12 **Abstract**

13 Atmospheric aerosols have important impacts on air quality and the Earth-atmospheric energy
14 balance. However, as computing power is limited, Earth system models generally use coarse spatial grids
15 and parameterize finer-scale atmospheric processes. These parameterizations and the simulation of
16 atmospheric aerosols are often sensitive to model horizontal resolutions. Understanding the sensitivities is
17 necessary for the development of Earth system models at higher resolutions with the deployment of more
18 powerful supercomputers. Using the Energy Exascale Earth System Model (E3SM) version 1, this study
19 investigates the impact of horizontal grid spacing on the simulated aerosol mass budget, aerosol-cloud
20 interactions, and the effective radiative forcing of anthropogenic aerosols (ERF_{aer}) over the contiguous
21 United States. We examine the resolution sensitivity by comparing the nudged simulation results for 2016
22 from the low-resolution model (LR) and the regional refinement model (RRM).

23 As expected, the simulated emissions of natural dust, sea salt, and marine organic matter are
24 substantially higher in the RRM than in the LR. In addition, RRM simulates stronger aqueous-phase
25 production of sulfate through the enhanced oxidation of sulfur dioxide by hydrogen peroxide due to
26 increased cloud liquid water content. In contrast, the gas-phase chemical production of sulfate is slightly
27 suppressed. The RRM resolves more large-scale precipitation and produces less convective precipitation
28 than the LR, leading to increased (decreased) aerosol wet scavenging by large-scale (convective)
29 precipitation.

30 Regarding aerosol effects on clouds, RRM produces larger temporal variabilities of large-scale liquid
31 cloud fractions than LR, resulting in increased microphysical cloud processing of aerosols (more
32 interstitial aerosols are converted to cloud-borne aerosols via aerosol activation) in RRM. Water vapor
33 condensation is also enhanced in RRM compared to LR. Consequently, the RRM simulation produces
34 more cloud droplets, a larger cloud droplet radius, a higher liquid water path, and a larger cloud optical
35 depth than the LR simulation. A comparison of the present-day and pre-industrial simulations indicates

36 that, for this contiguous United States domain, the higher resolution increases ERF_{aer} at the top of the
37 model by about 12%, which is mainly attributed to the strengthened indirect effect associated with
38 aerosol-cloud interactions.

39 1 Introduction

40 Atmospheric aerosols have played essential roles in the deterioration of air quality in recent decades,
41 especially in rapidly developing countries (Li et al., 2019; Lim et al., 2020; Xiao et al., 2021). Besides
42 directly degrading atmospheric visibility and with substantial impacts on human health (Apte et al., 2015;
43 Wang et al., 2019), aerosols are also involved in the formation of other major atmospheric pollutants,
44 such as ozone and nitrogen oxides (Perring et al., 2013; Pusede et al., 2015). In addition, atmospheric
45 aerosols from natural and anthropogenic sources considerably affect the radiation balance of the Earth
46 system. The present-day (PD) (the year 2014) anthropogenic aerosol effective radiative forcing (ERF_{aer})
47 relative to the pre-industrial (PI) period (the year 1850) is estimated to range from -0.63 to -1.37 W m^{-2}
48 according to 17 Earth system models (ESMs) participating the Coupled Model Intercomparison Project
49 Phase 6 (CMIP6) (Smith et al., 2020). Aerosols can modulate the earth-atmospheric energy balance via
50 several pathways. Firstly, they directly scatter and absorb shortwave and longwave radiation. Secondly,
51 they are involved in cloud formation by acting as cloud condensation nuclei (CCN) and ice nuclei, thus
52 influencing cloud radiative forcing. Thirdly, light-absorbing aerosols depositing on snow and ice
53 ~~surfacesurfaces~~ can change the snow and ice melting by absorbing more solar radiation, leading to
54 changes in surface albedo and energy budgets (Qian et al., 2015). Aerosols can also indirectly affect the
55 global energy budget by influencing the ocean biogeochemistry and terrestrial ecosystems (Hamilton et
56 al., 2022; Jickells et al., 2005; Mahowald et al., 2017).

57 Accurate simulation of atmospheric aerosols in ESMs is challenging due to complex physical and
58 chemical processes (e.g., emissions, nucleation, coagulation, condensation, dry deposition, wet
59 scavenging and resuspension, droplet activation, gas- and aqueous-phase chemistry, and radiation) and
60 our incomplete understanding of these processes. Substantial parameterizations are designed to represent
61 the aerosol lifecycle and its interactions with clouds and radiation in the Energy Exascale Earth System
62 Model (E3SM) (Burrows et al., 2022; Wang et al., 2020) — a state-of-the-science ESM sponsored by the

63 United States (US) Department of Energy (DOE) for scientific and energy mission applications (Golaz et
64 al., 2022; Golaz et al., 2019). However, these parameterizations are primarily developed and evaluated at
65 ESM scales, and their performance at higher resolution is generally unclear. As the computing power
66 continues to increase, future ESMs are expected to run at much higher resolutions (Caldwell et al., 2021;
67 Dueben et al., 2020; Heinzeller et al., 2016). Therefore, it is crucial to understand the fidelity of these
68 aerosol parameterizations and how the simulated aerosol lifecycle and aerosol effects on cloud and
69 radiation will change as model resolution increases. These efforts are critical for parameter tuning and
70 model development at high resolutions (Caldwell et al., 2019; Ma et al., 2014; Ma et al., 2015).

71 Caldwell et al. (2019) and Feng et al. (2022) investigated the impacts of model horizontal resolutions
72 on some aspects of the aerosol lifecycle in E3SM. However, both studies were based on simulations with
73 global uniform resolutions, which will be computationally expensive when the model resolution increases
74 further to convection-permitting. To reduce the computational cost and maintain high-resolution features,
75 variable-resolution techniques with high-resolution grids in the region of interest transitioning to low-
76 resolution meshes in others have been widely applied in ESMs (Harris et al., 2016; Schwartz, 2019;
77 Zarzycki et al., 2014). Tang et al. (2019) developed a regional refinement model (RRM) configuration for
78 E3SM version 1 (E3SMv1) with high-resolution meshes (~25 km) over the contiguous US (CONUS) and
79 low-resolution meshes (~100 km) in other areas. They found that RRM highly resembles the uniform
80 high-resolution simulation in the refined region, indicating that RRM can be an effective and
81 computationally efficient configuration for high-resolution model development.

82 This study investigates the impact of horizontal grid spacing on aerosol mass budget, aerosol-cloud
83 interactions, and ERF_{aer} over the CONUS in 2016 using the RRM configuration. We compare E3SMv1
84 simulations with a global uniform grid spacing of ~100 km (hereafter referred to as the low-resolution
85 (LR) simulations) to the RRM simulations using the same configuration as Tang et al. (2019) with higher
86 resolution (~25km) meshes over CONUS. Our findings provide insights into aerosol parameterization
87 development and their dependence on model horizontal resolution. The paper is organized as follows.

88 Section 2 describes the E3SMv1 model and the simulation configurations. Section 3 discusses the impacts
89 of increasing resolution on 1) the natural aerosol sources, 2) the aerosol wet scavenging, 3) the aerosol
90 chemical production, 4) the aerosol-cloud interactions, and 5) ERF_{acr} , where apparent discrepancies are
91 found between the LR and RRM simulations. Finally, the study is summarized in Section 4.

92 **2 Model setup**

93 **2.1 E3SMv1 model description**

94 Aerosol processes are primarily represented in the E3SM Atmosphere Model version 1 (EAMv1)
95 (Rasch et al., 2019), which uses the High-Order Methods Modeling Environment (HOMME) Spectral
96 Element dynamical core (Dennis et al., 2012). The dynamical core and the physics parametrizations are
97 computed on cubed-sphere grids with data stored at Gauss-Lobatto-Legendre (GLL) nodes. The EAMv1
98 standard low-resolution configuration has 30 spectral elements per cube face (ne30) and 4 GLL nodes per
99 spectral element (np4), corresponding to a horizontal grid spacing of ~ 100 km. The model has 72 vertical
100 layers with a vertical resolution of ~ 20 m near the surface and a vertical resolution higher than 200 m
101 below 1.5 km, and the model top reaches up to ~ 60 km (≈ 0.1 hPa). The model uses an updated version of
102 the Zhang and McFarlane (1995) (ZM) deep convection scheme with a modified dilute plume calculation
103 (Neale et al., 2008), the Cloud Layers Unified By Binormals (CLUBB) scheme for turbulence, shallow
104 convection, and stratiform clouds (Bogenschutz et al., 2013; Golaz et al., 2002; Larson et al., 2002; Xie et
105 al., 2018), the version 2 of the Morrison and Gettelman (2008) (MG2) 2-moment cloud microphysics
106 scheme with a classical-nucleation-theory-based ice nucleation parameterization (Hoose et al., 2010;
107 Wang et al., 2014), the revised version of the four-mode version of the Modal Aerosol Module (MAM4)
108 (Liu et al., 2016; Wang et al., 2020), and the Rapid Radiative Transfer Model for GCMs (RRTMG)
109 (GCM: general circulation model) (Iacono et al., 2008; Mlawer et al., 1997).

110 MAM4 considers seven aerosol species: mineral dust, sea salt, marine organic matter (MOM), black
111 carbon (BC), primary organic matter (POM), secondary organic aerosol (SOA), and sulfate (SO₄) (Wang
112 et al., 2020). Dust emission is parameterized as a function of surface wind speed, soil erodibility, [friction](#)
113 [velocity](#), and a friction velocity threshold following the scheme of Zender et al. (2003) in the land
114 component of E3SMv1. The emissions of sea salt and MOM are estimated from sea spray fluxes, which
115 are parameterized as a function of surface wind speed and sea surface temperature (Burrows et al., 2022).
116 Emissions of other aerosol species and precursor gases are prescribed using CMIP6 emission datasets
117 (Hoesly et al., 2018; Van Marle et al., 2017). The physical properties (including the size distribution,
118 density, and hygroscopicity) of the seven aerosol species are summarized in Burrows et al. (2022).
119 MAM4 represents aerosol particles in four modes with distinct size properties: Aitken mode,
120 accumulation mode, coarse mode, and primary carbon mode (Burrows et al., 2022; Liu et al., 2016; Wang
121 et al., 2020). The primary carbon mode is specified for freshly emitted BC, POM, and MOM, the aging of
122 which is treated explicitly — a feature different from the three-mode version of MAM (MAM3) (Liu et
123 al., 2012). The Aitken mode consists of sea salt, MOM, SOA, and SO₄, while all seven species can exist
124 in accumulation and coarse modes. MAM4 assumes that aerosol species are internally mixed within each
125 mode but externally mixed across different modes. Aerosol particles in each mode can suspend in the air
126 (i.e., interstitial aerosols) or exist in cloud droplets (i.e., cloud-borne aerosols). The evolution of aerosol
127 particles involves many physical and chemical processes, such as emissions, nucleation, coagulation,
128 condensation, [convective transport](#), activation, dry deposition, wet scavenging, resuspension, and gas-
129 phase and aqueous chemistry. More details of these processes and their interactions with radiation and
130 cloud microphysics are described in Liu et al. (2012), Liu et al. (2016), Wang et al. (2020), and Zhang et
131 al. (2022a).

132 EAMv1 has been evaluated against observations and other ESMs in Xie et al. (2018), Rasch et al.
133 (2019), and Golaz et al. (2019). The simulation of aerosol properties and ERF_{aer} have been evaluated in
134 [Table S1 and Figures S1-S2](#), Wang et al. (2020), Burrows et al. (2022), Feng et al. (2022), and Zhang et

135 al. (2022a). Our investigation focuses on comparing LR and RRM simulations, and the known model
136 biases, such as the dry biases over the Great Plains of the US, the Amazon region, and Southeast Asia
137 (Xie et al., 2018) and the cold bias between the 1950s and the 2000s (Golaz et al., 2019), are not expected
138 to affect the overall model sensitivity to the resolution change.

139 **2.2 E3SMv1 LR and RRM simulations**

140 In addition to the standard LR E3SMv1 simulation with a globally uniform resolution of ~100 km
141 for EAMv1 and the land component, we conduct an RRM simulation following the configuration of Tang
142 et al. (2019) with a relatively high-resolution mesh (~25 km) over the CONUS for the atmospheric and
143 land components (Figure 1). The simulation period is from October 1, 2015, to January 1, 2017, with the
144 first three months as model spin-up (Zhang et al., 2022a). The component set used in the simulations. We
145 use the “FC5AV1C-04P2” compset in E3SMv1 for our study. FC5AV1C-04P2 comprises the coupling of
146 an active atmospheric component — EAMv1, an active land component (version 4.5 of the Community
147 Land Model — CLM4.5) (Oleson et al., 2013), a simplified active sea ice component, and a data ocean
148 model with prescribed historical sea surface temperature and sea ice fractions (Hurrell et al., 2008).

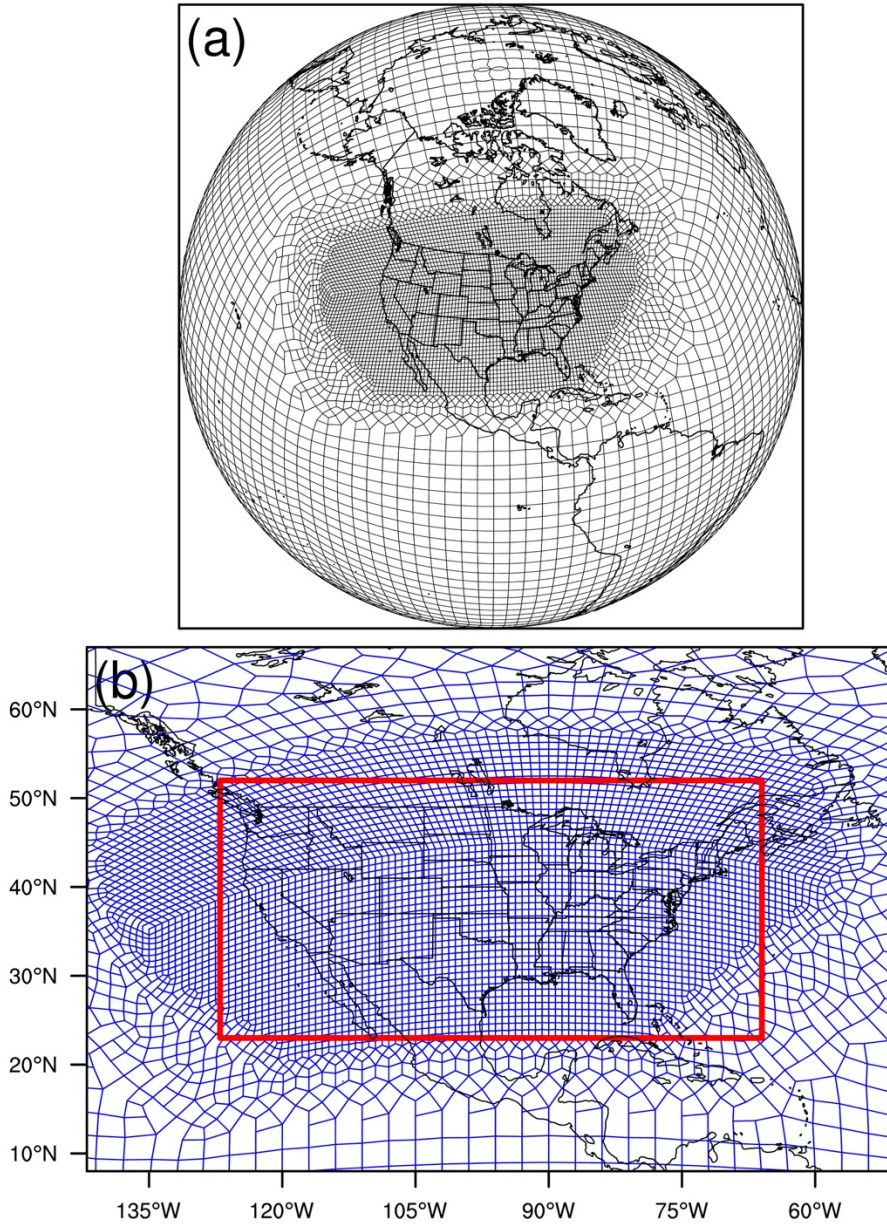

149 The atmospheric and land initial conditions in the LR simulation are derived from an earlier
150 E3SMv1 simulation, which has reached equilibrium. The RRM initial conditions are regridded from those
151 of the LR simulation to exclude the potential impact of distinct initial conditions on the simulation results.
152 Anthropogenic and biomass-burning emissions of BC, POM, and SO₄ and precursor gas sulfur dioxide
153 (SO₂) are from the CMIP6 emission inventory (Feng et al., 2020; Hoesly et al., 2018). Notably, we use
154 the emission data in 2014 instead of in 2016 due to the data availability of CMIP6. Dimethyl sulfide
155 (DMS) emissions in 1850, 2000, and 2100 are estimated from a coupled model simulation with a detailed
156 representation of DMS formation in the seawater (Wang et al., 2018). We obtain the DMS emissions in
157 2014 through linear interpolation of the emissions in 1850, 2000, and 2100. The 3-D SOA production
158 rates (implemented similarly to emissions) are derived from the simulation from Shrivastava et al. (2015).

