accompanying code (*Paleoseismic EArthquake CHronologies*, *PEACH*) to meet this challenge. By using integration of multi-site paleoseismic records through probabilistic modelling of the event times and an unconditioned correlation, *PEACH* improves the objectivity of constraining paleoearthquake chronologies along faults, 15 including highly populated records and poorly dated events. Our approach reduces uncertainties in event times and allows increased resolution of the trench records. By extension, the approach can potentially reduce the uncertainties in the estimation of parameters for seismic hazard assessment such as the earthquake recurrence times and coefficient of variation. We test and discuss this methodology in two well-studied cases: the Paganica Fault in Italy and the Wasatch Fault System in the United States.

1 Introduction

20 A principal challenge in paleoseismic research is having complete and properly time-constrained paleoearthquake catalogues. The presence of large sedimentary hiatuses due to depositional intermittency, imbalanced erosion-deposition rates or scarce availability of datable material are common limitations leading to poor age control in trenches. These uncertainties in the event age constraints add to the difficulty of site correlations and hence in establishing a reliable paleoearthquake chronology 25 representative of the whole fault.

To assess the correlation problem, two approaches have been developed (Fig. 1). The first one (DuRoss et al. 2011) addressed this issue in a segment of the Wasatch Fault (United States) by correlating site chronologies computed with the Bayesian modelling software OxCal (Bronk Ramsey, 2009, 1995). After an overlap analysis of the event probability density functions (PDFs) among sites, the correlation (product of PDFs) was restricted between the PDF pairs that showed the highest overlap 30 in each site (Fig. 1b). This model demonstrated a reduction in event time uncertainties and refined the chronology of the

Wasatch Fault but carries some limitations. First, basing the correlation on PDF overlaps can be problematic in other datasets with larger uncertainties, where one event PDF in a site may partially or fully overlap with more than one event PDF in another site (Fig. 1b). Second, it can hamper the ability of identifying additional events that might not have ruptured in all sites; for instance, PDFs in different sites that overlap but that are skewed in opposite directions could be in fact two different events.

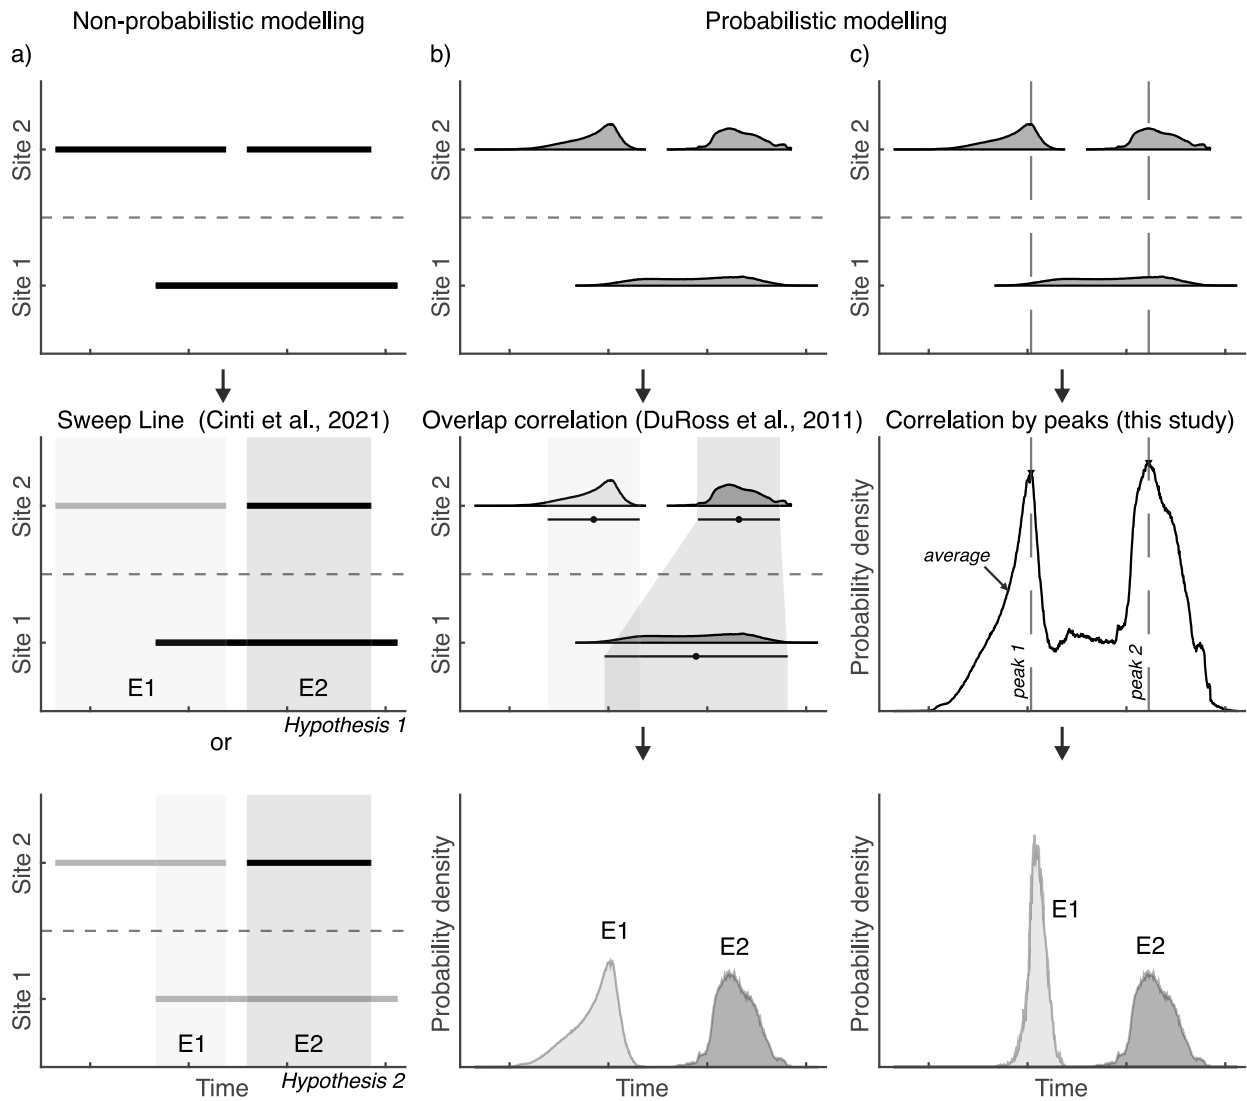
35 In these cases, restricting correlation to individual events can reduce the accuracy of the analysis.


Figure 1: Schematic comparison of the existing approaches to correlate paleoseismic sites with our method. The example is artificial. a) Method by Cinti et al. (2011) using a non-probabilistic modelling of event times. The Sweep-line algorithm moves from left (older times) to right (younger times) and evaluates the intersections between events in each site. The outcome in the example are two

possible correlation hypotheses (middle and bottom panels). This figure is originally drawn for the present example but based on the method illustrated by Cinti et al. (2021). b) Method by DuRoss et al. (2011) using event times modelled as probability density functions (PDFs) in OxCal. This method analyzes the overlap between PDFs and correlates those with higher overlap. In the example of the middle panel, the two younger (right) PDFs of sites 1 and 2 are correlated and the older (left) in site 2 is left alone as a single-

45 **site event. The final chronology (bottom panel) consists of the product PDF between the two correlated PDFs in site 1 and 2 (E2), and the un-correlated PDF of site 2 (E1). The PDF shapes of the two top sub-panels are drawn from the OxCal models provided in the Supplements by DuRoss et al. (2011). c) Method in this study. We also consider event times modelled as PDFs but, instead of imposing which PDFs are correlated, we compute the average distribution of all PDFs (middle panel). Then, the peaks of probability in this distribution (considered as event occurrence indicators), are used to extract all event PDFs intersecting its positions (dashed**

50 **lines) and are multiplied into a product PDF. This allows one event PDF to participate in more than one correlation: for instance, the event in site 1 is intersected by both peaks 1 and 2 and therefore participates in the computation of both E1 and E2 product PDFs. This unrestricted correlation accommodates the possibility of the event in site 1 being two events, as supported by its overlap with both events in site 2.**

More recently, Cinti et al. (2021) developed an approach to model earthquake occurrences from paleoseismic data at the fault

55 system scale in Central Italy. In this case, their approach does not model events probabilistically, but considers equal occurrence likelihood throughout the whole uncertainty range of the event time (Fig. 1a). Using a Sweep Line algorithm, their approach explores scenarios of event correlation between sites within a same fault and along the whole fault system to identify potential multi-fault ruptures. This algorithm passes a vertical line along the time axis and searches all intersections between event times among sites, providing the list of correlation hypotheses (Fig. 1a). Besides the differences in the event time

60 modelling, the approximation followed for site correlations is similar to DuRoss et al. (2011) in the sense that, for each scenario, only one event correlation hypothesis is considered. Although a set of scenarios with all correlation combinations are explored, the authors ultimately set their preferred ones based on expert judgement. Again, this is not the ideal solution when event ranges highly overlap because ranking scenarios becomes highly subjective, and working only with the event time ranges (without probabilities) adds further difficulty to this task. On top of this, both methodologies are developed for case-specific

65 needs, so their applicability to other settings might be diminished, especially where paleoseismic data is less well-constrained and scarcer than for the tested faults.

To accommodate the mentioned limitations, we present a new approach and accompanying code named *PEACH (Paleoseismic EArthquake Chronologies)*. Its main purpose is to probabilistically compute paleoearthquake chronologies in faults based on an objective and unrestricted correlation of paleoseismic data, accounting for common problematic situations inherent to

70 paleodata and reducing uncertainties related to event age constraints. This makes it flexible in terms of its applicability to other datasets worldwide. *PEACH* relies on i) simple and easy to compile inputs, including the option of using chronologies computed with OxCal, ii) a semi-automated workflow, and iii) outputs that can be further used to compute fault parameters for the hazard (e.g., earthquake recurrence intervals or coefficient of variation). To demonstrate and discuss the advantages of the method, we show applications in two real-case examples in Central Italy and the Wasatch range in the United States.

75 With *PEACH* we aim to introduce a reliable and objective tool to interpret multi-site paleoseismic data and to characterize the earthquake occurrences on faults, especially when the uncertainties or amount of data prevent establishing clear interpretations manually.

2 Fundaments of the approach

It can be assumed that, because earthquake ruptures can be recorded at more than one site of a fault, it should be possible to
80 identify correlations in paleoearthquakes between trenches along that fault. Furthermore, the differences in time constraints from site to site can help to better constrain the final event chronologies representative for the whole fault (e.g., DuRoss et al., 2011). Based on this assumption, the approach adopted herein is based on two main premises:

a) Correlations are restricted to the fault level, defined as in the Fault2SHA Central Apennines Database (CAD) (Faure Walker et al., 2021). According to that, a fault is a singular first-order structure that has the potential of rupturing the entirety of its
85 length and with prominent end boundaries that can cause ruptures to stop. A fault can be formed by smaller sections (traces) with different levels of activity evidence or location certainty, but that do not constitute sufficient barriers for rupture propagation. Fault to fault correlations are not considered yet in the approach, as they require a series of fault conditions (e.g., geometrical or physical; Boncio et al., 2004; Field et al., 2014) that are not applicable to all settings and they need to be implemented cautiously.

90 b) Trench paleoearthquake records are always a minimum, hence, the wider the uncertainties in event times, the higher the chance of underdetection. Along this reasoning, when an event in a site fully or partially overlaps in time with several events in another, the correlation is not favored to any of the possible combinations. Instead, all correlation combinations are allowed simultaneously by integrating all event probabilities as we explain further in the paper.

3 Data and workflow

95 *PEACH* is based on a code written in MATLAB (https://www.mathworks.com) that probabilistically models event times from paleoseismic data on a fault to derive its paleoearthquake chronology. Such data needs to be compiled into a series of inputs detailed below. The current version (version 1) of the code is available at the *Zenodo* repository of the article (Gómez-Novell et al., 2023).

3.1 Input data

100 The PEACH code relies on two simple input files. The first file (e.g., faultname.csv; Table 1A) contains a list of all paleoearthquakes classified by each site in the fault and the dates limiting its younger and older age bounds. The dates correspond to the calibrated numerical dates that limit the event horizons in the trenches (Fig. 2a). The second file (site specifications, site_specs.txt; Table 1B) specifies a series of calculation information (e.g., sigma level truncation or number of

random samples/seed) and allows the oldest and youngest dates for the exposed stratigraphy in each fault to be set in case these
105 are not available in the datasets.

A) First file: Paleoearthquake dates in fault R					
Event_num	Site	Event_date_old	Error	Event_date_young	Error_1
a1	Site A	-500 (Sa1)	30	Null	Null
a2	Site A	-3000 (Sa2)	50	-500 (Sa1)	30
a3	Site A	-3000 (Sa2)	50	-500 (Sa1)	30
a4	Site A	-3000 (Sa2)	50	-500 (Sa1)	30
b1	Site B	-400 (Sb2)	50	900 (Sb1)	10
b2	Site B	-2500 (Sb4)	50	-900 (Sb3)	50
b3	Site B	-4300 (Sb5)	50	-2500 (Sb4)	50
b4	Site B	-5600 (Sb6)	30	-4300 (Sb5)	50
B) Second file: Site specifications					
sigma_level	oldest_unfaulted	sd_unfaulted	oldest_faulted	sd_faulted	seed
0	1200	0	nan	nan	4000

Table 1. Input data required for the calculation with PEACH. Notes: A) Main input file containing the paleoseismic events and limiting dates for the example of Fault R in figure 2a (file faultR.csv in the "Inputs" folder at the code's *Zenodo* repository; Gómez-Novell et al., 2023). Events are sorted from youngest to oldest in each site and the dates (and corresponding samples in brackets)
110 **represent the age of the units limiting the event horizon in the trenches: "Event_date_old" is its older constraint and "Event_date_young" its younger age constraint. Error columns represent the 1σ uncertainties of the numerical dates. Dates should be provided with the BCE/CE notation: negative for BCE and positive for CE. "Null" means not available. B) Example of the site specifications file of fault R in figure 2 (site_specs.txt in the "Inputs" folder). The "sigma_level" allows to truncate the PDFs and work only with significant sigma levels: 1 for 1σ, 2 for 2σ, 3 for 3σ and 0 for full σ. See text for details on when this truncation is**
115 **recommended. The "oldest faulted" corresponds to the oldest available date affected by faulting. The code uses this date in the cases when the oldest age bound of the first event in a trench is not available in the first file (Null). If not provided in the "site_specs" file, the code automatically assigns the date of the oldest faulted materials along the whole fault. The "oldest unfaulted" is the oldest available date not affected by faulting (e.g., the younger age bound of the last event). This might correspond to the maximum age for surface ruptures in the historical catalogue of a study area. If this date is not provided when needed, an error is returned.**
120 **Otherwise, if there are no dates missing in the dataset, the mentioned fields should state "nan". The "seed" is the number of samples that the code iterates in each limiting numerical date to compute the event PDF (see text for details). All mentioned parameters except for the truncation level are skipped by the code when working with OxCal chronologies as inputs.**