159 Besides the PD LR and RRM simulations, we run two corresponding simulations with PI aerosol
160 emissions to calculate ERF_{aer} . The PI simulation configurations are the same as the corresponding PD
161 simulations except that emissions of BC, POM, SO_4 , SO_2 , DMS, and SOA (production) in 1850 are used
162 in the PI simulations.

163 We apply nudging globally in the LR and RRM simulations, which differs from Tang et al. (2019),
164 which used nudging only on the low-resolution meshes but not the high-resolution grids in CONUS. We
165 follow the nudging strategy from Zhang et al. (2014) and Sun et al. (2019), which demonstrated that a
166 simulation with constraint horizontal winds could reproduce the evolution characteristics of the observed
167 weather events and the model's long-term climatology. In addition, it has been corroborated that nudged
168 simulations with a relatively short simulation period (e.g., one year) can reproduce the annual mean
169 changes in aerosol burdens and optical depths caused by anthropogenic aerosols in the E3SM
170 Atmospheric Model Intercomparison Project (AMIP) simulations (Zhang et al., 2022a). The short nudged
171 simulations also have a similar estimate of ERF_{aer} as the AMIP-type free-running simulations (Zhang et
172 al., 2022a). Moreover, by constraining the large-scale circulation, nudging helps ~~to~~ suppress the noises
173 caused by the chaotic response to model changes and facilitates the comparison between the LR and RRM
174 simulations. Similarly, nudging is also used to estimate ERF_{aer} , as recommended by previous studies
175 (Kooperman et al., 2012; Sun et al., 2019; Zhang et al., 2014). In short, nudging helps increase the signal-
176 to-noise ratio and identify the impact caused by regional refinement more quickly. In our simulations, the
177 horizontal winds are nudged toward the European Centre for Medium-Range Weather Forecasts
178 Reanalysis v5 (ERA5) (Hersbach et al., 2020) with a relaxation time of 6 hours (Zhang et al., 2022b). To
179 avoid the errors caused by vertical interpolation-extrapolation from ERA5 to E3SM vertical levels, we
180 don't apply nudging for model levels below 950 hPa and above 10 hPa.

181 Several parameters differ between the E3SMv1 standard LR and CONUS RRM default
182 configurations. For example, the time step for most physical processes and the coupling between physics
183 and dynamics is 30 minutes in the LR configuration. In comparison, CONUS RRM uses a time step of 15

184 minutes. Many physical processes are sensitive to the time step and parameter setting (Wan et al., 2015;
185 Wan et al., 2021; Zhao et al., 2013). Our sensitivity tests show substantial differences in the aerosol mass
186 and energy budgets even outside of the refined region when the respective default configurations are used
187 in the LR and RRM simulations, which is mainly attributed to their distinct physical time steps (not
188 shown). Therefore, it would be better to keep the tuning parameters and time step the same between the
189 LR and RRM simulations to isolate the regional refinement effect (horizontal resolution sensitivity), as
190 recommended by earlier studies (Caldwell et al., 2021; Ma et al., 2015). Therefore, for the LR simulation,
191 we use the time step of 15 minutes and the parameter setting from the default CONUS RRM
192 configuration. With such changes, LR shares the same configuration as RRM, except for regional
193 refinement around CONUS (Figure 1) and resolution-relevant input files (e.g., topography and nudging-
194 prescribed wind fields). As expected, the results are very close between the LR and RRM simulations in
195 the low-resolution (~100 km) areas (not shown), facilitating our subsequent investigation of the impacts
196 of regional refinement on the aerosol mass budget and the aerosol forcing over CONUS.

197
 198 Figure 1. E3SMv1 RRM domain (spectral elements) in (a) an orthographic projection and (b) a cylindrical
 199 equidistant projection. (a) and (b) show the boundaries of spectral element grids. The red rectangle in (b) outlines
 200 the region we focus on in the following analyses, referred to as the RRM region.

201 **3 Results and Discussions**

202 We focus our analysis on the refined region, as outlined by the red box in Figure 1b (hereafter
 203 referred to as the RRM region), and the annual mean simulation results in 2016 unless stated otherwise.

204 The LR and RRM simulation results have been regridded to $1^\circ \times 1^\circ$ to facilitate their comparison unless
205 otherwise indicated.

206 **3.1 Aerosol natural sources**

207 Table 1 summarizes the annual mean sources and burdens of the seven aerosol species in the RRM
208 region from the LR and RRM simulations. We find the largest relative differences in the sources and mass
209 burden of the natural wind-driven aerosols between the RRM and LR simulations. With higher horizontal
210 resolution, the RRM simulation produces more dust (154%), sea salt (13%), and MOM (10%) emissions
211 than LR. The dust emission enhancement by RRM is concentrated in several inland regions with high
212 dust emissions, especially in the Mohave and Sonoran deserts (referred to as Region 1) and the northern
213 North American Prairie (referred to as Region 2) (Figures 2a and 2b). In comparison, the increases in sea
214 salt and MOM emissions mainly occur around the coastal lines (Figures 2c-2f). That dust emissions
215 increase with finer model resolutions has been identified in earlier studies (Caldwell et al., 2019; Feng et
216 al., 2022; Ridley et al., 2013), which attributed the increase to more frequent occurrences of strong winds
217 in high-resolution simulations. Dust emissions are nonlinearly correlated with surface winds and are
218 particularly sensitive to strong winds (Zender et al., 2003). We find larger (~~11.27~~-8%) annual mean
219 surface wind speeds and more frequent strong winds in Region 1 in the RRM simulation compared to the
220 LR simulation (Figures 3ca and 3de), which can explain the dust emission increase in Region 1 under
221 regional refinement (Figure 2b). However, in Region 2, the annual mean surface wind speeds differ
222 slightly (~~2.21~~-6%) between the RRM and LR simulations. Besides, the probability density functions
223 (PDFs) of wind speed in Region 2 are similar between the two simulations (Figures 3ca and 3ed), as well
224 as the PDFs of friction velocity (not shown), indicating that surface winds and friction velocities alone
225 cannot explain the dust emission enhancement in the RRM simulation. In addition to surface winds and
226 friction velocity, soil moisture can also influence dust emissions by improving the friction velocity
227 threshold (Namikas and Sherman, 1997; Zender et al., 2003). Therefore, high soil moisture may inhibit

228 saltation and thus reduce dust emissions. We find lower (-7.1%) volumetric soil water content in the
 229 surface layer in Region 2 in the RRM simulation than in the LR simulation (Figure 3b), which is
 230 consistent with the dust emission increase in the region by RRM (Figure 2b). The reduced surface soil
 231 water content in Region 2 is likely related to less precipitation (-3.0%) in the RRM simulation compared
 232 to the LR simulation (Figure 4c).

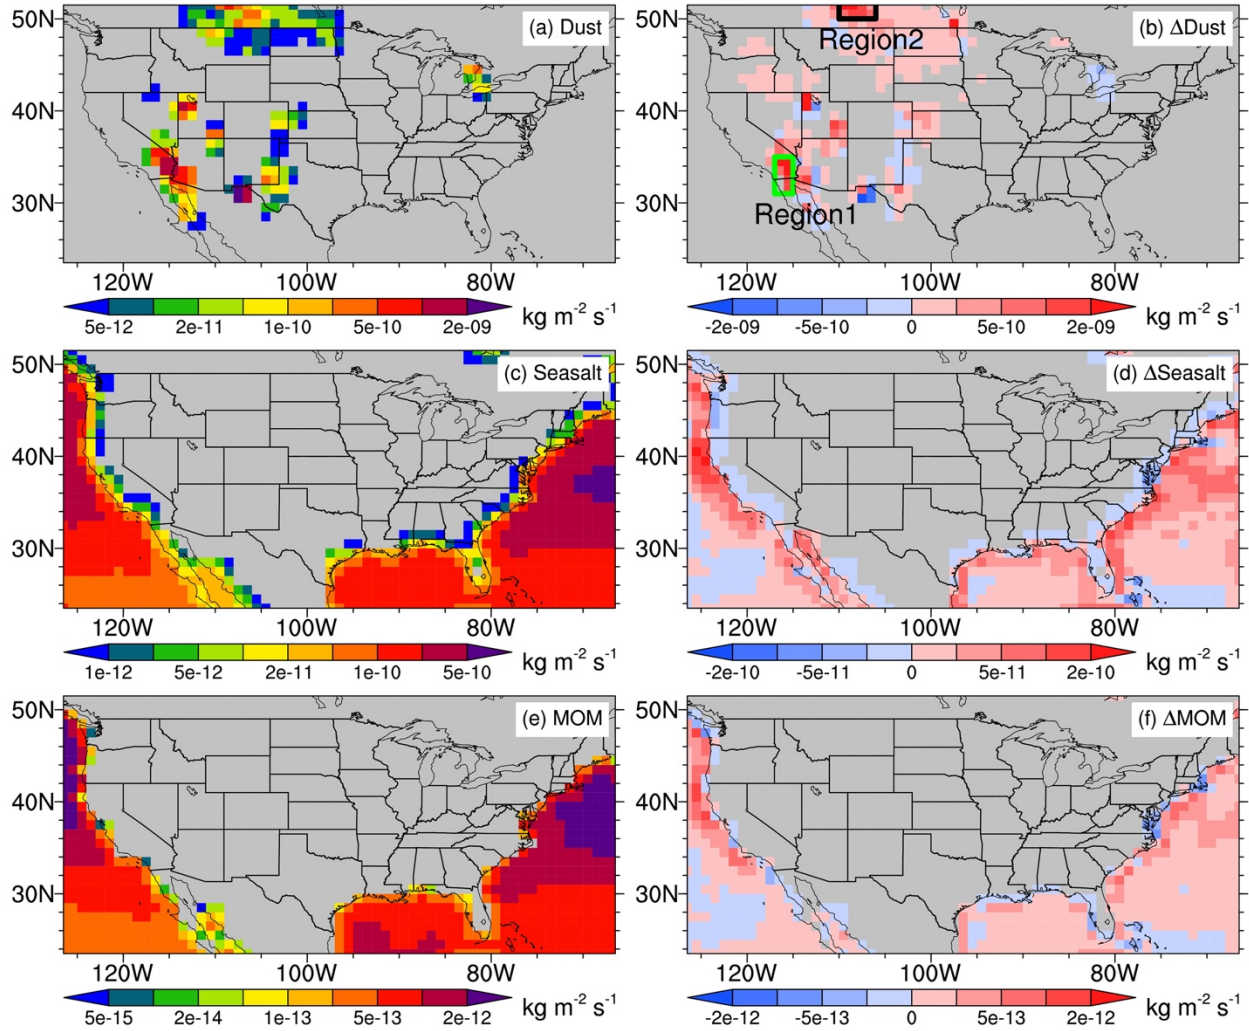

233 **Table 1.** Total annual mean sources and burden in the RRM region for the seven aerosol species

	Sources			Burden		
	RRM / Tg yr ⁻¹	LR / Tg yr ⁻¹	Relative diff ¹ / %	RRM / Tg	LR / Tg	Relative diff / %
Dust	22.3	8.79	154	0.126	0.0910	39
Sea salt	39.4	34.9	13	0.0875	0.0782	12
MOM	0.192	0.175	10	0.00114	0.00104	9.8
BC	0.268	0.268	0.0030	0.00446	0.00446	-0.050
POM	1.15	1.15	0.022	0.0287	0.0286	0.30
SOA	2.70	2.68	0.72	0.0859	0.0857	0.26
SO ₄ ²	1.74	1.69	2.8	0.0216	0.0215	0.41

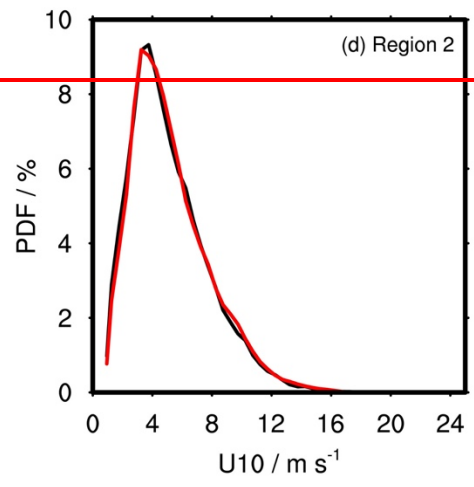

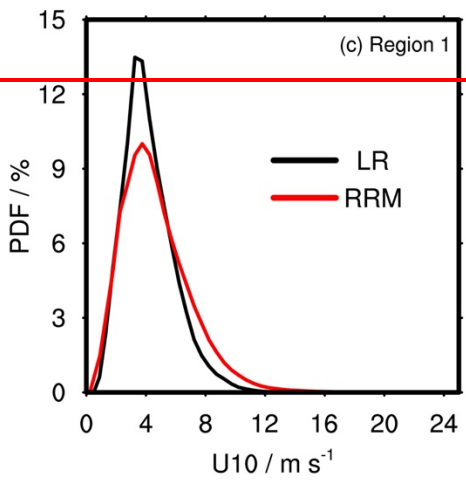

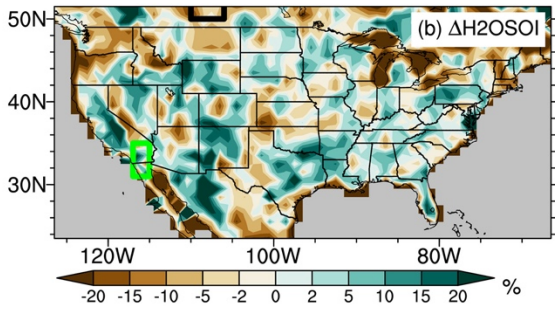

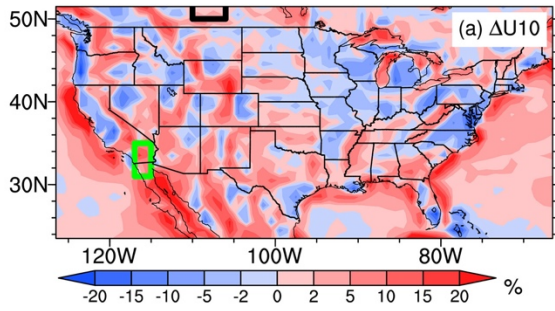

234 ¹Relative diff = (RRM/LR - 1) × 100%.