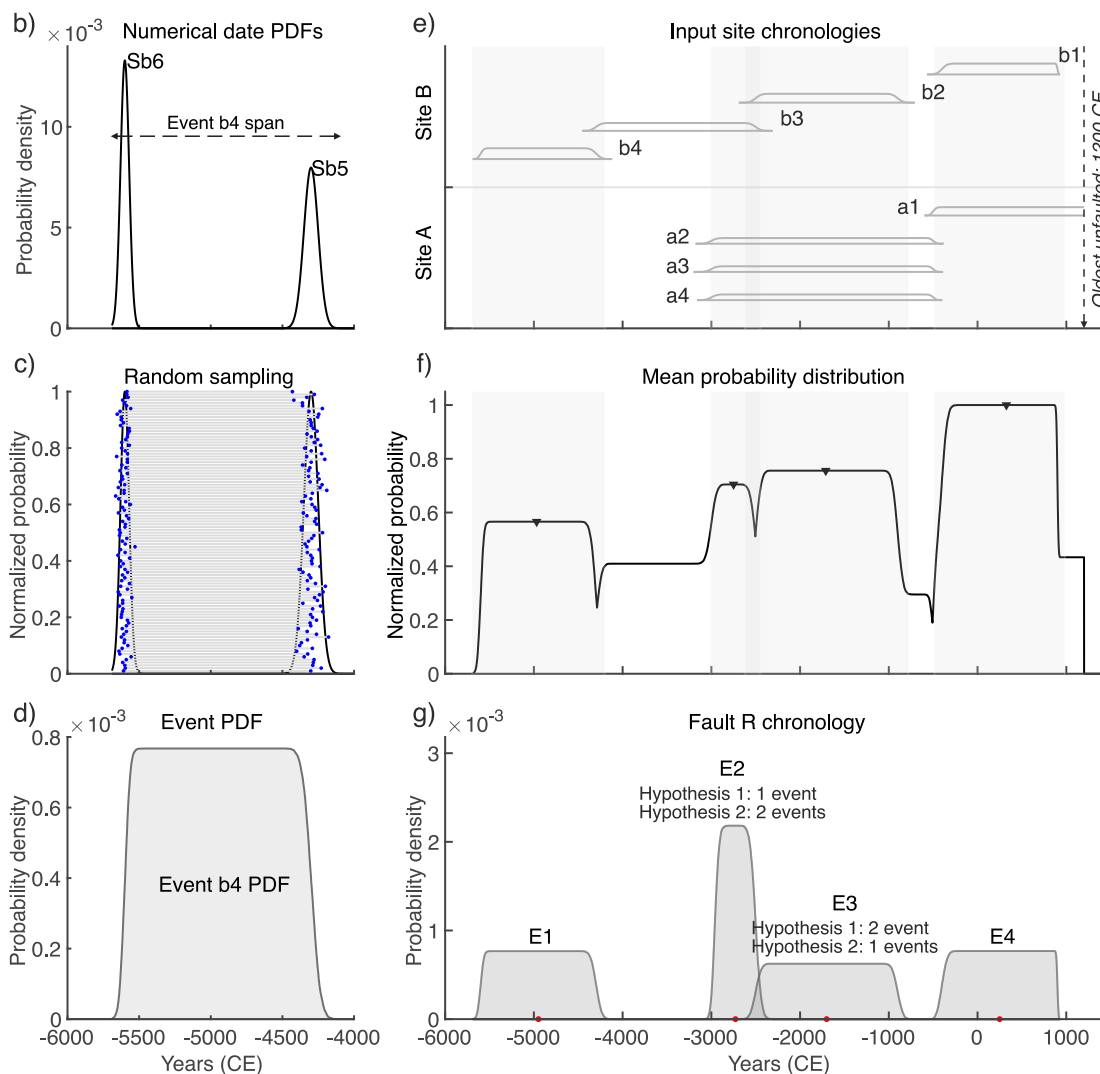
a) **INPUT DATA SOURCES**
WORKFLOW


Figure 2. a) Trench logs of an artificial fault R in two paleoseismic sites (site A and B). Stars indicate the event-horizon locations in

125 **the trenches. Each paleoseismic trench has four paleoseismic events recognized: events a1 to a4 in site A and events b1 to b4 in site**

B. The numerical dates of the limiting units (Sa1 and Sa2 in site A and Sb1 to Sb6 in site B) are available in Table 1A. Note that the insufficient date availability in site A, limit the capability of constraining individually the dates of events a4 to a2; all three events have the same age limits (Fig. 2e). CW: Colluvial wedge. b) Conversion of the numerical dates and 1σ uncertainties of the input table (Table 1A) into normal PDFs. The dates limiting event b4 are taken as example; c) Random sampling (100 samples depicted here)

130 of the numerical dates (dots) and establishment of time ranges between them (grey horizontal lines); d) Event b4 PDF resulting from adding all time ranges and scaling them so that the sum of the probabilities equals one; e) Input site chronologies of sites A and B with the event PDFs depicted. The grey bands indicate the 2σ ranges of the final chronology in panel g). The historical limit (oldest unfaulted date in the site specifications input file; Table 1B) is the age above which the seismic catalogue is complete for the surface ruptures in the region. Here we test a hypothetical date of 1200 years CE; f) Mean distribution and detected peaks resulting from

135 averaging all event PDF probabilities in the studied time span. The peak locations are used to integrate all PDFs from the input chronologies intersecting them. The grey bands indicate the 2σ ranges of the final chronology in the next panel. g) Final chronology for fault R with the mean value (dot) indicated for each PDF. Note that, because events E2 and E3 cover a time span where three events have the same age constraints in site A, there are two mutually exclusive hypotheses of event count that are provided for each PDF: if one hypothesis considers E2 as being one event, then E3 should correspond to two events and vice versa. In all cases the total

140 count of the whole chronology is five events contained in four PDFs, coincident with the total event count in the whole fault (panel e).

3.1.1 OxCal paleoearthquake chronologies

Nowadays, most paleoseismic studies use OxCal to compute site chronologies because it not only allows the user to statistically model complex stratigraphic sequences with sometimes conflicting numerical date distributions, but also because it allows to

145 impose a series of conditions to date events based on expert geological observations. That is, for instance, skewing the event PDF towards a limiting date due to the presence of coseismic evidence (e.g., colluvial wedges). To allow the preservation of such expert rationales for the correlation, our code also accepts event PDFs computed and exported from OxCal, instead of the previously explained input. To do so, the PDFs of all sites expressed as probabilities versus time need to be provided in a single input file following a similar format to the one provided by OxCal.

150 For information on the OxCal input file preparation check the *PEACH* user manual available at the *Zenodo* repository of this paper (Gómez-Novell et al., 2023). There you will also find all the input files used for the calculations in this paper.

3.2 Workflow

The *PEACH* source code is structured in four consecutive steps that are executed automatically. Note that, in case of using chronologies computed with OxCal, the first step of the workflow is skipped.

155 I) Building individual event PDFs

The individual event PDFs (event PDFs from now on) are built from the trench numerical dates that limit each event horizon (Fig. 2c). First, the numerical dates are transformed into normal PDFs. Second, for each pair of numerical dates that limit an event, a random sampling of "n" iterations is performed based on the event probabilities and "n" time ranges are established

in reality, how does this deal with multi-peaked calibrated C-14 calibrations?

will it always be 4000, why?

between sample pairs (Fig. 2c). The number of random samples (seed in the site specifications file; Table 1B) is set at 4000

160   here by after a sensitivity analysis (Fig. 3). For the datasets tested in this paper (the synthetic example of table 1A and the

Paganica Fault in Central Italy; Table 2), this seed ensures a robust and stable PDF modelling in several code runs and implies

minor changes in the computed average PDF probabilities with respect to larger seed increases (see figure 3).

   Lastly, all time ranges computed are added to derive the event PDF and scaled so that the sum of all probabilities per PDF

equals one (Fig. 2d). This process is done for all events and all sites analyzed in the fault.

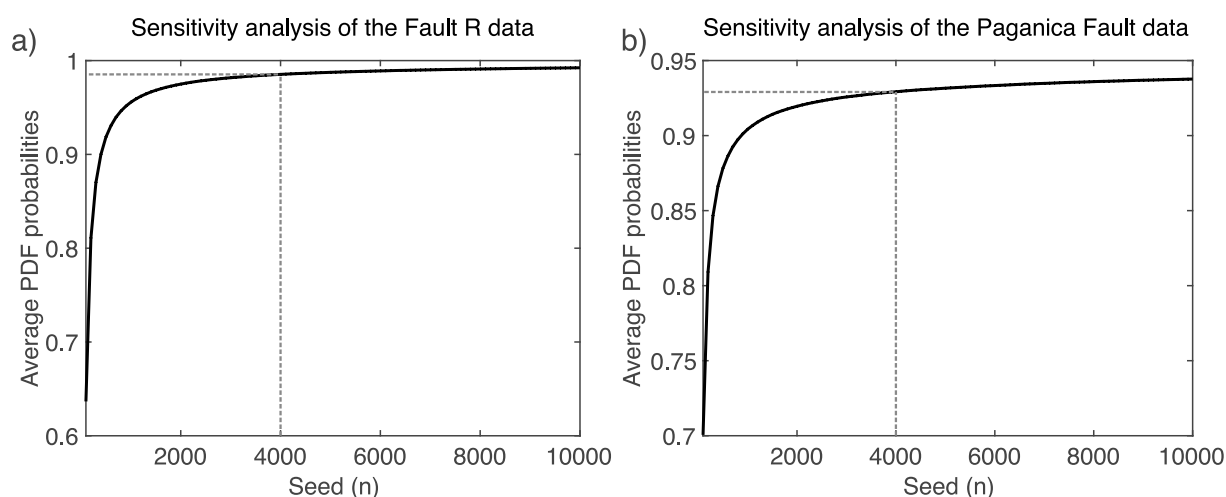
165


Figure 3. Sensitivity analysis for the number (n) of random samples (seed) explored within the numerical date PDFs to build the event PDFs for the a) synthetic example of Fault R depicted in figure 2 and b) the Paganica Fault depicted in figure 5. The seed sensitivity is analyzed with respect to the global mean of the mean probabilities of all PDFs in the respective fault datasets. For

170   **smaller seeds below ~4000 samples the average probabilities are highly variable. Above this value, increasing seeds lead to small changes in the PDF probabilities as the curve gets asymptotic, while computation time increases. For the Wasatch Fault System example this analysis is not performed because the event PDFs are taken from previously computed OxCal chronologies (see section 4.2).**

II) All site PDF average

175   A mean probability distribution is computed by averaging the maximum probabilities of the event PDFs from each site and

for each year time bin. The maximum is used so the average outlines the maximum probability areas of each event PDF and

to avoid peaks in PDF intersections. This average distribution depicts the overall earthquake occurrence probabilities in the

fault for the time span observed (Fig. 2f). Because the probability (height) of each event PDF is inversely proportional to the

width of its uncertainties, the better constrained events have higher contribution (i.e., higher height) to the average distribution.