235 ²SO₄ is represented in the mass of sulfur (TgS y⁻¹ for sources and TgS for burden). Besides direct anthropogenic
 236 emissions of SO₄, other SO₄ sources include gas-aerosol exchange, aqueous-phase production (aqueous-phase
 237 chemistry and cloud water uptake), and new particle formation.

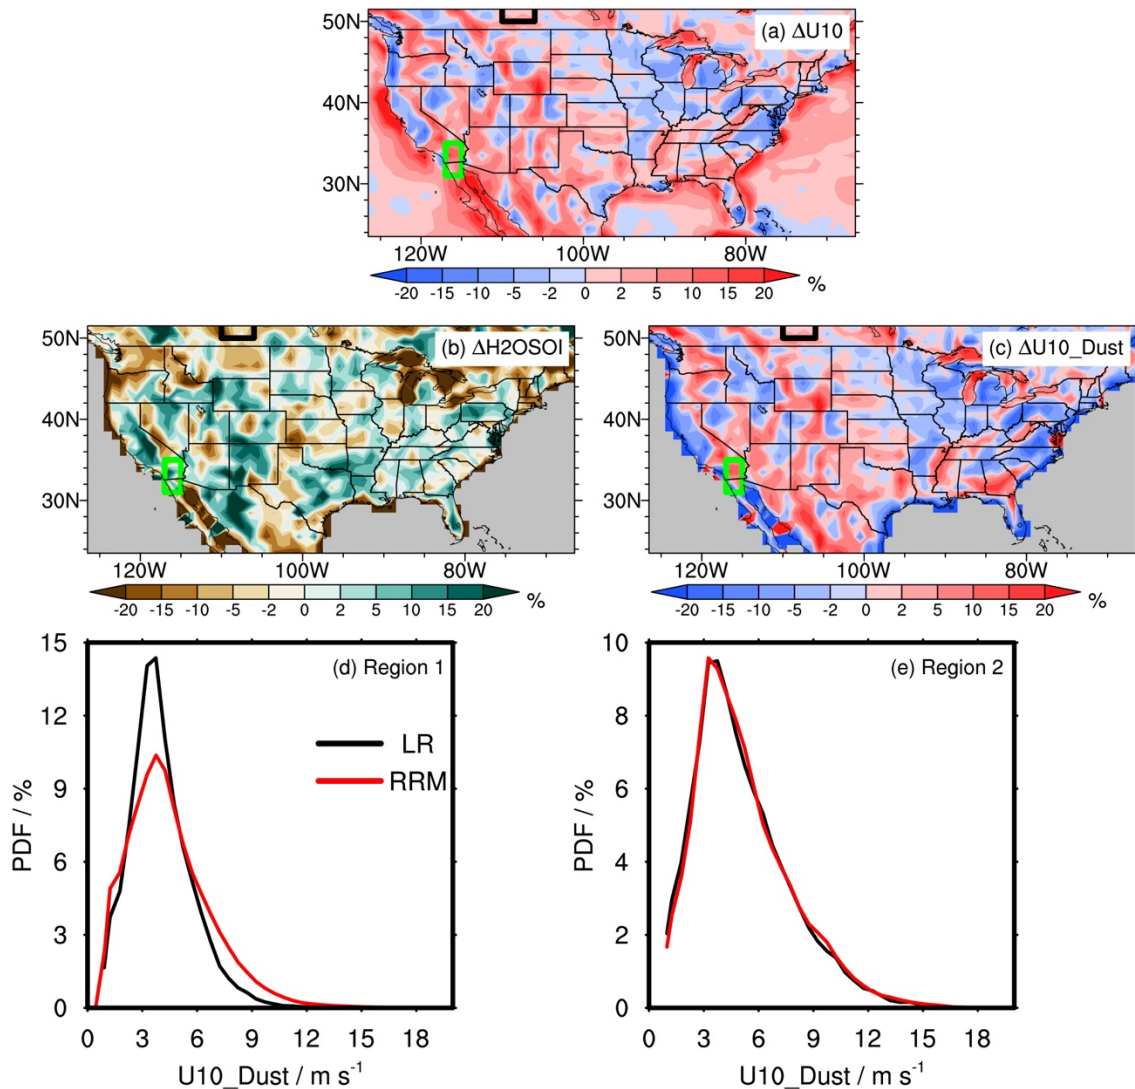

238 As mentioned above, sea salt and MOM emissions are related to surface wind speed and sea surface
 239 temperature (Burrows et al., 2022; Liu et al., 2012). We attribute the increased sea salt and MOM
 240 emissions in the RRM simulation to enhanced surface wind speeds at the finer model resolution, as shown
 241 in Figure 3a. In addition, since sea salt and MOM are only emitted over the ocean, the distinct land-ocean
 242 boundaries may also partially contribute to the discrepancies in sea salt and MOM emissions between the
 243 RRM and LR simulations.

244
 245 Figure 2. Left column: spatial distributions of annual mean sources of (a) dust, (c) sea salt, and (e) MOM from the
 246 LR simulation. Right column: the same as the left column but for the absolute differences between the RRM and LR
 247 simulations ($RRM-LR$). The green and black boxes in (b) highlight two subregions with substantial changes in dust
 248 emissions when applying regional refinement. Region 1 is around the Mohave and Sonoran deserts, and Region 2 is
 249 in the northern North American Prairie.

250

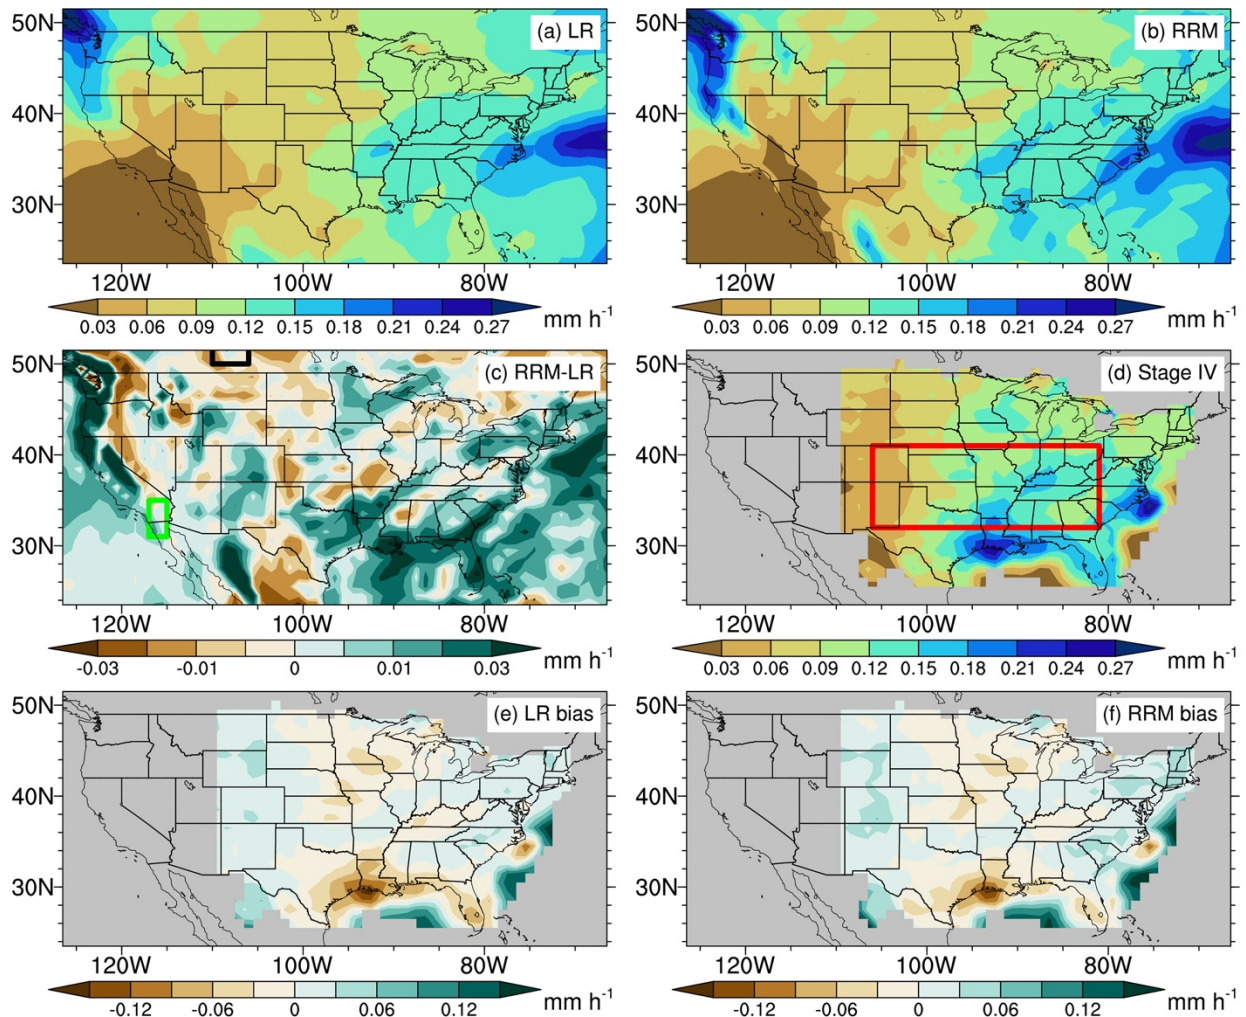

251
 252 Figure 3. Spatial distributions of the relative differences in annual mean (a) 10-m wind speed from the E3SMv1
 253 atmospheric component (U10), and (b) surface-layer volumetric soil water content (H2OSOI), and (c) 10-m wind
 254 speed used in the dust emission parameterization (U10_Dust) between the RRM and LR simulations (RRM-LR).
 255 The green and black boxes in (a), (b), and (c) are the same as those in Figure 2b. (d, e) Probability density
 256 functions (PDFs) of $U10_Dust$ in (d) Region 1 and (e) Region 2. The black lines are for the LR simulation, while
 257 the red lines are for the RRM simulation. $U10_Dust$ on native model grids with an output frequency of 15 minutes is
 258 used to derive the corresponding PDF. Notably, $U10_Dust$ is slightly different from $U10$, which considers the
 259 convective gustiness effect.

260 3.2 Aerosol wet scavenging by convective vs. large-scale precipitation

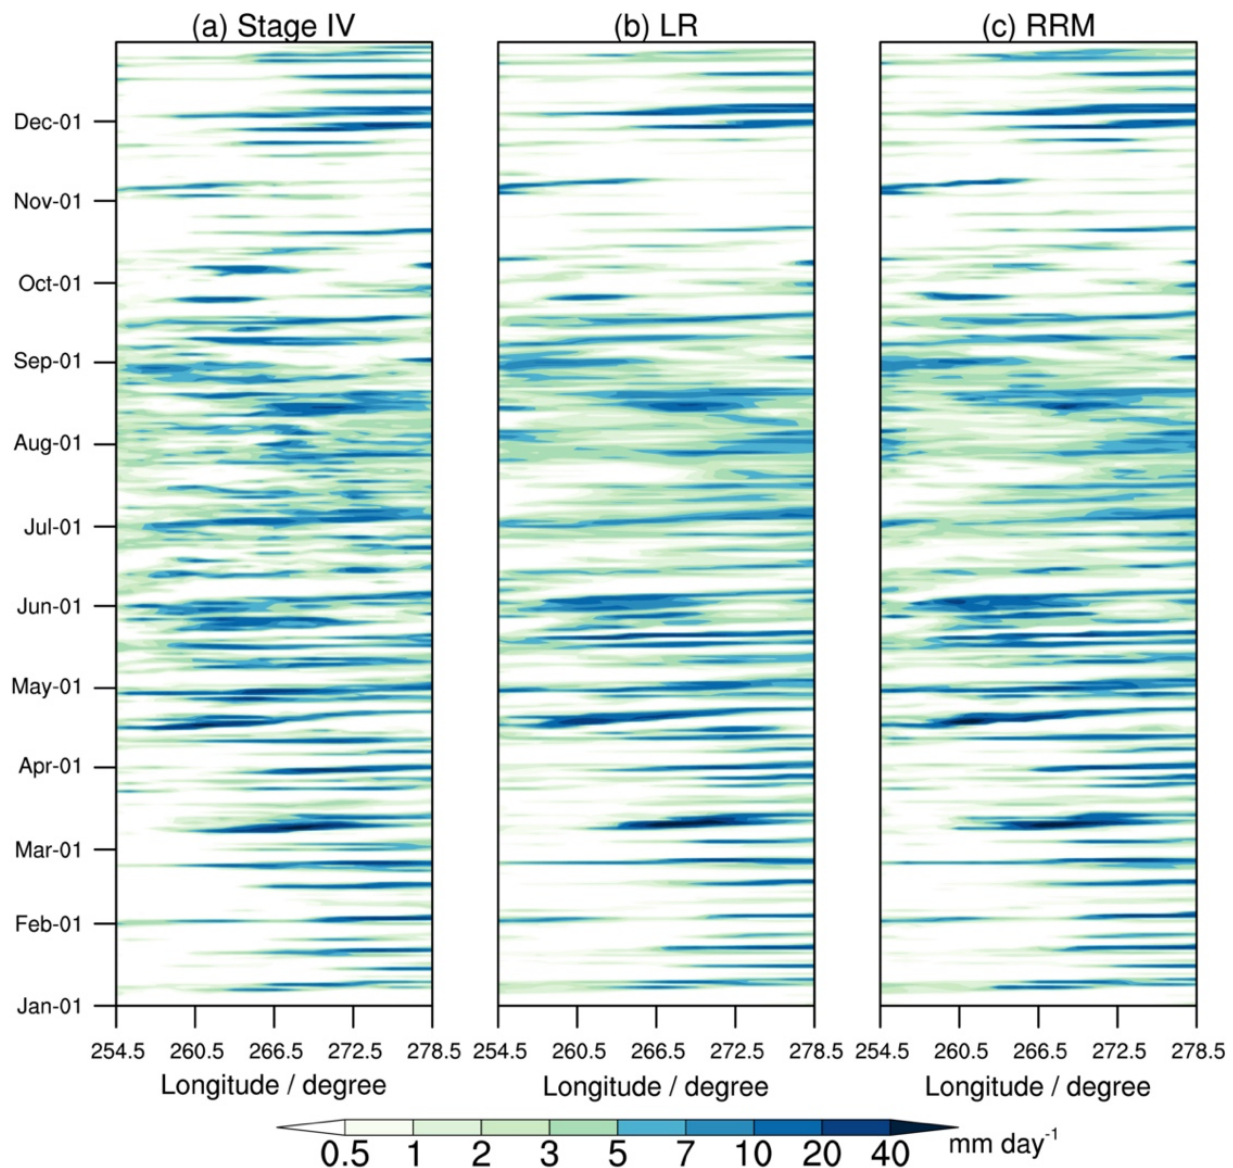

261 In the RRM region, wet scavenging is the primary sink for most aerosol species [in both simulations](#)
262 except for dust and sea salt, the sinks of which are dominated by dry deposition. To understand the impact
263 of [RRM horizontal grid spacing](#) on aerosol wet scavenging, it is necessary first to investigate how
264 precipitation differs between the LR and RRM simulations.