180   The peaks of probability in this distribution are thus assumed as an indicator of higher earthquake probability of occurrence.

Their detection and time location are therefore crucial to derive the chronology.

III) Probability peak detection

The peaks of the mean distribution are detected based on their prominence, which measures how much the peak's height stands out compared to the rest of the peaks in the distribution. First, a reference base level is set at the local minimum in the valleys around each peak and then the prominence is measured from this level to the peak value. To avoid noisy detections and underdetection, a minimum prominence threshold (*minprom*) is set above which all peaks should be detected.

The target parameter to define the *minprom* is ½ the minimum peak probability (*minP*) of the event PDFs, namely the PDF with the widest uncertainty of them all (Fig. 4a). The half probability is because the peak is detected in the mean curve, which averages all the probabilities in each time bin. Then, because the mean distribution is normalized, the half probability value is also normalized using the maximum probability of all PDFs (*maxP;* Fig. 4a), yet again divided by two because the maximum height of all PDFs is ½ *maxP* in the mean distribution. See Eq. (1):

$$minprom = (0.5 * minP)/(0.5 * maxP) \tag{1}$$

The peak detection works also in plateau-shaped peaks (e.g., Fig. 2f), where the peaks are placed in the median point of the plateau, instead of its corners (default). This is achieved by running the detection function twice in opposite directions in the time scale (left to right and right to left) and computing the median value between the corners to set the peak.

IV) Extraction of the paleoearthquake chronology

The peak locations do not correspond to the final event times; they indicate times of higher event likelihood (i.e., higher event overlaps) in the fault's timeline, which need to be translated into distributions that probabilistically express the event timing in each peak position. To do so, all the event PDFs from all sites that intersect each peak position (Fig. 2e) are correlated (multiplied) into a product PDF (i.e., final PDFs). The product operation is used because i) it places the higher probability of the final PDFs at the overlaps of the input PDFs, which is where the events are most likely located, and ii) it reduces the uncertainties of these final PDFs compared to the input chronologies (e.g., Fig 2e vs. 2g).

The set of product PDFs represents the final chronology of the fault (Fig. 2g). Note that two event PDFs can participate in more than one product PDF if they intersect more than one peak position (Fig. 1c and 2e). Note also that, given the random nature of the PDF computation process, the same input data might yield slightly different results in each calculation.

3.2.1 Refinements of the chronology

After the extraction of the paleoearthquake chronology, four types of problematic situations linked to the data used to build the model may arise, requiring further refinements. These refinements are necessary to produce a more reliable or realistic chronology, as explained below.

a) Overlapping event PDFs: In some sites, the lack of age constraints can yield age ranges of consecutive events that overlap highly in time or even show the same exact age (e.g., three older events in site A; Fig. 2e). Such an overlap makes it difficult to produce a mean curve with individual peaks corresponding to each event and therefore can mask events in the final chronology. To solve this, for each final PDF, the code identifies the sites where these overlaps occur and counts them. The

outcomes are final PDFs that can represent the occurrence of more than one event. The number of events that each PDF

215   represents corresponds to the maximum number of overlaps identified in any site at that time position. If there is more than

one final PDF in the time span covered by the overlapping events, the number "N" of such overlapping events is divided

between the number of PDFs. If the division is odd, all combinations that add to "N" are generated (E2 and E3; Fig. 2g).

b) Peak over-detection. In some cases, the prominence threshold might not be enough to avoid noisy detections (Fig. 4). In

this case the code is prepared to automatically clear out repeated final PDFs in the chronology that come from peaks very close

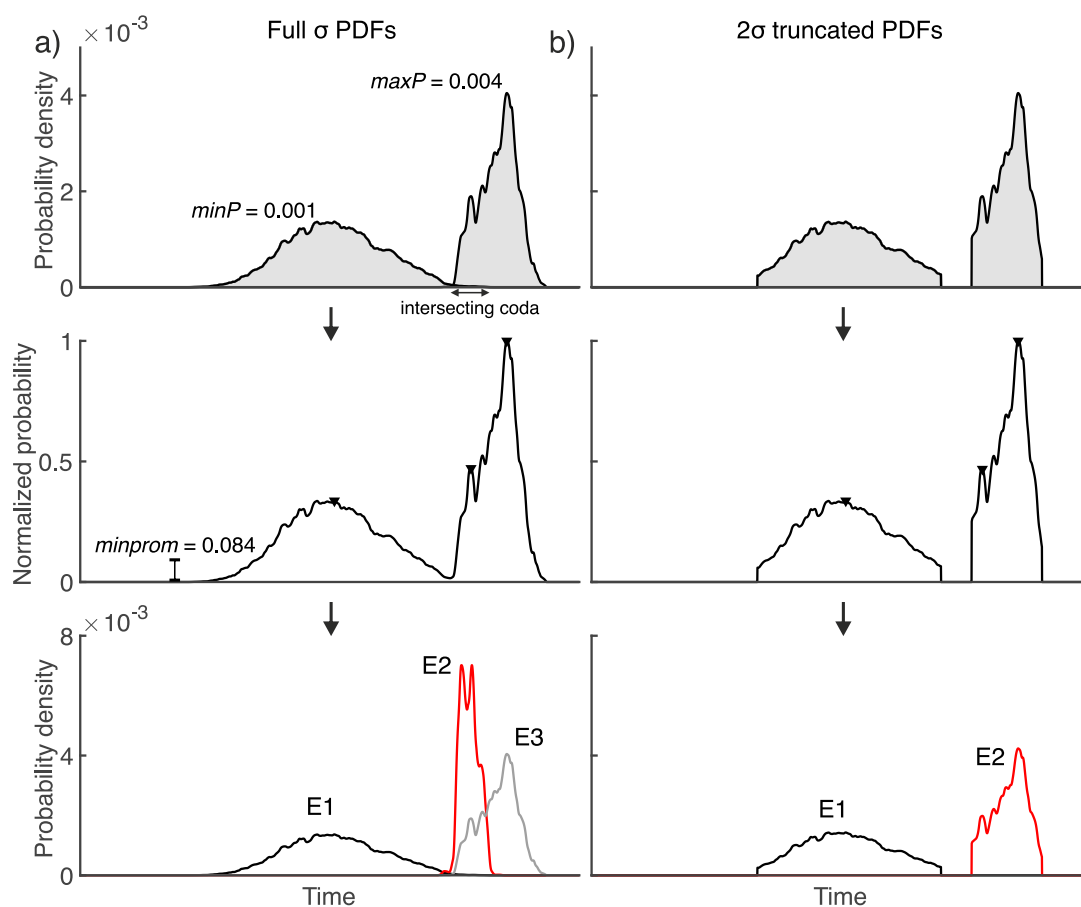
220   in time (e.g., peak clusters in jagged-shaped peaks; Fig 4).