265 Figure 4 evaluates the LR and RRM simulated precipitation against the observational Stage IV data.
266 Stage IV is a radar-based precipitation product with rain-gauge bias adjustment and has a native
267 resolution of 4 km (Lin and Mitchell, 2005). We regrid the Stage IV data to $1^\circ \times 1^\circ$ for comparison with
268 our simulation results. Both simulations can capture the observed east-west precipitation gradient in the
269 US east of the Rocky Mountains. The spatial correlation coefficient between the LR simulation and Stage
270 IV is 0.52, similar to that between RRM and Stage IV. Moreover, most observed precipitation events in
271 the central-eastern US (red box in Figure 4d) are well simulated by the LR and RRM simulations
272 according to the Hovmöller diagrams of meridionally averaged daily precipitation rates in Figure 5, which
273 is attributed to the appropriate nudging strategy applied to the simulations. However, apparent dry biases
274 are found near the coastal areas of the southern US in the LR simulation (Figure 4e). By producing more
275 precipitation than the LR simulation around the US coastal areas, RRM can reduce the dry bias in the
276 southern coastal regions. However, its precipitation is still much lower than observed (Figure 4f). Minor
277 dry biases are also found in the northern Great Plains in both simulations. The model dry biases in the
278 southern and northern Great Plains may be due to the limitation of E3SM in predicting extreme
279 precipitation events, such as mesoscale convective systems (Feng et al., 2021; Wang et al., 2021), which
280 is the dominant precipitation contributor in the Great Plains (Li et al., 2021). A noticeable improvement
281 of the RRM simulation compared to the LR simulation is the production of more frequent heavy
282 precipitation ($> 7.6 \text{ mm h}^{-1}$), which is mainly attributed to the intensification of large-scale precipitation
283 (Figure 6), consistent with the results from Caldwell et al. (2019). More frequent heavy precipitation can

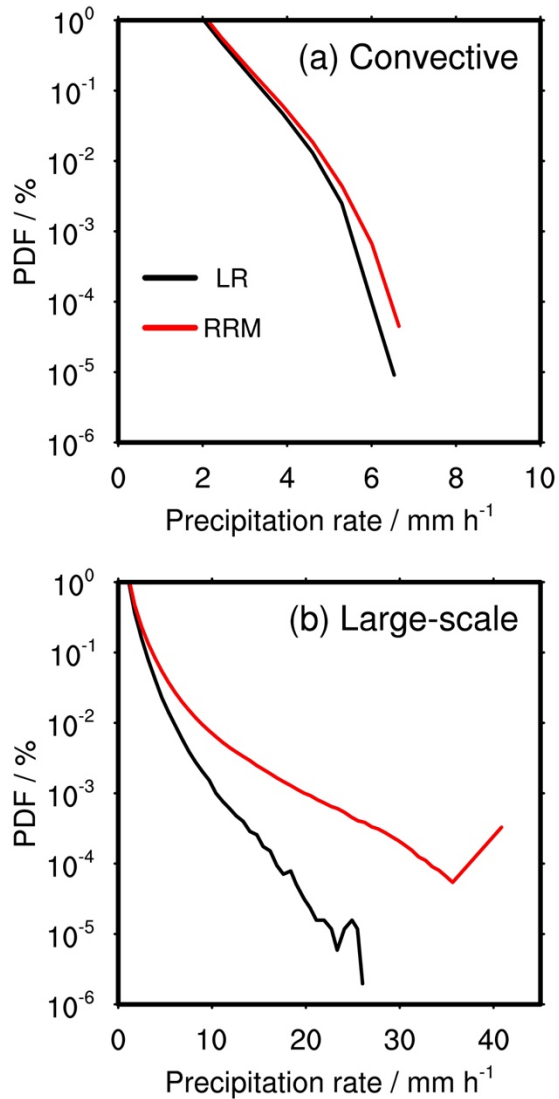

284 partially alleviate the “too frequent, too weak” problem in low-resolution E3SM simulations (Caldwell et
 285 al., 2019). However, our result contradicts Tang et al. (2019), which found more light precipitation but
 286 less heavy precipitation as model horizontal resolution increases. It may be because Tang et al. (2019)
 287 didn’t apply nudging to their low-resolution and RRM simulations, and precipitation varied much
 288 between the two simulations.

289
 290 Figure 4. (a-c) Spatial distributions of annual mean total precipitation rates (large-scale and convective) for the (a)
 291 LR and (b) RRM simulations and (c) their differences (RRM-LR). The green and black boxes in (c) are the same as
 292 those in Figure 2b. (d-f) Spatial distributions of annual mean precipitation from Stage IV and the precipitation bias
 293 of the LR and RRM simulations against Stage IV. The regional mean biases of the LR and RRM simulations are
 294 0.004 mm h⁻¹ and 0.010 mm h⁻¹ compared to Stage IV with a regional mean precipitation of 0.107 mm h⁻¹. It
 295 is noteworthy that the data quality of Stage IV is poor over the open ocean and the western US due to limited radar
 296 coverage. The Hovmöller diagram in Figure 5 is based on the red box in (d).

297
 298 Figure 5. Hovmöller diagrams of meridionally averaged daily precipitation rates in the red box of Figure 4d for (a)
 299 Stage IV, (b) the LR simulation, and (c) the RRM simulation in 2016. The centered pattern correlation coefficient
 300 between LR and Stage IV is 0.28, the same as that between RRM and Stage IV. The root-mean-square errors of LR
 301 and RRM are 5.3 mm day^{-1} and 5.5 mm day^{-1} , respectively, against Stage IV.

302 Figure 6. Probability density functions (PDFs) of (a) convective and (b) large-scale precipitation rates in the RRM
 303 region for the LR (black lines) and RRM (red lines) simulations. Precipitation on native grids with an output
 304 frequency of 15 minutes is used to calculate the corresponding PDF.
 305

306 In addition to affecting total precipitation rates, the model resolution notably changes the partitioning
 307 between large-scale precipitation (that is computed by the MG2 cloud microphysics parameterization) and
 308 deep convective precipitation (that is computed by the ZM deep convection parametrization). As model
 309 resolution increases, more precipitation can be resolved, which leads to an increase in large-scale
 310 precipitation and a decrease in convective precipitation (Figures 7a and 7b) (Tang et al., 2019).

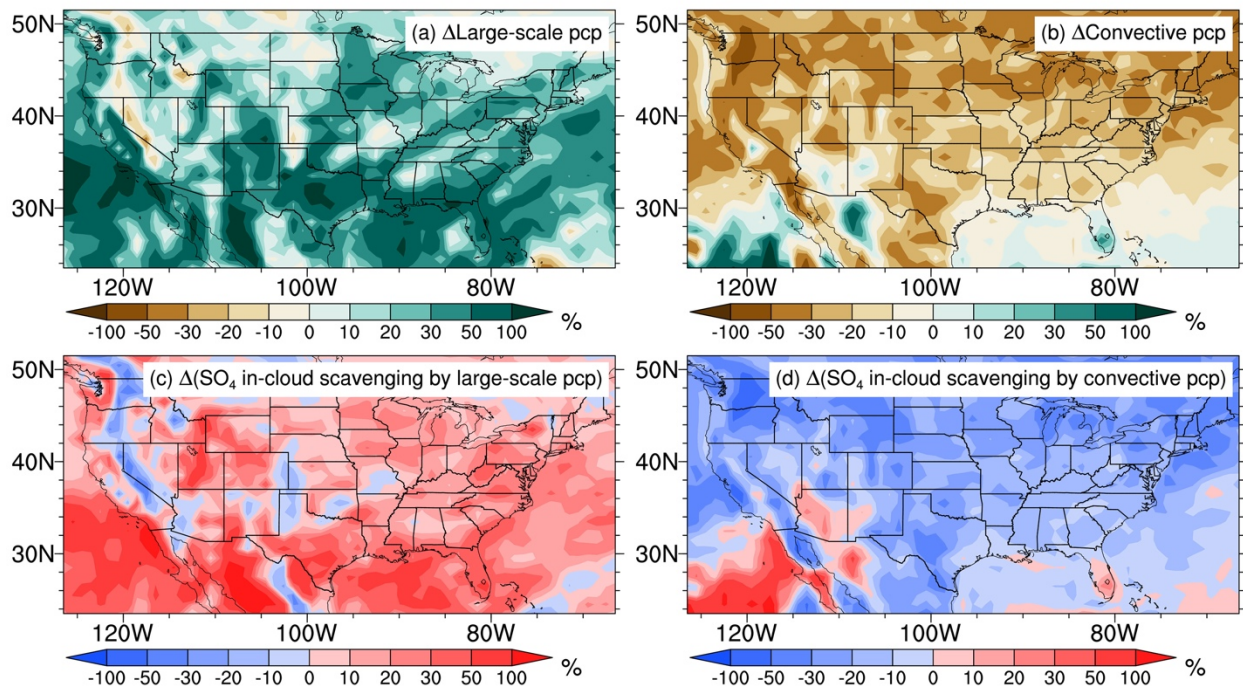

311 In E3SMv1, aerosol wet removal by large-scale and convective precipitation is comprised of in-
 312 cloud scavenging, which involves the activation of interstitial aerosol particles (IAPs) and the subsequent

313 removal of cloud-borne aerosol by precipitation, and below-cloud scavenging accounting for the removal
314 of IAPs by precipitation via impaction and Brownian diffusion (Liu et al., 2012; Wang et al., 2013). In-
315 cloud scavenging is the dominant process for all aerosol species in the RRM region, accounting for ~80%
316 of the wet removal of sea salt and dust and more than 98% of the other aerosol species (not shown).

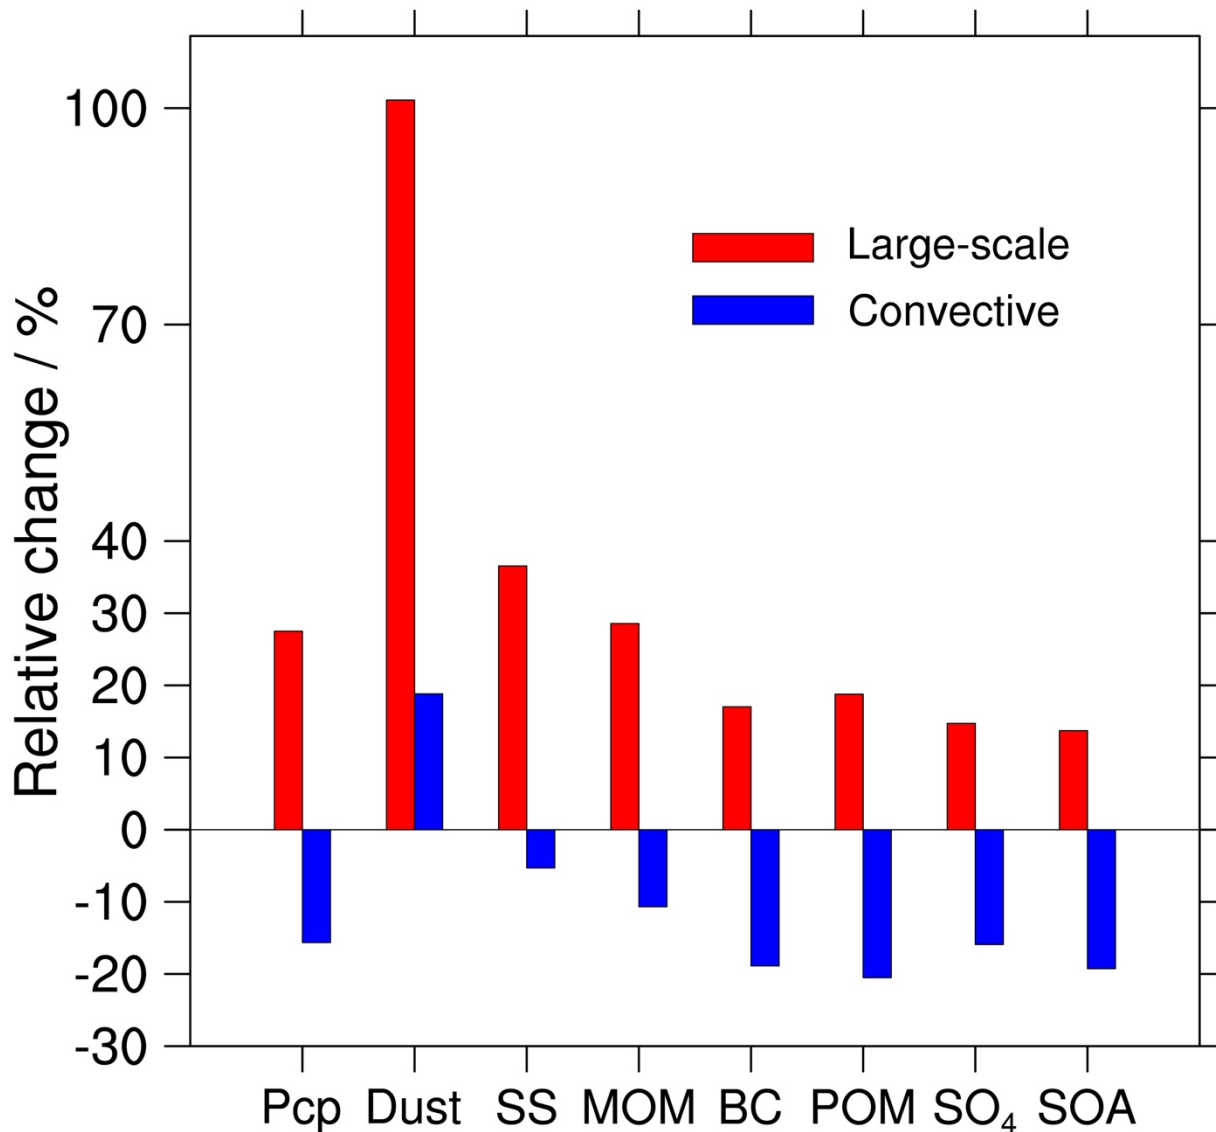

317 EAMv1 uses two different parameterizations to treat aerosol wet scavenging by large-scale clouds
318 and deep convective clouds. Here, “large-scale clouds” refer to clouds represented by the CLUBB and
319 MG2 parameterizations, and “deep convective clouds” refer to clouds represented by the ZM deep
320 convection parameterization. In large-scale clouds, aerosol activation is parameterized as a function of
321 subgrid vertical velocity (W_{sub}), aerosol properties, and environmental conditions (Abdul-Razzak and
322 Ghan, 2000). The first-order loss rates of aerosol are computed by multiplying a solubility factor by the
323 first-order loss rate of cloud water, which is computed as a function of cloud fraction, cloud water, and
324 precipitation production rate profiles (Barth et al., 2000; Rasch et al., 2000). In deep convective clouds,
325 the cloud-borne aerosol mixing ratios are computed by multiplying interstitial aerosol mixing ratios by
326 the prescribed convective-cloud activation fractions, which depend on aerosol modes and species to
327 represent the hygroscopicity (Liu et al., 2012; Wang et al., 2013). The solubility factor is a tunable
328 parameter, and the model uses different solubility factors for large-scale and deep convective clouds (Liu
329 et al., 2012; Wang et al., 2013).

330 Therefore, the change in the partitioning between large-scale and deep convective precipitation
331 should make a difference in aerosol wet removal. Taking SO_4 as an example, Figures 7c and 7d show a
332 significant increase in in-cloud scavenging of SO_4 by large-scale precipitation but a noticeable decrease
333 by deep convective precipitation in the RRM simulation compared to the LR simulation. The changing
334 patterns of in-cloud scavenging by large-scale and deep convective precipitation are consistent with the
335 changes in the corresponding type of precipitation rates. Figure 8 summarizes the relative differences in
336 regional mean large-scale and deep convective in-cloud scavenging of different aerosol species in the

337 RRM region between the RRM and LR simulations. Due to the increase in large-scale precipitation (28%)
 338 and the decrease in deep convective precipitation (-16%) in the RRM region, the large-scale in-cloud
 339 scavenging increases and the deep convective in-cloud scavenging reduces for all aerosol species but dust
 340 in the RRM simulation compared to the LR simulation. Dust exhibits a different response because dust
 341 emission is 154% higher in the RRM simulation than in the LR simulation. With the significant increase
 342 of dust emission and loading in the atmosphere in the RRM simulation, the wet removal of dust by both
 343 large-scale and deep convective clouds are higher than that in the LR simulation, even though the deep
 344 convective precipitation rate is lower.

345
 346 Figure 7. (a, b) Spatial distributions of the relative differences in annual mean (a) large-scale and (b) convective
 347 precipitation between the RRM and LR simulations. (c-d) same as (a) and (b) but for in-cloud scavenging of SO₄ by
 348 (c) large-scale and (d) convective precipitation.

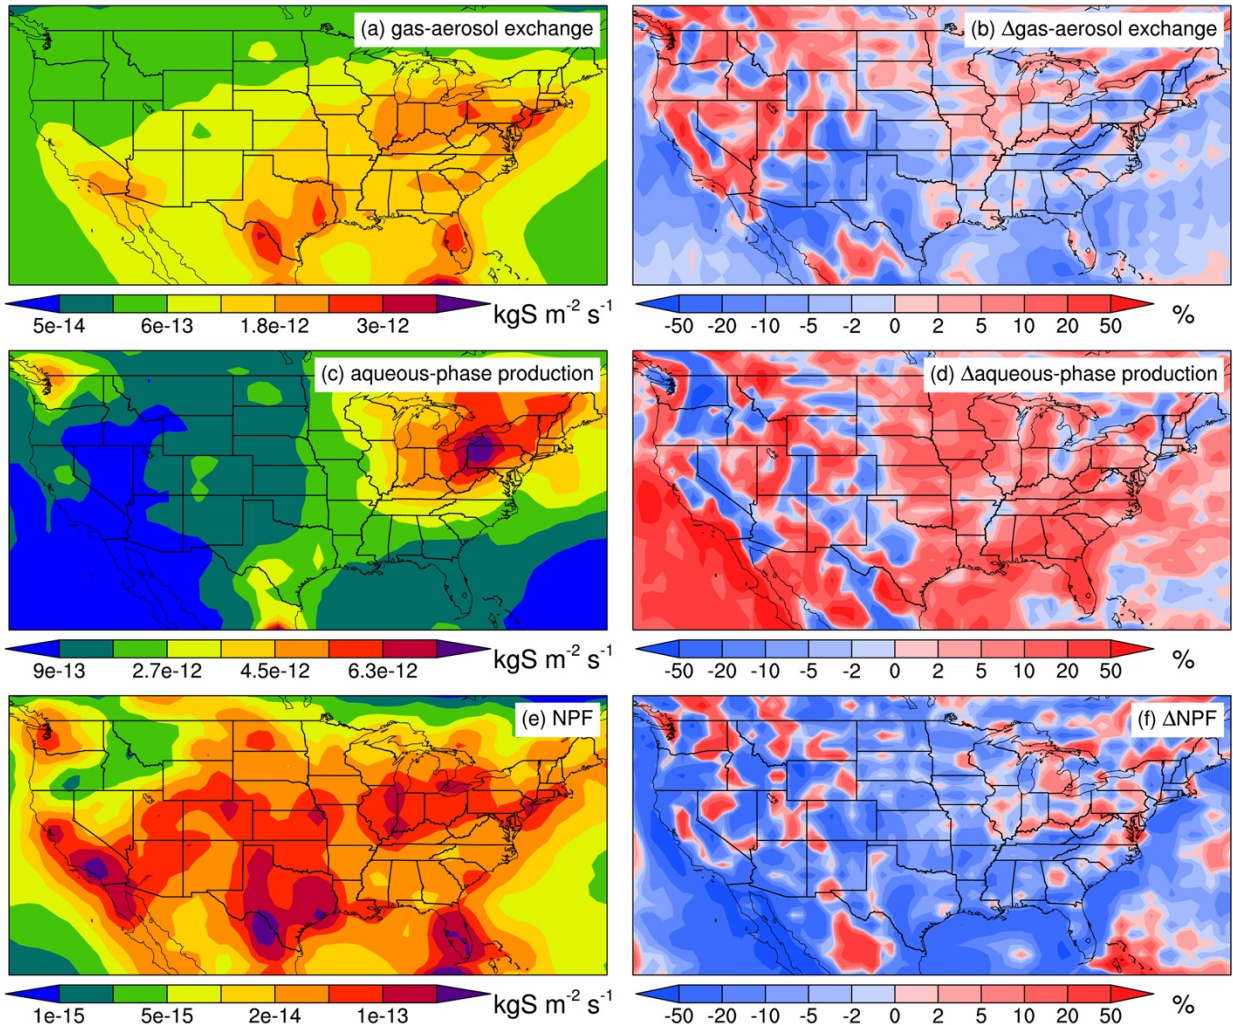

349 Figure 8. Relative differences in annual regional mean large-scale and convective precipitation and in-cloud
 350 scavenging of different aerosol species by large-scale and convective precipitation between the RRM and LR
 351 simulations. “Pcp” refers to precipitation, and “SS” denotes sea salt.
 352

353 3.3 Aerosol chemical production

354 As expected, anthropogenic aerosol emissions (e.g., BC, POM, and SOA) prescribed by offline
 355 emission inventories are almost the same between the RRM and LR simulations. However, the SO₄
 356 source in the RRM simulation is 2.8% higher (Table 1). MAM4 considers four source terms for sulfate
 357 aerosol. Two primary sources of SO₄ are gas-aerosol exchange and aqueous-phase production (Figure
 358 S13), which contribute to 31% and 63%, respectively, in the RRM region. The other two minor source

359 terms are (1) direct emission of sulfate aerosol and (2) new particle formation (NPF) (Figure S43),
360 accounting for about 5% and 1% of the total source. Figures 9a and 9c show the spatial distributions of
361 SO₄ production via the two major pathways from the LR simulation, generally consistent with the
362 distributions of precursor gases (sulfuric acid gas vapor (H₂SO₄) and SO₂ in Figures S24a and S24b) with
363 one peak in the northeastern US and another peak around southwestern Texas. The RRM simulation
364 generally produces more SO₄ via aqueous-phase production (6.2% on average over the RRM region) but
365 less via gas-aerosol exchange (-3.0%) than the LR simulation (Figures 9b and 9d). Figures 9e-9f show
366 that increasing resolution leads to significantly lower (-13.3%) NPF of SO₄.

367 SO₄ production via gas-aerosol exchange and NPF positively correlates with the H₂SO₄
368 concentration (Liu et al., 2012). We find a lower (-5.5%) H₂SO₄ concentration in the RRM than in the LR
369 (Figure S35a), which can explain the reduction of SO₄ production via gas-aerosol exchange and NPF
370 (Figure S43). The source of H₂SO₄ is the oxidation of gas-phase SO₂ by hydroxyl radical (OH) (Figure
371 S43). In our E3SMv1 configuration, OH concentrations are prescribed, and the reaction rate constants of
372 SO₂ and OH are similar between the RRM and LR simulations (not shown). Therefore, the H₂SO₄
373 production is dominated by the gas-phase SO₂ concentration, which shows a reduction (-2.3%) in the
374 RRM compared to the LR (Figure S35b). The sources of gas-phase SO₂ include direct emissions and the
375 oxidation of DMS by OH and nitrate radical (NO₃) (Figure S43). DMS and SO₂ emissions are read from
376 emission inventories, and the reaction rate constants of DMS + OH and DMS + NO₃ are close between
377 the RRM and LR simulations. Therefore, the gas-phase SO₂ source is similar between the two
378 simulations, and we need to understand the sinks of gas-phase SO₂ to explain the general reduction of
379 gas-phase SO₂ concentrations in the RRM simulation.

380
 381 Figure 9. Left column: spatial distributions of annual mean SO₄ sources from (a) gas-aerosol exchange, (c) aqueous-
 382 phase production, and (e) NPF in the LR simulation. Right column: the same as the left column but for the relative
 383 differences between the RRM and LR simulations.

384 We find that dry and wet deposition cannot explain the general reduction of gas-phase SO₂
 385 concentrations in the RRM compared to the LR (not shown). Another major sink of gas-phase SO₂ is the
 386 oxidation of SO₂ by hydrogen peroxide (H₂O₂) and ozone (O₃) to form SO₄ via aqueous-phase chemistry
 387 (Figures 10c, 10e, and S13). Another process to produce SO₄ in the aqueous-phase chemistry module of
 388 E3SMv1 is the cloud water uptake of H₂SO₄ (Figures 10a and S13). All three pathways are related to
 389 large-scale cloud liquid water content (LWC) (LWC at 700 hPa shown in Figure S24c). The RRM
 390 simulation generally produces a larger LWC than the LR simulation (700 hPa shown as an example in

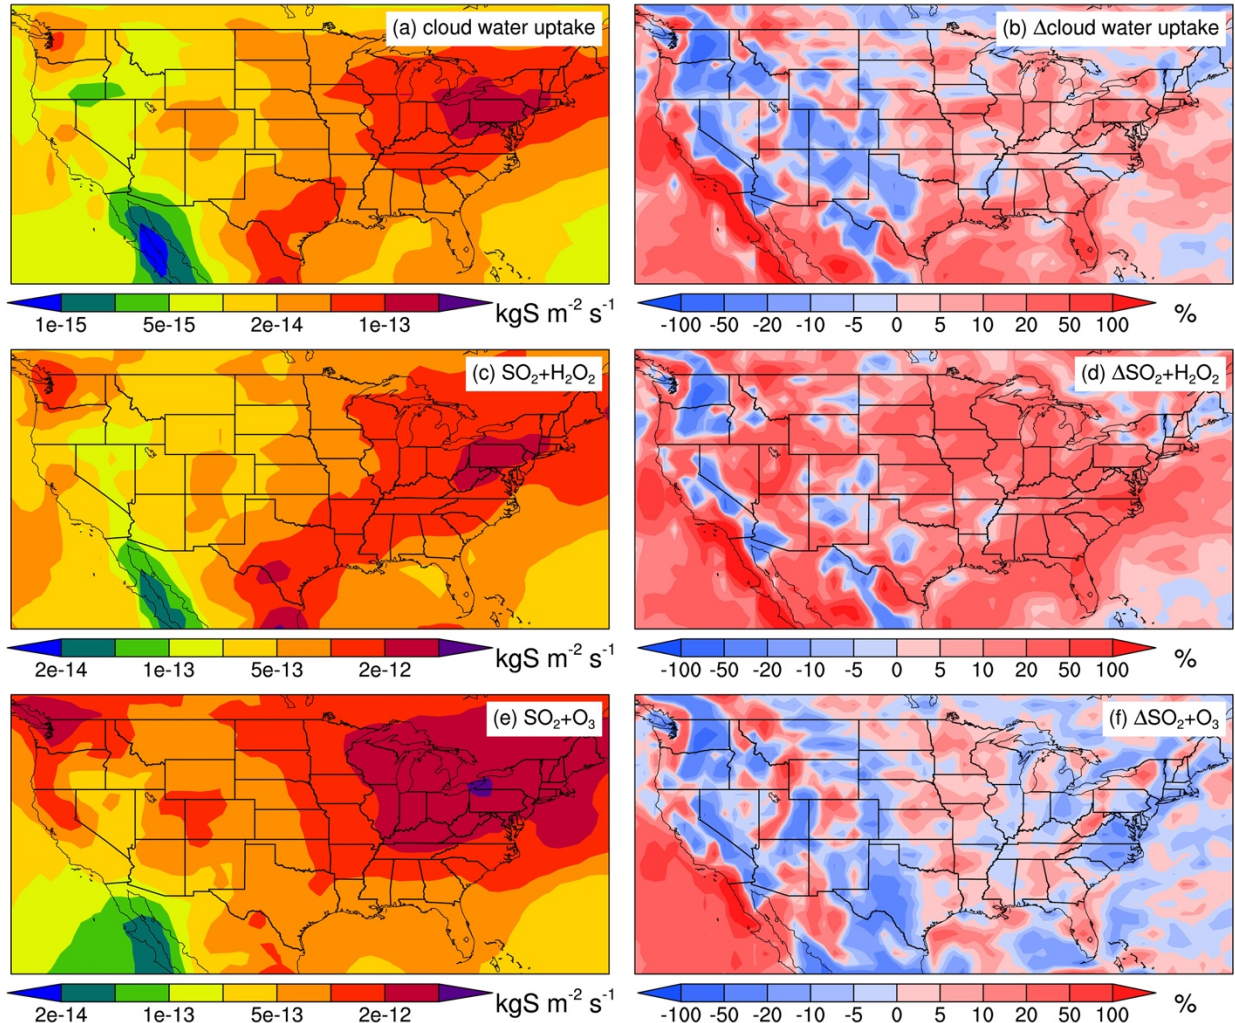

391 Figure S35c). Therefore, the cloud water uptake of H₂SO₄ is enhanced in the RRM simulation (Figures
392 10b and S43).