Figure 4. Definition of the parameters to calculate the prominence threshold (*minprom*; see Eq. (1)) and noise removal workflow in a simplified dataset of 2 event PDFs. a) Chronology computation with non-truncated (full σ) PDFs. In the upper panel minP and maxP are defined as the minimum and maximum peak probabilities of the PDFs in the dataset, respectively. Note that here the PDFs

225   **are not truncated (full σ) and that the less constrained PDF has a coda that intersects the better constrained PDF. The middle panel shows the next step in which all PDF probabilities are averaged, and the probability peaks are detected based on the *minprom* as defined by Eq. (1). Note that for the PDF on the right, the jagged shape leads to two peaks, one located at the true probability peak**

of the PDF and another that can be interpreted as noise. Because the chronology is extracted based on the peak positions, the final
PDFs (products) computed for both peaks are different because the noise peak intersects the coda of the neighboring PDF and the
230 **true peak does not. This computes an extra event (red PDF) that is, in fact, an artifact of the noise combined with a poorly constrained**
PDF and, as such, overestimates the chronology in terms of event count: three events instead of the two observed. b) Chronology
computation with PDFs truncated at 2 σ. In this case the truncation removes the coda intersection and the final chronology is two
events, consistent with the observed.

c) Peak under-detection. This can be due to poor peak definition related to a large overlap between PDFs. For such cases, the
235 user has the possibility to truncate the event PDFs to different levels of statistical confidence (sigma), which can help increasing
the peak prominence. However, for some datasets the prominence threshold might require re-adapting, so smaller thresholds
can be referenced manually in the code (see user manual; Gómez-Novell et al., 2023).

Datasets with known historical or instrumental ruptures can also fall in the underdetection problem. These events have no
timing uncertainties and, therefore, their peak probability equals one. Conversely, paleoseismic datasets have larger
240 uncertainties and therefore much smaller peak probabilities in the order of $1 \cdot 10^{-2}$ to $1 \cdot 10^{-3}$ or less (e.g., Fig. 2d). The
combination of both types of datasets in a calculation, generates a mean distribution whose shape is controlled by these
historical peaks, while the paleoseismic show practically negligible prominences. This scale contrast flattens the normalized
mean distribution in the regions where event PDFs have small prominences (poorly constrained; usually the older parts of the
records), and thus can go unnoticed by the code given the *minprom* threshold set. In such cases and if the target is to increase
245 resolution of the older paleoseismic record, we recommend leaving historical events out of the computation.

d) Event PDFs with wide codas. In such instances, the lower probabilities (close to 0) of the coda regions might interfere in
the computation of the product PDF by over-constraining them compared to the original datasets. In addition to the over-
constraining, the wide codas of PDFs can cause an incorrect clearance of the over-detection because they can intersect peaks
located farther in time from their higher probability region. As the example in figure 4: two close peaks detected in two jags
250 of the same high in the mean distribution correspond to the same event, only that one of them is redundant. Because they are
so close in time, in ideal conditions they will intersect the same event PDFs and yield the same final product PDFs, making it
easy for the code to clear out the repeated event. However, if one of the two peaks is intersected by a wide coda of a farther
PDF (a PDF that does not contribute to the probability high analyzed), the product PDFs computed will not be identical and
therefore, the code will interpret those two redundant peaks as two different events. Working with sigma-truncated event PDFs
255 can help to both exclude the low probability regions for the noise clearance (Fig. 4b) and to improve the over-constraining of
certain PDFs.

Check the user manual (Gómez-Novell et al., 2023) for details and examples on the situations explained for the refinements.

3.3 Outputs

Two types of outputs are generated. The first outputs are two csv files (*Final_PDFs.csv* and *Final_PDFs_stats.csv*) containing
260 i) the final PDFs expressed as probabilities as a function of time and ii) statistical parameters of the PDFs (mean and standard

deviation), respectively. These files also provide the number of events contained in each PDF in case of overlaps (e.g., hypothesis 1 and 2 in figure 2g). The second output (Final_PDFs.pdf) consists of three visualization figures: i) the event PDFs in each site (Fig. 2e), ii) the mean curve with the peak identification (Fig. 2f) and iii) the final chronology (Fig. 2g). All the output files of the examples shown in this paper (faultR, Paganica Fault and Wasatch Fault Zone) are available at the "Outputs"

265 folder of the code's *Zenodo* repository of the paper (Gómez-Novell et al., 2023).

Aside from the output files, the code produces a summary in the command window that informs the user of the number of events identified in the chronology, the uncertainty reduction compared to the input chronologies, as well as an estimation of the mean recurrence time and coefficient of variation (CV) of the chronology. The recurrence and CV values, estimated arithmetically from inter-event times, are intended to be indicative and should be taken with caution, especially because some

270 datasets might have completeness issues in the older parts of the sequences that can highly impact their reliability. For a more statistically robust computation and treatment of the uncertainties in the recurrence and CV, we recommend using the outputs of *PEACH* in other softwares such as *FiSH* (Pace et al., 2016), which are specifically designed for this purpose.

4 Applications to real cases

We show the application of *PEACH* in two datasets from two different tectonic contexts worldwide: the Paganica Fault in

275 Central Italy (Fig. 5) and the Weber Segment of the Wasatch Fault System in the United States (Fig.6). These faults are selected because they are well studied at multiple sites along their traces and, consequently, have populated paleoseismic records that are optimal to put the method at test. Furthermore, the fact that paleoseismic studies in the Wasatch Fault System have relied to the on OxCal modelling enables us to show the results of the approach also using such chronologies as inputs. Conversely, the artificial example shown in figure 2 demonstrates how the methodology is also able to work in simpler and less populated

280 datasets.

4.1 Paganica Fault

The Paganica Fault is an active normal fault accommodating NE-SW extension in the Central Apennines (Italy) and responsible for the devastating 2009 L'Aquila earthquake sequence, as demonstrated by seismicity (e.g., Chiarabba et al., 2009) and coseismic surface data (e.g., Falcucci et al., 2009; Boncio et al., 2010; Roberts et al., 2010). The Paganica Fault used in this ^rupture

285 example is the one defined in the CAD database (fault level; Faure Walker et al., 2021), composed of nine traces all of which demonstrated the capability of rupturing simultaneously during the 2009 event. The fault level considers first-order structures that can rupture entirely, but with prominent end boundaries able to stop ruptures from propagating further.

We compiled the published paleoseismic data from the eleven paleoseismic sites (Table 2) studied along the Paganica Fault, with a total of 25 paleoearthquakes defined by the numerical dates limiting each event horizon (Table 2). Two additional

290 paleoseismic sites (Trench 3 by Galli et al., 2011 and Trench C by Moro et al., 2013) have been excluded from this analysis due to the lack of numerical dates to establish a paleoearthquake chronology.

Table 2. Input data and related references of the Paganica Fault as used in this study. Notes: The model resulting from these data is shown in figure 5. "Null" indicates that the age bound of that event has no date available in the dataset. Therefore, the "oldest_unfaulted" and "oldest_faulted" parameters from the site specifications (bottom table) are used to assign a date to the respective younger and older missing event limits. The first is assigned a 1400 CE date as explained in the text. The second is assigned the oldest date available in the dataset as a conservative bound (4900±50 years BCE, from 250K site). Dates are in the BCE/CE notation: negative for BCE and positive for CE.

The compilation of the paleoseismic data implied a bibliographic revision in which we re-defined the age constraints of the events in those cases where the authors introduced expert judgments (e.g., assign a discrete historical date to an event based

only on the fact that its time range covers the timing of that historical event). Far from questioning the interpretations by the authors, this is done to ensure a dataset as objective as possible based only on independent numerical data. The criteria followed in the compilation is that the numerical dates selected to define the event time constraints are always: i) the ones closer to the

305 event horizons and ii) that have stratigraphic coherency. A series of conditions are applied: a) The same age constraints are assigned to events that cannot be dated individually. b) The surface rupture data here is considered complete from 1400 years CE, as suggested by Cinti et al. (2021) for the catalogue in Central Italy. Therefore, this date is considered as the "oldest unfaulted" date in the site specifications to be assigned when the youngest bound of the last event in a trench is not available
^prior to 2009?
(Table 2). However, this completeness value is not definitive and other dates could be tested.

310 The chronology of the Paganica Fault is computed considering 4000 random simulations (seed) based on the sensitivity analysis of figure 3.

4.1.1 Results

Our approach computes six final PDFs along the entire Paganica Fault, including the 2009 L'Aquila earthquake (Fig. 5) whose geological effects were observed in many trenches. The final chronology is better constrained compared to the chronologies of the individual sites as demonstrated by the average of the 1σ uncertainties of the event PDFs (~550 years) with respect to

315 the mean of those of the final PDFs (~40 years). This represents a ~93% reduction in the average uncertainties, although this should not be directly translated into a measure of the quality improvement of our model, especially in the older part of the sequence.