393 The aqueous-phase oxidation of SO₂ by H₂O₂ and O₃ would also be expected to increase with higher
394 LWC in the RRM simulation. However, we find a slight reduction (-1.2%) in SO₄ production via the O₃
395 pathway (Figure 10f). In contrast, the H₂O₂ pathway is enhanced by 17.0% in the RRM simulation
396 compared to the LR simulation (Figure 10d).

397 The H₂O₂ and O₃ pathways differ in two aspects. First, the O₃ concentrations are prescribed, while
398 the H₂O₂ concentrations are prognostic in our E3SMv1 configuration (Figures S43 and S24e). Second, the
399 O₃ pathway is highly sensitive to the pH of the cloud water (proton (H⁺) concentrations at 700 hPa shown
400 in Figure S24d), while the H₂O₂ pathway is hardly affected by pH (Seinfeld and Pandis, 2016). We find
401 that the gas-phase H₂O₂ concentrations are generally slightly higher in the RRM than the LR (Figure
402 S35e), even though the improved H₂O₂ pathway should consume more H₂O₂ under regional refinement.
403 The budget analysis (not shown) indicates that the reduction of the gas-phase H₂O₂ wet removal in the
404 RRM simulation contributes to the slightly enhanced H₂O₂ concentrations (Figures S43, S24f, and S35f).
405 The reduced wet removal is related to decreased net rain production (mainly convective) used in the wet
406 deposition parameterization of gas species (not shown). Notably, the oxidation of SO₂ by H₂O₂ releases
407 H⁺ into cloud water (Figure S43). With increased H₂O₂ concentrations, we expect higher H⁺
408 concentrations ([H⁺]) in large-scale clouds in the RRM simulation than in the LR simulation, as shown in
409 Figure S35d. Slightly higher [H⁺] (lower pH) would suppress the aqueous-phase oxidation of SO₂ by O₃
410 significantly (Seinfeld and Pandis, 2016). These results explain why the O₃ pathway is suppressed slightly
411 even though LWC increases in the RRM simulation compared to the LR simulation.

412 In short (Figure S43), higher LWC leads to more SO₄ production via cloud water uptake and the
413 aqueous-phase oxidation of SO₂ by H₂O₂. However, the oxidation of SO₂ by O₃ is slightly suppressed due
414 to the combination of larger LWC and lower pH. Finally, the total aqueous-phase SO₄ production is

415 enhanced in the RRM, which consumes more SO₂ and leads to lower gas-phase SO₂ concentrations
 416 compared to the LR.

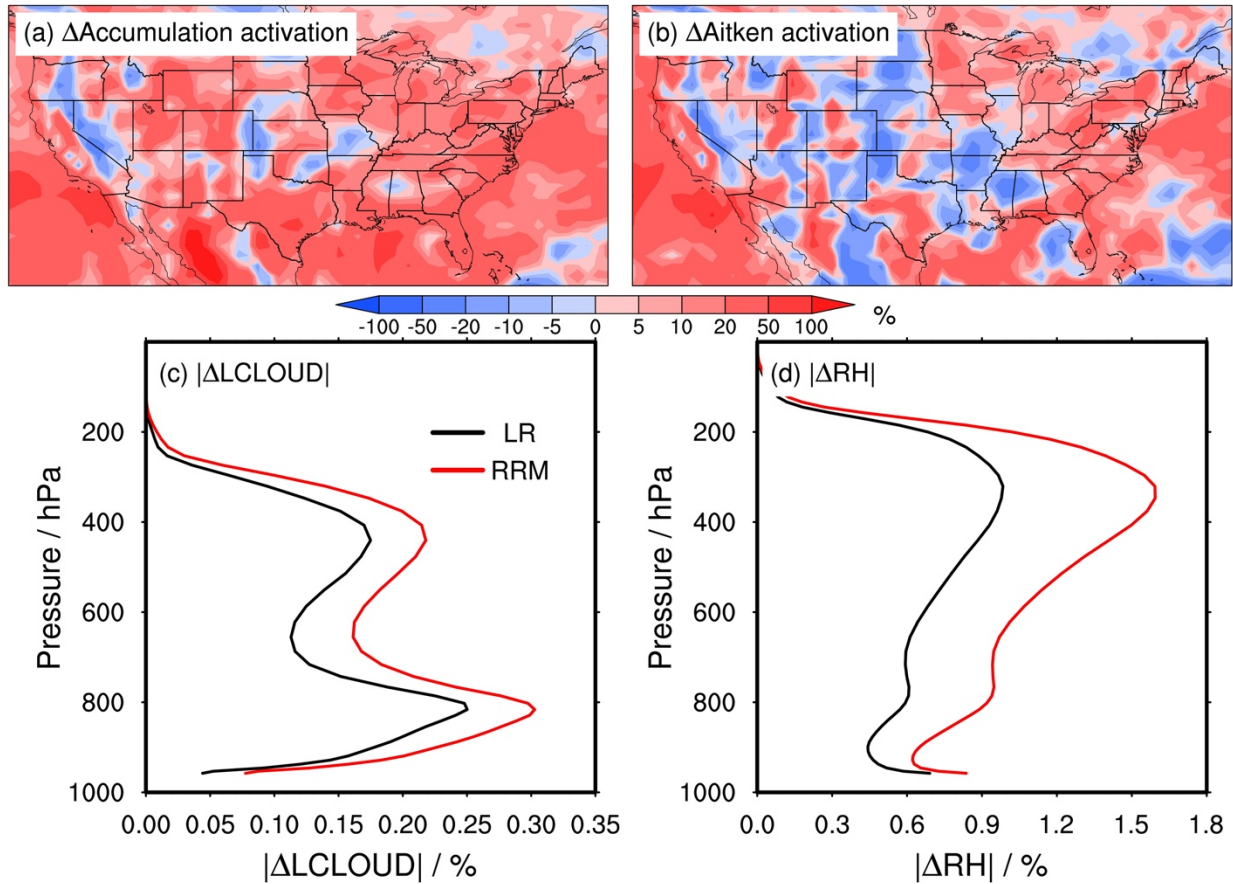

417
 418 Figure 10. Left column: spatial distributions of annual mean SO₄ aqueous-phase productions through (a) cloud water
 419 uptake, (c) the H₂O₂ oxidation pathway, and (e) the O₃ oxidation pathway in the LR simulation. Right column: the
 420 same as the left column but for the relative differences between the RRM and LR simulations. It is noteworthy that
 421 the aqueous-phase production occurs in large-scale clouds.

422 3.4 Aerosol-cloud interactions

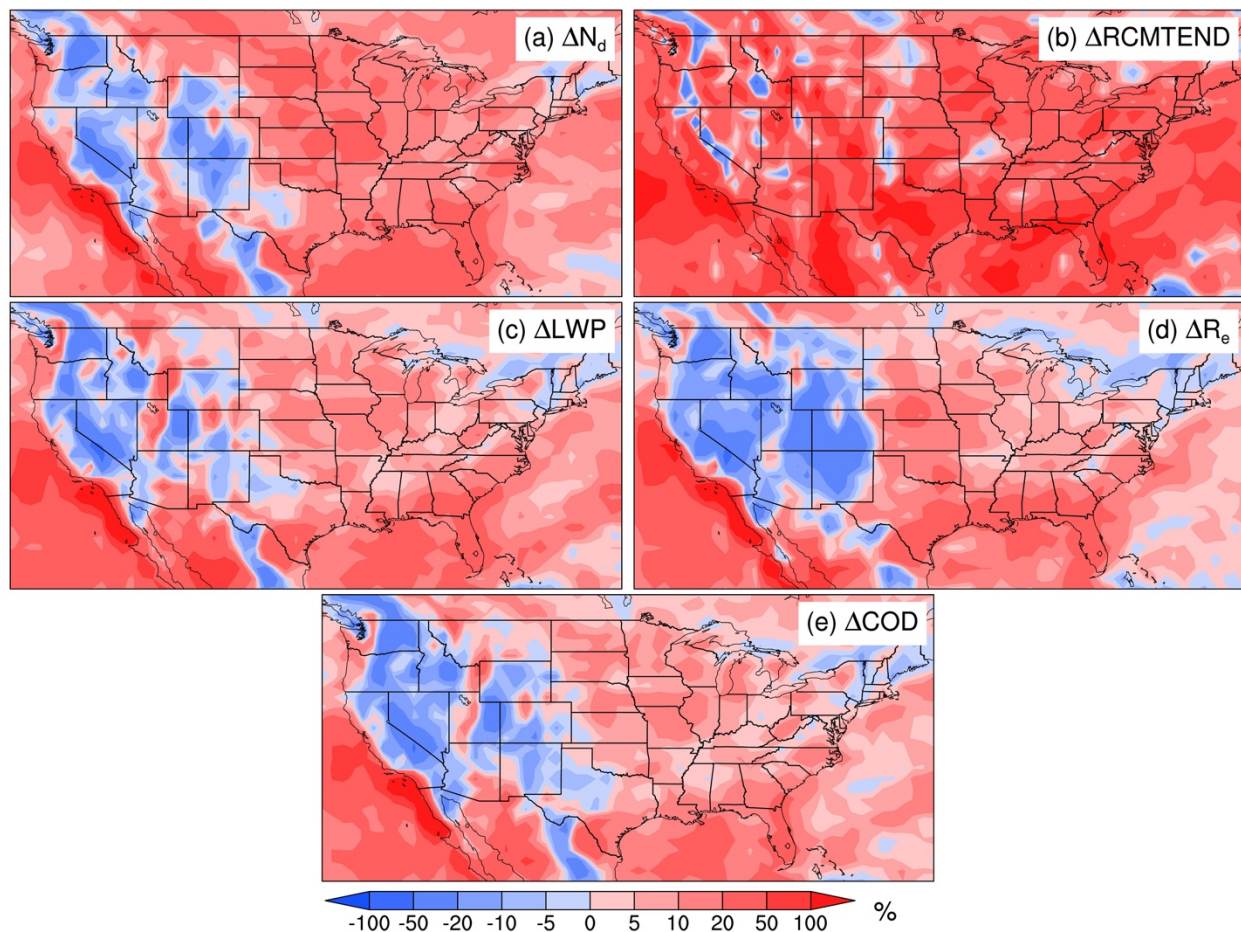

423 Aerosol activation in large-scale clouds is parameterized consistently with droplet nucleation. In
 424 EAMv1, most IAPs exist in accumulation and Aitken modes (Figures S46a and S46b). We find the
 425 aerosol activation in the RRM is, on average, enhanced by 13.7% (accumulation mode) and 5.8% (Aitken
 426 mode) compared to the LR (Figures 11a and 11b). Aerosol activation in large-scale clouds primarily

427 occurs in two pathways. One is related to cloud expansion (i.e., increase in cloud fraction, which leads to
428 aerosol activation) and shrinkage (i.e., decrease in cloud fraction, which leads to aerosol resuspension) in
429 the same grid box (hereafter referred to as the cloud-intermittency pathway) between model timesteps.
430 The other refers to the activation of IAPs that are brought to the cloud base by updrafts (hereafter referred
431 to as the updraft pathway) (Liu et al., 2012). We find that the cloud-intermittency pathway contributes to
432 almost all the aerosol activation enhancement in Aitken mode but only about half of the enhancement in
433 accumulation mode under regional refinement (not shown). The updraft pathway accounts for the other
434 half of the enhancement in accumulation mode. The contrast RRM impacts on the updraft pathway
435 between the accumulation and Aitken modes may be related to the distinct vertical profiles of IAPs from
436 the two modes (Figure S46c). The cloud-intermittency pathway is parameterized as a function of W_{sub} ,
437 aerosol properties, and the change of large-scale liquid cloud fractions between two consecutive time
438 steps ($\Delta L C L O U D$) (Abdul-Razzak and Ghan, 2000; Zhang et al., 2022a). Positive $\Delta L C L O U D$
439 corresponds to cloud expansion, and negative $\Delta L C L O U D$ denotes cloud shrinkage. We do not find any
440 noticeable differences in W_{sub} and aerosol properties between the RRM and LR simulations. However,
441 $|\Delta L C L O U D|$ is considerably larger in the RRM, which indicates larger L C L O U D temporal variability
442 (Figure 11c), resulting in increased microphysical cloud processing of aerosols and more aerosol
443 activation via the cloud-intermittency pathway. The larger L C L O U D temporal variability is consistent
444 with the larger relative humidity (RH) temporal variability in the RRM than in the LR (Figure 11d)
445 (Golaz et al., 2002).

446
 447 Figure 11. (a, b) Spatial distributions of the relative differences in the annual mean vertical-integrated IAP activation
 448 fluxes in large-scale clouds for (a) accumulation and (b) Aitken modes between the RRM and LR simulations. (c)
 449 Vertical profiles of the annual regional mean absolute temporal variabilities of large-scale liquid cloud fractions
 450 ($|\Delta L CLOUD|$). $|\Delta L CLOUD| = |L CLOUD_{t_2} - L CLOUD_{t_1}|$; t_2 and t_1 indicate two consecutive model time steps. The
 451 red line indicates the RRM simulation and the black line for the LR simulation. (d) the same as (c) but for relative
 452 humidity (RH).

453 Enhanced aerosol activation results in higher droplet number concentrations (N_d) in the RRM
 454 compared to the LR (Figure 12a). Moreover, the CLUBB vertical-integrated cloud liquid water tendency
 455 (RCMTEND), which is dominated by water vapor condensation, is generally remarkably larger in the
 456 RRM simulation (Figure 12b), which leads to higher large-scale cloud liquid water path (LWP) and LWC
 457 (Figures 12c and S35c). Larger RCMTEND may also contribute to larger droplets at the cloud top in the
 458 RRM simulation (R_e in Figure 12d; R_e — grid-cell mean droplet effective radius at the top of liquid water
 459 clouds), even though N_d increases. With higher LWP and larger R_e , cloud optical depth (COD) is also
 460 higher (Figure 12e).

461
 462 Figure 12. Spatial distributions of the relative differences in annual mean (a) grid-cell mean vertical-integrated
 463 droplet number concentrations (N_d), (b) CLUBB vertical-integrated cloud liquid water tendency (RCMTEND), (c)
 464 grid-cell mean liquid water path (LWP), (d) grid-cell mean droplet effective radius at the top of liquid water clouds
 465 (R_e), and (e) grid-cell mean cloud optical path (COD) between the RRM and LR simulations. It is noteworthy that
 466 N_d , RCMTEND, LWP, and R_e are exclusively for large-scale clouds, while COD considers both large-scale and
 467 convective clouds but is dominated by large-scale (not shown). The spatial distributions of N_d , RCMTEND,
 468 LWP, R_e , and COD from the LR simulation are shown in Figure S57.