Before the Common Era (CE), the site chronologies are generally poorly constrained. In this regard, our probabilistic modelling

320 shifts the timing of the first event (E1) towards the better constrained (younger) part of the chronology (Fig. 5c), based mainly on the correlation with the older events in T2_Ga and TA sites (Fig. 5a). Although its timing is coherent with the data, its real uncertainty should be considered higher towards BCE times. For this same reason, in the BCE our method is not able to extract a chronology because the wide uncertainties generate poor definition in the average distribution for the peak identification (Fig. 5b). Moreover, the fact that the Paganica Fault dataset includes the 2009 event changes the shape (prominences) of the

325 mean distribution and likely reduces even more the code's capability to detect events in the older part of the sequence. This is because the 2009 event has no uncertainty and therefore, its probability is maximum (equal to one), as opposed to the much lower probabilities generated by older events (Fig. 5b). In fact, note that in figure 5 the scale is cut at the maximum probability
^5
of the peaks older than the 2009 event to ensure visualization.
this sentence may be redundant as you describe this in the caption
The Paganica Fault final chronology increases by one the number of events identified by Cinti et al. (2011) in the most

330 populated site along the Paganica Fault (TRET) for the past 2900 years BCE. We attribute this additional event to the correlation with observations in other sites and to the probabilistic modelling of event times, whose peak probability locations can allow an increased resolution of the paleoearthquake record. For instance, the last two penultimate events E4 and E5 are identified thanks to the different positions of the peak probabilities of the last event PDFs in sites TRET and TB, respectively (Fig. 5a). Excluding the probabilities, the event time spans would not be sufficient criteria to confidently correlate them as two

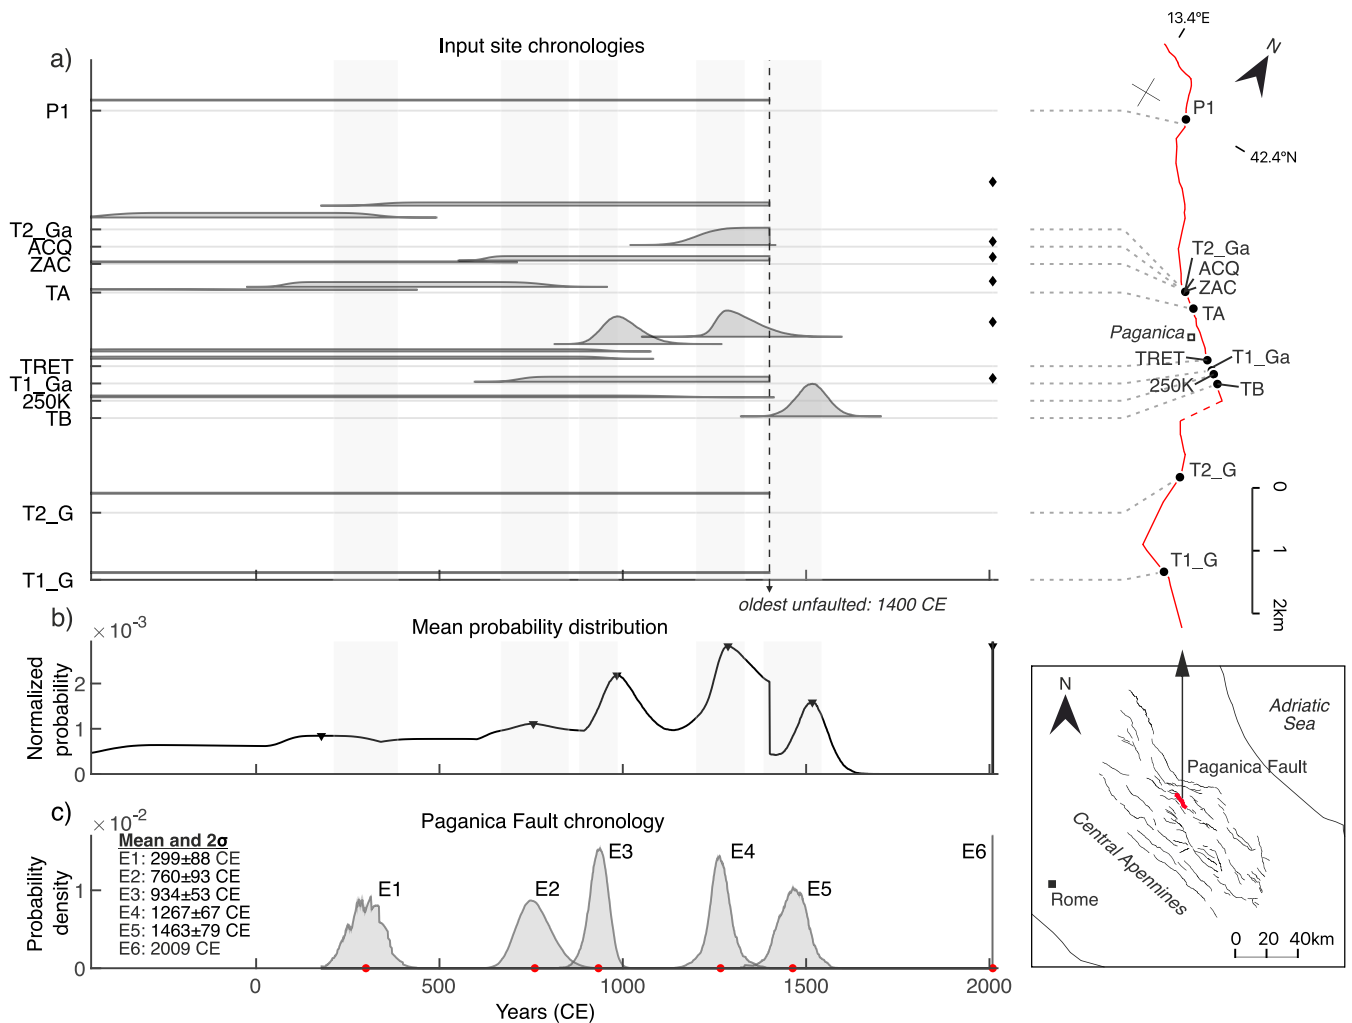
335   events because of their considerable overlap (>50% of the range of the event in TB). That is, in fact, the interpretation by Cinti
       et al. (2021) using the same dataset as ours: two penultimate events at 1461/1703 CE (equivalent to our E5) and another one
       at 950/1050 CE (equivalent to our E3). The PDF of the last event at the TRET site allows us to identify also E4.   *invert these words*
       In general, the results we obtain in the Paganica Fault are coherent with those already published. Our modelling allows us to   *for*
       refine the event identification and to improve the constraints of the event timing uncertainties, which is important for a more
340   reliable characterization of fault parameters such as the average recurrence interval and coefficient of variation.


Figure 5. Results of the application of our approach to the Paganica Fault using paleoseismic data from eleven sites (see Table 2). a) Input site chronologies for all sites studied, including the 2009 L'Aquila earthquake (dots). The location of the sites along the Paganica Fault trace is indicated in the right part. The location of the Paganica Fault within the Central Apennines is indicated in
345   **the inset at the lower-right corner of the figure. Only the chronologies for the past 2500 years BCE are depicted in the figure because they are the ones that allowed to compute the final chronology (see text for details). PDFs are scaled so that their probabilities add**   *I think this reads better*

to 1 (wider uncertainties mean less probability/height). The grey bands indicate the 2σ ranges of the final chronology in panel c). Fault traces are extracted from the Fault2SHA Central Apennines Database (Faure Walker et al., 2020). b) Mean distribution resulting from the average of all event PDFs and probability peaks. Note that the vertical scale is cut at the normalized probability

350 of the maximum peaks older than the 2009 peak (2009 L'Aquila earthquake). This is done to ensure visualization of the whole distribution because the probability of the 2009 peak is one (corresponds to an event with no uncertainties; Table 2). c) Final chronology for the Paganica Fault with the mean value (dot) indicated for each PDF.

4.2 Wasatch Fault Zone

The Wasatch Fault Zone is the longest continuous normal fault system in the United States that constitutes the eastern structural

how about 'States. It const.'

355 boundary of the Basin and Range Province (Machette et al., 1991; DuRoss et al., 2011) and accommodates about half of its extension in the northern Utah-eastern Nevada sector (Chang et al., 2006). The Wasatch Fault Zone is divided into ten primary segments (Schwartz and Coppersmith, 1984; Machette et al., 1991) out of which the five central ones show vast evidence of repeated Holocene surface rupturing events (e.g., McCalpin et al., 1994; DuRoss and Hylland, 2015; Personius et al., 2012; Bennett et al., 2018; DuRoss et al., 2009). The prominent structural boundaries between the segments, along with timing of

360 paleoseismic data seem to support that the Wasatch Fault Zone, although with exceptions, generally follows a segmented fault model (Schwartz and Coppersmith, 1984; Machette et al., 1991; DuRoss et al., 2016; Valentini et al., 2020). Based on this data, in the Wasatch Fault Zone we can confidently correlate data only within the primary segments, those based on the most prominent, first-order segment boundaries, where ruptures are believed to stop most frequently (DuRoss et al. 2016). The primary segment concept in the Wasatch Fault Zone is equivalent *^to* the fault level used to define the Paganica Fault in the CAD

365 database (Faure Walker et al., 2021).

We select the Weber Segment because it is where the first approach to objectively correlate multi-site paleoearthquake chronologies was implemented (DuRoss et al., 2011). Hence, it is a good opportunity to test and compare our results. We re-computed the OxCal paleoearthquake chronologies from four paleoseismic sites in the Weber Segment using the OxCal models (scripts) performed and discussed by DuRoss et al. (2011), which are available in their Supplements: Rice Creek (RC), Garner

370 Canyon (GC), East Ogden (EO) and Kaysville (K). These models depict a total paleoearthquake record of 17 events is recorded throughout all sites for the past 7-8 ka BP. The input file with the computed OxCal PDFs used for our calculations is available at the *Zenodo* repository of this paper (Gómez-Novell et al., 2023)

4.2.1 Results

We compute a total of six paleoearthquakes for the past 7 ka BP in the Weber Segment (Fig.6). In general, the final PDFs are

375 well-constrained with an average standard deviation of 107 years, about 65% lower than the average standard deviation of the input OxCal chronology (302 years). In this case, the uncertainty reduction is regarded as an improvement on the chronology, mainly because the uncertainties of the final chronology compare reasonably to those of the site PDFs (i.e., no overconstraining) (Figs. 6c and 6d).

The main discrepancy between the model herein and that proposed by DuRoss et al. (2011) concerns the event count, as we
380   identify one event more than DuRoss et al. (2011) (Fig.6d). This discrepancy is mainly due to different assumptions in the
event site correlation: DuRoss et al. (2011) select the PDFs to be correlated beforehand by computing a PDF overlap analysis,
which leaves the correlation to one PDF per site (Fig. 1b). Then the final PDF is computed by averaging or multiplying these
pre-selected PDFs (depending on the overlap). From our perspective, this condition overlooks the possibility of underdetection
for the case when event PDFs have wide uncertainties and thus the confidence that it corresponds to a single event decrease.
385   Based on this, our approach allows correlation of site PDFs without restrictions; that is, one event PDF can be correlated with
several PDFs as long as these overlap totally or partially with its time span.

In the Weber Segment, the additional event using *PEACH* is obtained from correlating the two events between 3 and 5 ka BP
at the RC, GC and EO sites. DuRoss et al. (2011) derive two events because they correlate only one PDF of the pair for each
site. In our chronology, instead, the correlation is driven by the position of the peak probabilities in the different site PDFs
390   that, because they are skewed in opposite directions (e.g., RC towards older times and GC and EO towards the present; Fig.6a)
they generate three well-defined peak probability positions in the mean distribution (Fig.6b) suggesting the presence of three
events instead of two. Furthermore, such correlation method allows partial segment or inter-segment rupture hypotheses. For
instance, E4 being mainly defined at the RC site could mean that i) the event only ruptured the northern tip of the Weber
Segment (Fig.6) or that ii) the event corresponds to an inter-segment rupture that also ruptured the neighboring segment to the
395   north (Brigham Segment). In this line, both scenarios agree with DuRoss et al. (2016) in the sense that, the authors state that
partial segment ruptures near or across the primary segment boundaries are feasible. In detail, they find that E1 at RC in the
Weber Segment can be correlated with the youngest and only event recorded at the Pearsons Canyon site (southernmost part
of the Brigham Segment), unveiling a potential inter-segment rupture. Hereby, a similar scenario can be discussed for E4 at
RC, although it would require further analysis with *PEACH* using the paleoseismic datasets of both segments.
400   Another difference in our modelling results is that the uncertainties associated with E2 are considerably reduced compared to
those estimated by DuRoss et al. (2011) (Figs. 6c and 6d). That is because, for this event, DuRoss et al. (2011) compute the
mean instead of the product PDF as they debate that the poor PDF overlap of the penultimate events in all sites would result
in overconstraining. In the *PEACH* approach instead, the product of PDFs constrains the event in the overlapping area of all
PDFs that is, in fact, where the event is most likely to have happened. More so, the shape and uncertainties of the product PDF
405   are comparable to the better-constrained event at that time position (penultimate event at RC site; Fig.6a). A mean PDF
approach instead of a product one would lead to uncertainty estimates almost as large as the mean (993±747 years BP) and
larger than the variance of any of the input event PDFs.

Besides the similarity of the DuRoss et al. (2011) and *PEACH* models, we propose that *PEACH* performs better in
two regards. First, *PEACH* provides a more independent analysis of event timings because we do not pre-impose nor condition
410   correlation to specific PDF pairs. Secondly, *PEACH* seems to increase the resolution in the event detection by adding one
event more, while keeping the uncertainties of the event PDFs within acceptable ranges, overall representative and coherent
with the input data.

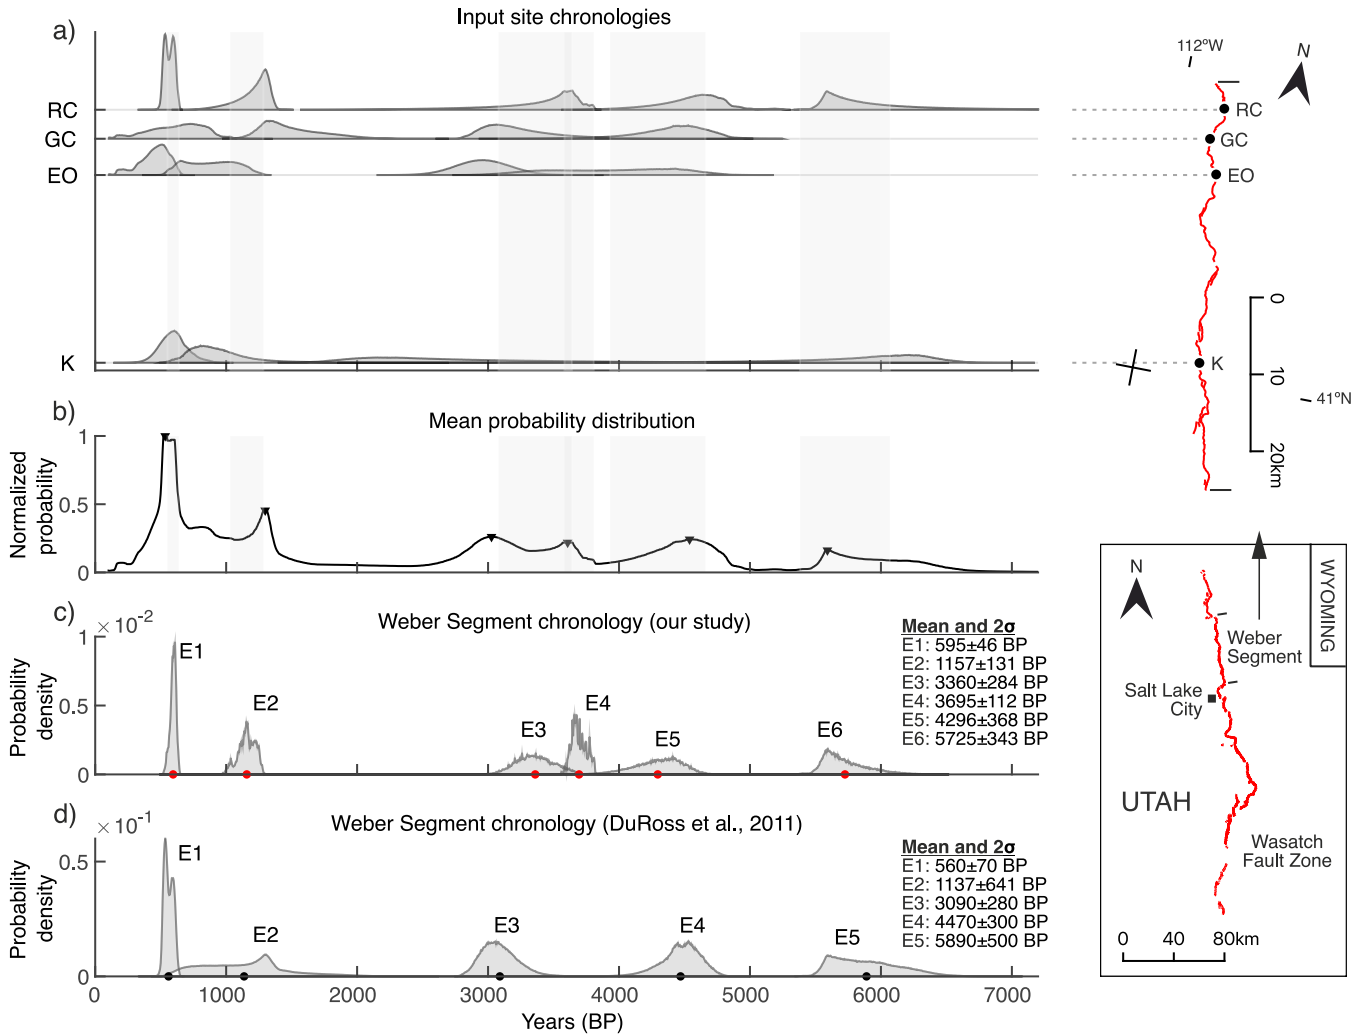
How do you express a statistical confidence that there is geologically an extra event (or 1 less), because it also affects
the confidence of another event next to it?
How does this go on to impact ideas/versions of fault rupture segmentation?