469 3.5 Anthropogenic aerosol effective radiative forcing

470 With considerable impacts on cloud properties, the regional refinement should also influence ERF_{aer} .

471 We use the Ghan (2013) method to decompose ERF_{aer} into direct, indirect, and surface albedo effects.

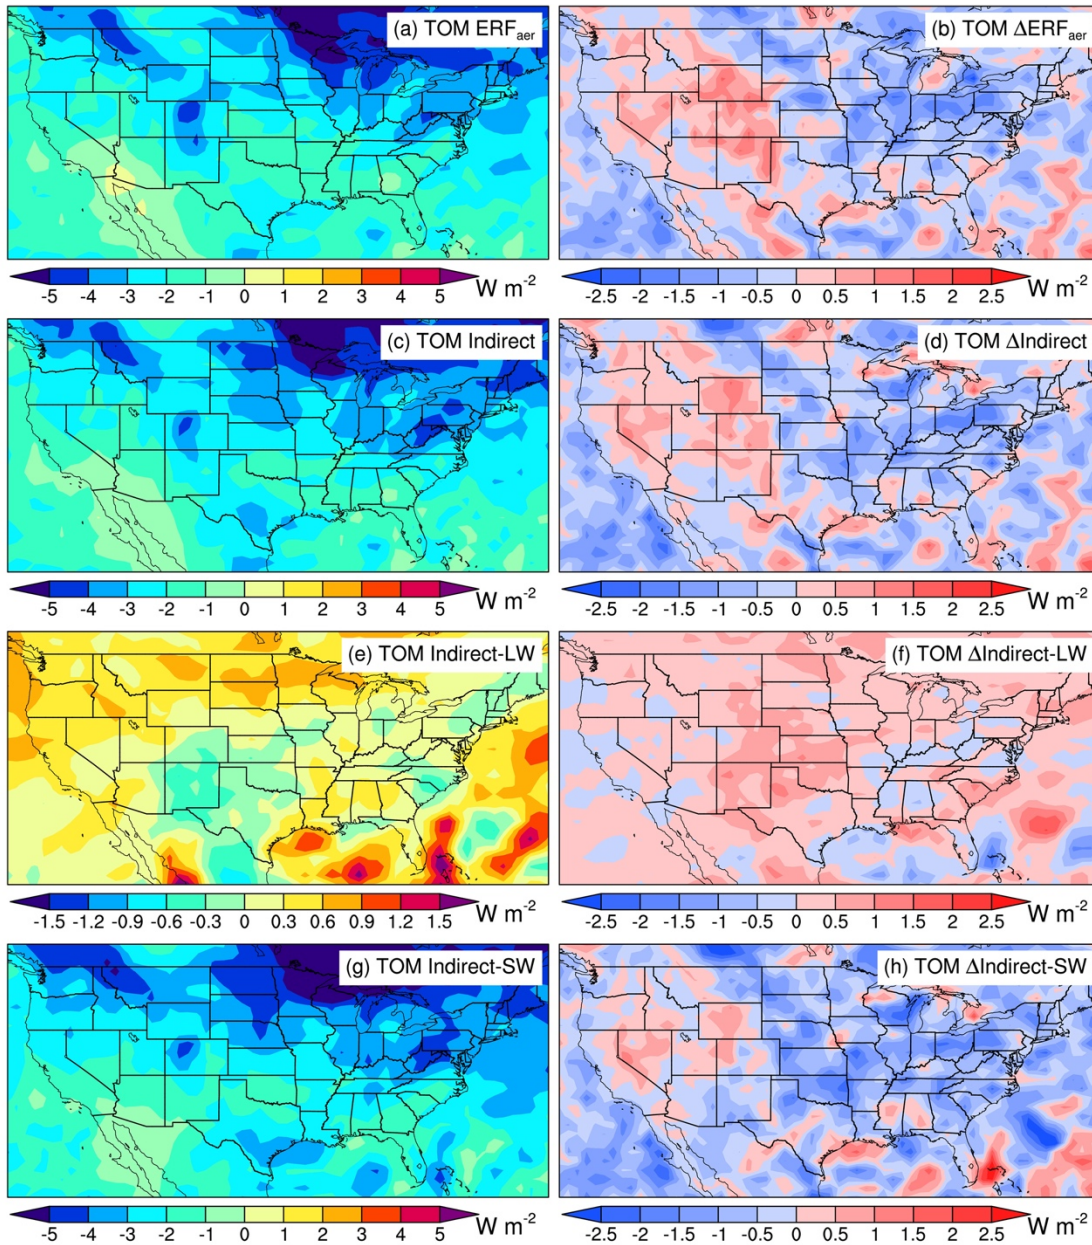

472 Figure 13 shows a stronger (more negative) anthropogenic aerosol shortwave indirect effect (-0.52 W m^{-2})

473 and enhanced longwave indirect effect (0.21 W m^{-2}) at the top of the model (TOM) in the RRM

474 simulation compared to the LR simulation. The net (shortwave + longwave) indirect effect is 0.31 W m^{-2}

475 more negative in the RRM simulation compared to the LR simulation, which is about a 12%

476 enhancement. The total ERF_{aer} at TOM is 0.27 W m^{-2} more negative in the RRM simulation, about a 12%
 477 enhancement compared to the LR simulation. We also find that the RRM simulation produces a 10%
 478 enhancement of ERF_{aer} at the surface (Figure S68).

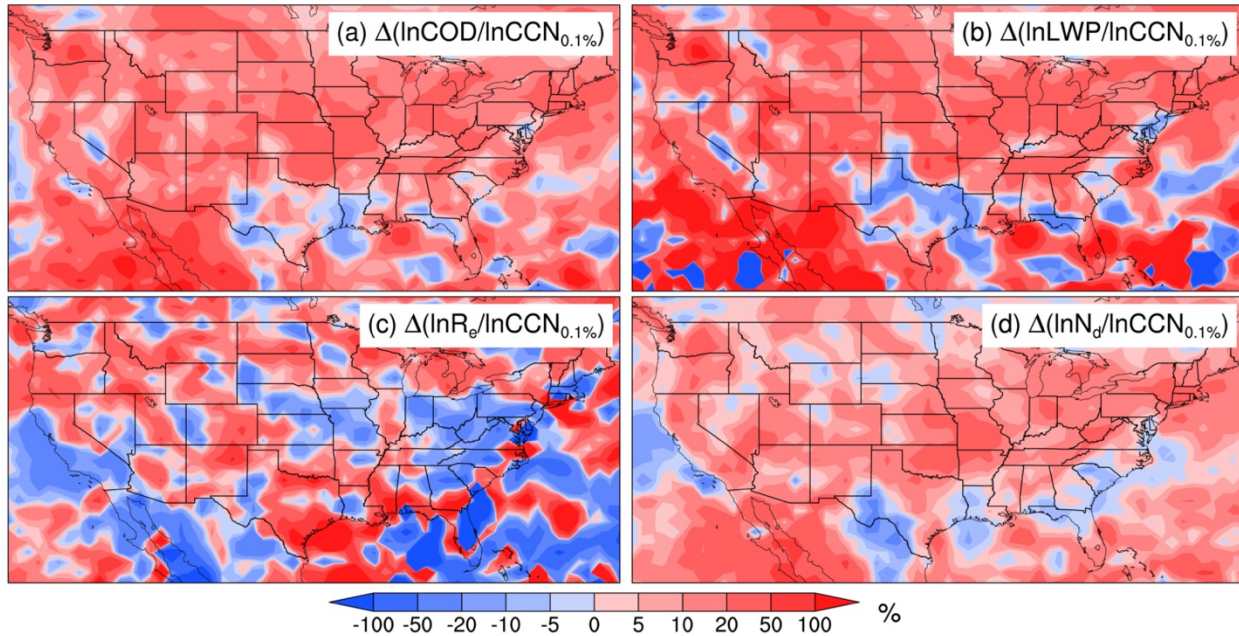

479
 480 Figure 13. (a) Spatial distribution of annual mean ERF_{aer} at the top of the model (TOM) from the LR simulation. (c,
 481 e, g) Same as (a) but for ERF_{aer} attributed to (c) aerosol indirect effect (longwave + shortwave), (e) aerosol
 482 longwave indirect effect, and (g) aerosol shortwave indirect effect. The right column is the same as the left but for
 483 the absolute differences between the RRM and LR simulations.

484 To understand the enhancement of ERF_{aer} in the RRM experiment, we compare the production
485 efficiencies of N_d , R_e , LWP, and COD due to anthropogenic aerosols between the RRM and LR
486 simulations (Figure 14). In Figure 14, the relative changes of N_d , LWP, and COD per relative change of
487 CCN at 0.1% supersaturation ($CCN_{0.1\%}$) between the PD and PI simulations are generally larger in the
488 RRM simulation, consistent with our earlier analysis of the enhanced aerosol activation in RRM. Because
489 cloud properties are more sensitive to anthropogenic aerosols in the RRM, the RRM configuration
490 produces stronger anthropogenic-aerosol-cloud interactions and ERF_{aer} (Figure 13).

491 This result differs from Ma et al. (2015), which demonstrated that higher model resolutions would
492 weaken the aerosol indirect effect. Ma et al. (2015) identified the increased droplet nucleation in
493 simulations with higher resolutions, leading to a stronger first aerosol indirect effect, which is consistent
494 with this study. However, their LWP response to anthropogenic aerosols weakens (lower LWP) as
495 resolution increases, leading to reduced second aerosol indirect effect, in contrast to the larger LWP
496 production efficiencies in our RRM simulation (Figure 14b). The discrepancies may be caused by
497 different parameterizations of water vapor condensation to form cloud liquid water. The water vapor
498 condensation is parameterized in CLUBB on the basis of joint PDFs of vertical velocity, temperature, and
499 moisture in our simulations (Golaz et al., 2002), while it was calculated in CAM5 in Ma et al. (2015)
500 using a saturation equilibrium adjustment approach (Park et al., 2014). The water vapor condensation
501 parameterization affects not only LWP but also the subsequent aqueous-phase chemistry calculation
502 discussed in Section 3.3. Therefore, it is necessary to evaluate the sensitivity of water vapor condensation
503 to model resolutions when different parametrizations are used, as their resolution sensitivity can be very
504 different.

505 Our finding regarding the stronger aerosol indirect effect as resolution increases is also different
506 from Caldwell et al. (2019), which found that the aerosol indirect effect changed only slightly from the
507 low-resolution to high-resolution simulations. This discrepancy might be attributed to the fact that the
508 model timesteps used in low- and high-resolution model simulations are very different in Caldwell et al.

509 (2019) but are kept the same in this study. Since model timestep can affect model aerosol and clouds,
 510 aerosol indirect effects can be affected.

511
 512 Figure 14. Spatial distributions of the relative differences in (a) $\frac{\ln \text{COD}}{\ln \text{CCN}_{0.1\%}}$, (b) $\frac{\ln \text{LWP}}{\ln \text{CCN}_{0.1\%}}$, (c) $\frac{\ln R_e}{\ln \text{CCN}_{0.1\%}}$, and (d)
 513 $\frac{\ln N_d}{\ln \text{CCN}_{0.1\%}}$ between the RRM and LR simulations. Here, $\ln x$ denotes the relative change of x between the PD and PI
 514 simulations, i.e., $\ln x = \frac{PD_x - PI_x}{PI_x}$. Therefore, $\frac{\ln x}{\ln \text{CCN}_{0.1\%}}$ reflects the production efficiency of x by anthropogenic
 515 aerosols.

516 4 Conclusions

517 We investigate the impact of increasing model horizontal resolution on the aerosol mass budget and
 518 ERF_{aer} over the CONUS in 2016 by comparing E3SMv1 LR and RRM simulations (Tables 1 and 2). The
 519 RRM simulation produces more dust, sea salt, and MOM emissions than the LR simulation due to larger
 520 surface wind speeds, more frequent strong surface winds, or drier soil. Besides influencing the natural
 521 aerosol sources, RRM also affects SO_4 production from gas-aerosol exchange, aqueous-phase chemistry,
 522 and NPF (Table 2). The reduced SO_4 production from gas-aerosol exchange and NPF by RRM is due to
 523 decreased gas-phase SO_2 and H_2SO_4 concentrations in the RRM simulation. Enhanced aqueous-phase SO_4
 524 production consumes more SO_2 under regional refinement, leading to lower gas-phase SO_2

525 concentrations. The improved aqueous-phase SO₄ production is attributed to more cloud water uptake of
 526 H₂SO₄ and more oxidation of SO₂ by H₂O₂ in large-scale clouds with higher LWC in the RRM
 527 simulation. In contrast, the oxidation of SO₂ by O₃ is slightly suppressed due to the lower pH of large-
 528 scale clouds in the RRM simulation compared to the LR simulation, which is a consequence of slightly
 529 increased gas-phase H₂O₂ concentrations releasing more H⁺ through the oxidation of SO₂ by H₂O₂.

530 **Table 2.** Comparison of aerosol-relevant properties in the RRM region between the LR and RRM
 531 simulations

		RRM	LR	Relative diff ¹ / %
Precipitation / mm day ⁻¹	Large-scale	1.55	1.21	27.5
	Convective	1.00	1.18	-15.6
SO ₄ in-cloud scavenging / TgS yr ⁻¹	Large-scale precipitation	0.982	0.856	14.7
	Convective precipitation	0.356	0.424	-15.9
	Gas-aerosol exchange	0.515	0.531	-3.0
SO ₄ production / TgS yr ⁻¹	Aqueous-phase production	1.13	1.06	6.2
	NPF	0.0182	0.0210	-13.3
Aerosol activation / 10 ⁵ m ⁻² s ⁻¹	Aitken mode	10.09	8.87	13.7
	Accumulation mode	2.22	2.09	5.8
N _d / 10 ¹⁰ m ⁻²		1.30	1.17	11.5
R _c / μm		1.56	1.45	7.7
LWP / g m ⁻²		33.0	30.7	7.3
COD		5.14	4.86	5.6
TOM ERF _{aer} / W m ⁻²	Indirect shortwave	-3.27	-2.74	19.1
	Indirect longwave	0.50	0.29	72.0
	Total indirect	-2.76	-2.45	12.8
	Total (indirect + direct + albedo)	-2.66	-2.38	11.5

532 ¹Relative diff = (RRM/LR - 1) × 100%.

533 Increasing model horizontal resolution affects the partitioning between large-scale and convective
 534 precipitation (Table 2). With more resolved large-scale precipitation and less parameterized deep

535 convective precipitation, in-cloud scavenging of aerosols by large-scale (deep convective) precipitation
536 generally increases (decreases) in the RRM simulation compared to the LR simulation.

537 RRM enhances the activation of IAPs in large-scale clouds due to the larger temporal variability of
538 LCLOUD in the RRM simulation compared to the LR simulation (Table 2). Enhanced aerosol activation
539 leads to more cloud droplets. In addition, RRM enhances water vapor condensation, resulting in larger
540 LWP and R_e , which leads to larger COD. Since aerosol activation is stronger in the RRM simulation,
541 cloud droplets, LWP, and COD are more sensitive to anthropogenic aerosols. Consequently, the
542 anthropogenic aerosol indirect effect and ERF_{aer} in the RRM are stronger than in the LR simulation (Table
543 2).