Figure 6. Results of the application of our approach to the Weber Segment of the Wasatch Fault Zone using the OxCal models by
415   **DuRoss et al. (2011) at Rice Creek (RC), Garner Canyon (GC), East Ogden (EO) and Kaysville (K). a) Input site chronologies for all four sites studied. The location of the Weber Segment within the Wasatch Fault Zone is indicated in the inset at the lower-right corner of the figure. The grey bands indicate the 2σ ranges of the final chronology in panels c) and d). Fault traces are from the Quaternary fault and fold database for the United States (US Geological Survey and Utah Geological Survey, 2019). b) Mean distribution resulting from the average of all event PDFs**
420   **and probability peaks. c) Final chronology for the Weber Segment with the mean value (dot) indicated for each PDF. d) Final chronology by DuRoss et al. (2011) computed using the OxCal models provided by these authors in their Supplements. Dots indicate the mean value of each PDF. Note that here the time scale is in years BP and event numbers increase for older times to ensure direct comparison with the model by DuRoss et al. (2011).**

5 Discussion and conclusions

425

The *PEACH* approach seeks to maximize refinement of paleoseismic records using a workflow that relies on a probabilistic modelling of event times from trench numerical dates or pre-computed chronologies from the widely used OxCal software. The approach is flexible and versatile to accommodate several situations of paleodata, e.g., events that cannot be constrained in time individually (site A; Fig. 2e). More so, the inputs for the calculations are simple to compile and the outputs can be

430   easily used to compute fault parameters for the seismic hazard (e.g., average recurrence times and coefficient of variation) in external softwares (e.g., *FiSH*; Pace et al., 2016).

Our approach is capable of reliably constraining paleoearthquake chronologies from populated records, that otherwise would be difficult to correlate manually. The chronologies significantly reduce the uncertainties in the event timing compared to the original data (more than 50% in the cases exemplified). In addition, the probabilistic treatment of the event times along with a

435   non-restricted site correlation of events seems to perform better in the event detection, allowing an increased total count compared to the trench observations. This can be observed in both cases we exemplify at the Paganica Fault in Central Italy and the Weber Segment in the Wasatch Fault Zone (Figs. 5 and 6) and is a coherent outcome for paleoseismic data, where events evident in trenches are always a minimum relative to the actual number of events that occurred.

Another strong advantage of our method is that it does not rely on strong expert judgments in the event computation nor the

440   correlation. In detail, first, the event PDFs are built considering only the age constraints provided in the input, which should presumably correspond to numerical dates independently dated. That is, the shape of the event PDF (skewness, width and height) exclusively depends on the shape of the date PDFs that limit it. Second, the correlation is done independently of the event PDFs involved, meaning that all PDFs that contribute to a peak in the mean distribution and thus, that intersect it, are integrated to compute the final PDF of that event. This removes a layer of expert judgment introduced when correlating only

445   between PDF pairs, like DuRoss et al. (2011), which we suggest could eventually decrease the capability of detecting additional events in the dataset (e.g., smaller events not recorded in all sites).

Besides the advantages, there are limitations in the *PEACH* approach. Firstly, the use of only a pair of numerical dates to constrain each event PDF can be an over-simplification. This is because some stratigraphic layers can have several dates available with different ages (even inverted stratigraphically) that result from sample-specific anomalies. In radiocarbon, for

450   instance, two samples in the same unit and stratigraphic position can show dissimilar ages due to contamination or carbon inheritance (e.g., Frueh & Lancaster, 2014), especially in the case of snail shells (Goodfriend and Stipp, 1983). The selection of only one date to describe the age of the layer can be inaccurate. Secondly, because the PDFs from radiocarbon dates rarely show the shape of a normal distribution (Fig. 2b), but an irregular one due to the calibration, the age limits and shape of the resulting event PDFs we compute could be affected. For now, in datasets with multiple numerical dates (e.g., sites with several

455   dates of a same stratigraphic horizon), using OxCal might be the preferred option to compute site chronologies. Nonetheless,

is that true?
can there be an
over-interpretation of events?

future improvements of the approach certainly should allow the introduction of more than one numerical date to define the event time constraints and more complex radiocarbon PDF shapes.

In terms of event count, our approach strongly relies on the peaks detected in the mean distribution (Figs. 4, 5b and 6b). That is, the peak prominence threshold (*minprom*) has a high impact on the number of peaks that are detected and therefore on the

460   final number of events in the chronology. As the prominence threshold is dependent on the probabilities of the data themselves (Equation 1) and the final shape of the mean distribution, we cannot discard that for some datasets incorrect peak detections could appear. This includes both overdetection and underdetection. The code has several refinements implemented to solve these situations (noisy cluster clearance, sigma truncation, etc.; see section 3.2.1), but even when all of them work properly, we strongly recommend the end-user to check that the number of events in the final chronology is coherent with the site data.

465   One way to check this could be comparing the event count with the cumulative deformation observed in the trenches, i.e., evaluating whether the number of events is too large or too small to explain the observed deformation. Along this line of reasoning, we clarify that the universality of the approach to all datasets cannot be guaranteed.

With *PEACH* we highlight how the correlation of paleoseismic datasets with different event completeness degrees and age constraining quality improves the detection of paleoearthquakes and reduces the uncertainties in event timing. By extension,

470   it can potentially reduce the uncertainties in fault parameter estimates like average recurrence intervals or behavior indicators like the coefficient of variation. Also, the number of events correlated per site and time, compared to their location along the fault trace can give insight on fault rupture length (e.g., Figs. 5a and 6a). Ultimately these results can be useful to seismic hazard practitioners, as the uncertainties in such parameters are frequent challenges for seismic hazard assessment. For now, we estimate that our method can be reliably used in correlations within the fault level. A measure of the extent of correlation

475   along-fault can come from historical data of surface ruptures. For automatic correlations outside of the fault boundaries (e.g., multi-fault ruptures), further improvements regarding site location/fault distance conditions should be implemented.

We encourage the use of our tool by researchers working on paleoseismology and active tectonics in general, with emphasis on those seeking to improve the time constraints of paleoearthquakes. On top of that, we also invite its users to give the necessary and pertinent feedback to improve our approach in the future.

480   **Data and code availability**

The current version of *PEACH* (version 1) is available from the GitHub repository: https://github.com/octavigomez/PEACH under the license CC-BY-NC 4.0 (https://creativecommons.org/licenses/by-nc/4.0/deed.es). The exact version of the model used to produce the results used in this paper is archived on *Zenodo* (Gómez-Novell et al., 2023) as are input data and scripts to run the model and produce the plots for the fault examples presented in this paper. This archive also contains the user manual

485   with extended information of the approach and a step-by-step guide on how to use the code. Subsequent updates and releases of the code will be posted on GitHub.