544 Although the study is limited to comparing the E3SMv1 LR (~100 km) and CONUS RRM (~25 km)
545 simulations, the methodology shown in the study is helpful for future studies to investigate the potential
546 impacts of model resolutions on the simulation results, as RRM is significantly less expensive
547 computationally compared to the global high-resolution model. ~~And some~~Some findings from this study
548 may also apply to E3SM simulations at higher resolutions or even convection-permitting scales, such as
549 the enhancement in natural aerosol emissions due to stronger winds, the partitioning between large-scale
550 and convective precipitation and associated wet scavenging, and improved IAP activation in large-scale
551 clouds. However, we must also emphasize that the aerosol mass budget and ERF_{aer} are sensitive to model
552 configurations and regional characteristics such as aerosol properties, land use and land cover, and
553 climate. Aerosol and clouds in other regions can be very different. Furthermore, some resolution
554 sensitivities may differ as model resolution advances to convection-permitting and subgrid-scale
555 processes ~~becomes~~become more significant. Moreover, although nudging is applied in the study to
556 minimize the impacts of large-scale circulations on aerosol properties as horizontal resolution changes,
557 differences in meteorology still exist between the RRM and LR simulations (e.g., surface wind speed and
558 precipitation). Therefore, the results above contain the meteorological effect, although the meteorological
559 differences are also caused by the change in horizontal grid spacing.

561 **Code availability**

562 The E3SMv1 source code is available at <https://doi.org/10.11578/E3SM/dc.20180418.36> (E3SM
563 Project, 2018) (last access: April 11, 2022).

564

565 **Data availability**

566 We use the Stage IV precipitation data from the MCS-IDC data product, available at
567 <http://dx.doi.org/10.25584/1632005> (Li et al., 2020). The LR and RRM simulation results are available at
568 <https://doi.org/10.5281/zenodo.7782985> (Li et al., 2023). [The level-3 Moderate Resolution Imaging](#)
569 [Spectroradiometer \(MODIS\) gridded \(\$1^\circ \times 1^\circ\$ \) monthly Dark Target aerosol optical depth \(AOD\)](#)

574 [Interagency Monitoring of Protected Visual Environments \(IMPROVE\) data is available at](#)
575 <https://views.cira.colostate.edu/fed/QueryWizard/> (last access: May 26, 2022).

576

577 **Author contributions**

578 KZ and JL designed the study. JL conducted the simulations under the instructions of KZ and with
579 the help of TH, BS, and QY. KZ and SZ determined the nudging strategy, and JL prepared the ERA5
580 nudging files under the instructions of SZ and KZ. JL performed the analyses with discussions with KZ,
581 TH, PM, and HH. JL prepared the paper with contributions from all coauthors.

582 **Competing Interests**

583 Po-Lun Ma is a Topical Editor of Geoscientific Model Development. Other authors declare that they
584 have no conflict of interest.

585

586 **Acknowledgments**

587 The study was supported as part of the Enabling Aerosol–cloud interactions at GLobal convection-
588 permitting scales (EAGLES) project (project no. 74358) sponsored by the United States Department of
589 Energy (DOE), Office of Science, Office of Biological and Environmental Research, Earth System Model
590 Development (ESMD) program area. The Pacific Northwest National Laboratory (PNNL) is operated for
591 the DOE by the Battelle Memorial Institute under Contract DE-AC05-76RL01830. The research used
592 high-performance computing resources from the PNNL Research Computing and resources of the
593 National Energy Research Scientific Computing Center (NERSC), a U.S. Department of Energy Office of
594 Science User Facility located at Lawrence Berkeley National Laboratory, operated under Contract No.
595 DE-AC02-05CH11231 using NERSC awards ALCC-ERCAP0016315, BER-ERCAP0015329, BER-
596 ERCAP0018473, and BER-ERCAP0020990. IMPROVE is a collaborative association of state, tribal, and
597 federal agencies, and international partners. US Environmental Protection Agency is the primary funding
598 source, with contracting and research support from the National Park Service. The Air Quality Group at
599 the University of California, Davis is the central analytical laboratory, with ion analysis provided by
600 Research Triangle Institute, and carbon analysis provided by Desert Research Institute. We thank Ilya
601 Slutsker and many other Principal Investigators (PIs) or co-PIs and their staff for establishing and
602 maintaining the AERONET sites used in the study.

13 Table S1. Evaluation statistics of aerosol optical depth (AOD) at 550 nm based on Figure S1

	<u>MODIS¹</u>	<u>LR</u>			<u>RRM</u>		
	<u>Mean²</u>	<u>Mean</u>	<u>RMSE</u>	<u>r</u>	<u>Mean</u>	<u>RMSE</u>	<u>r</u>
<u>ANN</u>	<u>0.159</u>	<u>0.130</u>	<u>0.084</u>	<u>0.66</u>	<u>0.130</u>	<u>0.084</u>	<u>0.66</u>
<u>JJA</u>	<u>0.164</u>	<u>0.149</u>	<u>0.098</u>	<u>0.72</u>	<u>0.149</u>	<u>0.099</u>	<u>0.72</u>
<u>DJF</u>	<u>0.162</u>	<u>0.130</u>	<u>0.092</u>	<u>0.68</u>	<u>0.129</u>	<u>0.093</u>	<u>0.68</u>

14 ¹We use the level-3 MODIS (Moderate Resolution Imaging Spectroradiometer) gridded (1° × 1°) monthly Dark
 15 Target AOD products (MOD08_M3 and MYD08_M3) in 2016 (Platnick et al., 2015). MOD08_M3 provides
 16 monthly mean AOD at 10:30 local solar time (LST), while MYD08_M3 provides monthly mean AOD at 13:30
 17 LST. The averages of monthly MOD08_M3 and MYD08_M3 AOD are used to calculate the MODIS annual, JJA
 18 (June, July, and August), and DJF (December, January, and February) mean AOD all over the globe in Figure S1,
 19 which are then used to derive the statistics here.

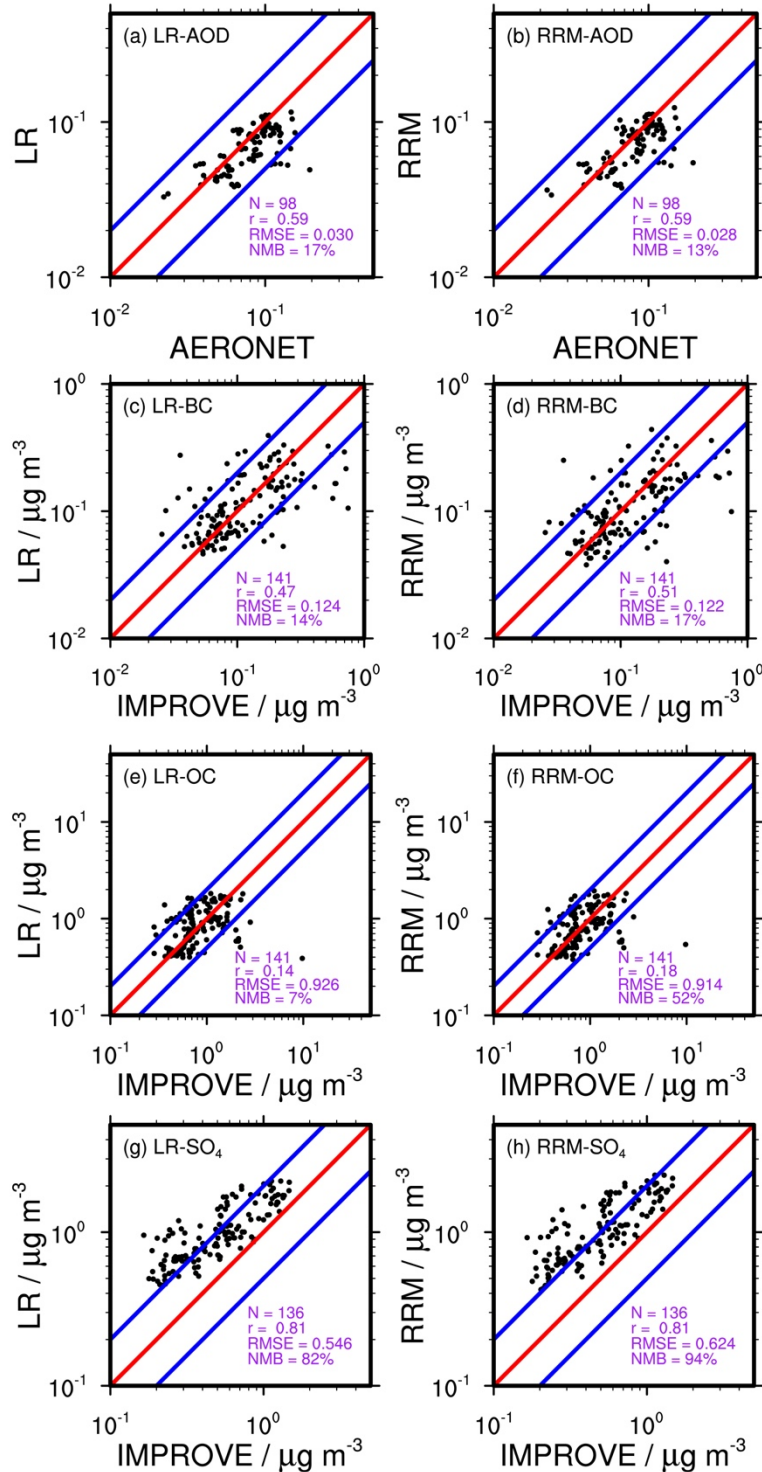

20 ²“Mean” refers to the global mean; RMSE (root-mean-square-error) and r (Pearson correlation coefficient) are
 21 against MODIS observations.

32

Figure S1. Spatial distributions of AOD at 550 nm from the (a, d, g) LR and (b, e, h) RRM simulations and (c, f, i) the MODIS datasets in 2016. (a, b, c) ANN refers to the annual mean, (d, e, f) JJA indicates the mean AOD during June, July, and August, and (g, h, i) represents the mean during December, January, and February. For the LR and RRM simulations, we output averaged AOD during 10:00-11:00 LST and 13:00-14:00 LST each day to match MOD and MYD observations, respectively. Calculated monthly AOD during the two periods from the LR and RRM simulations are then filtered using the corresponding data availability of MOD08_M3 and MYD08_M3 AOD at 550 nm, which are then used to calculate averaged AOD of the two periods. Finally, we use the monthly averaged AOD to calculate the annual, JJA, and DJF mean AOD for the LR and RRM simulations and the MODIS datasets.

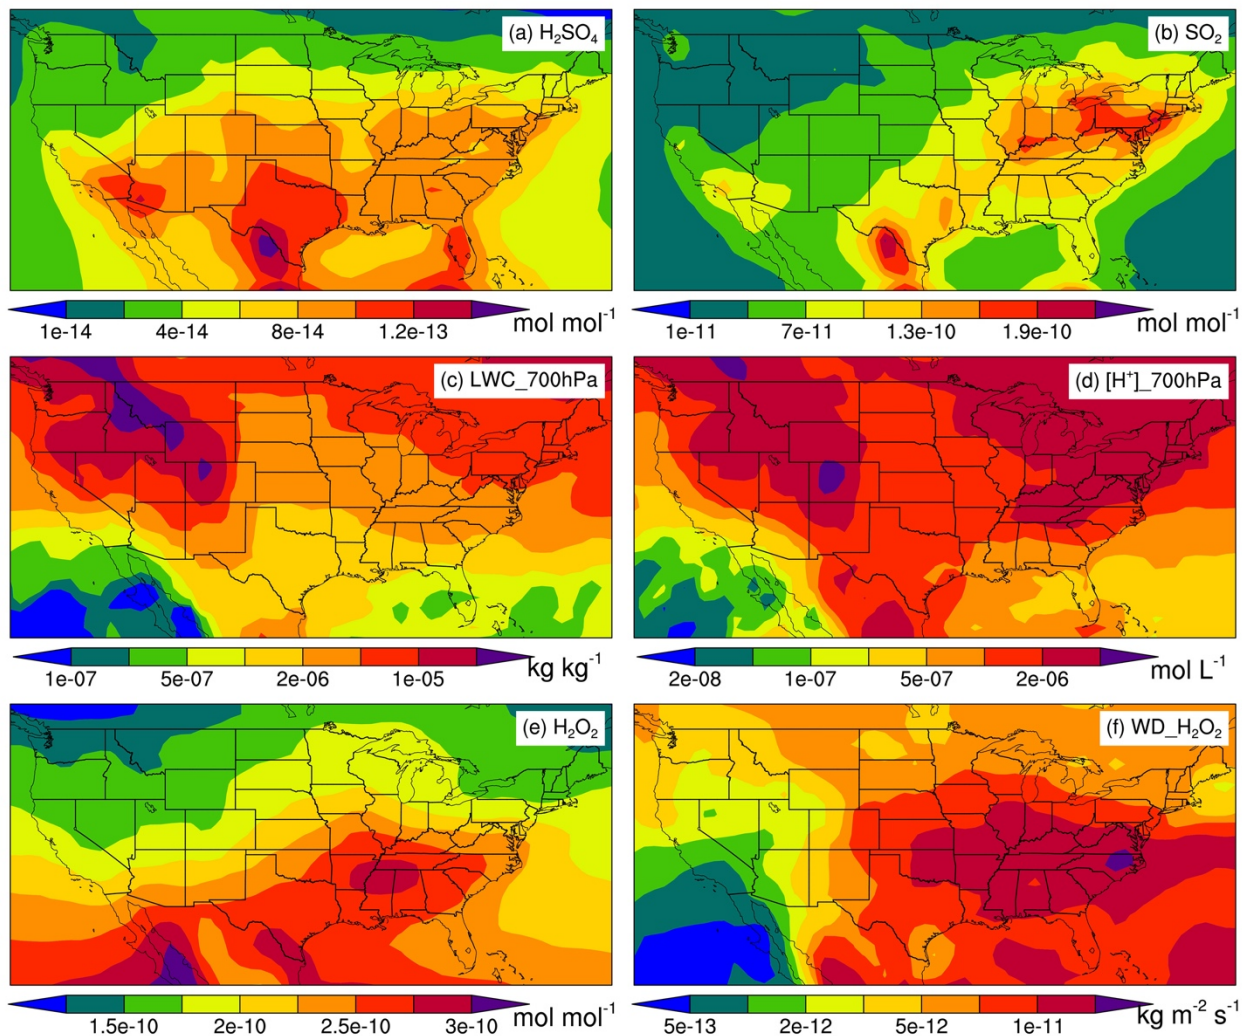

33
 34 Figure S2. Evaluations of the (left column) LR and (right column) RRM simulated annual mean (a, b)
 35 AOD at 550 nm and fine (c, d) BC, (e, f) organic carbon (OC), and (g, h) SO₄ mass concentrations against
 36 ground-based observations from AERONET (AERosol RObotic NETwork) and IMPROVE (Interagency
 37 Monitoring of Protected Visual Environments) (Malm et al., 1994) in the RRM region in 2016.
 38 AERONET V3 level 2.0 provides daily mean AOD at 500 nm and daily mean Angstrom exponent for
 39 440-870 nm (Slutsker, 2018), which are used to derive daily mean AOD at 550 nm. IMPROVE provides
 40 daily mean mass concentrations of fine BC, OC, and SO₄ (Cira/Csu, 2023). The daily mean observations

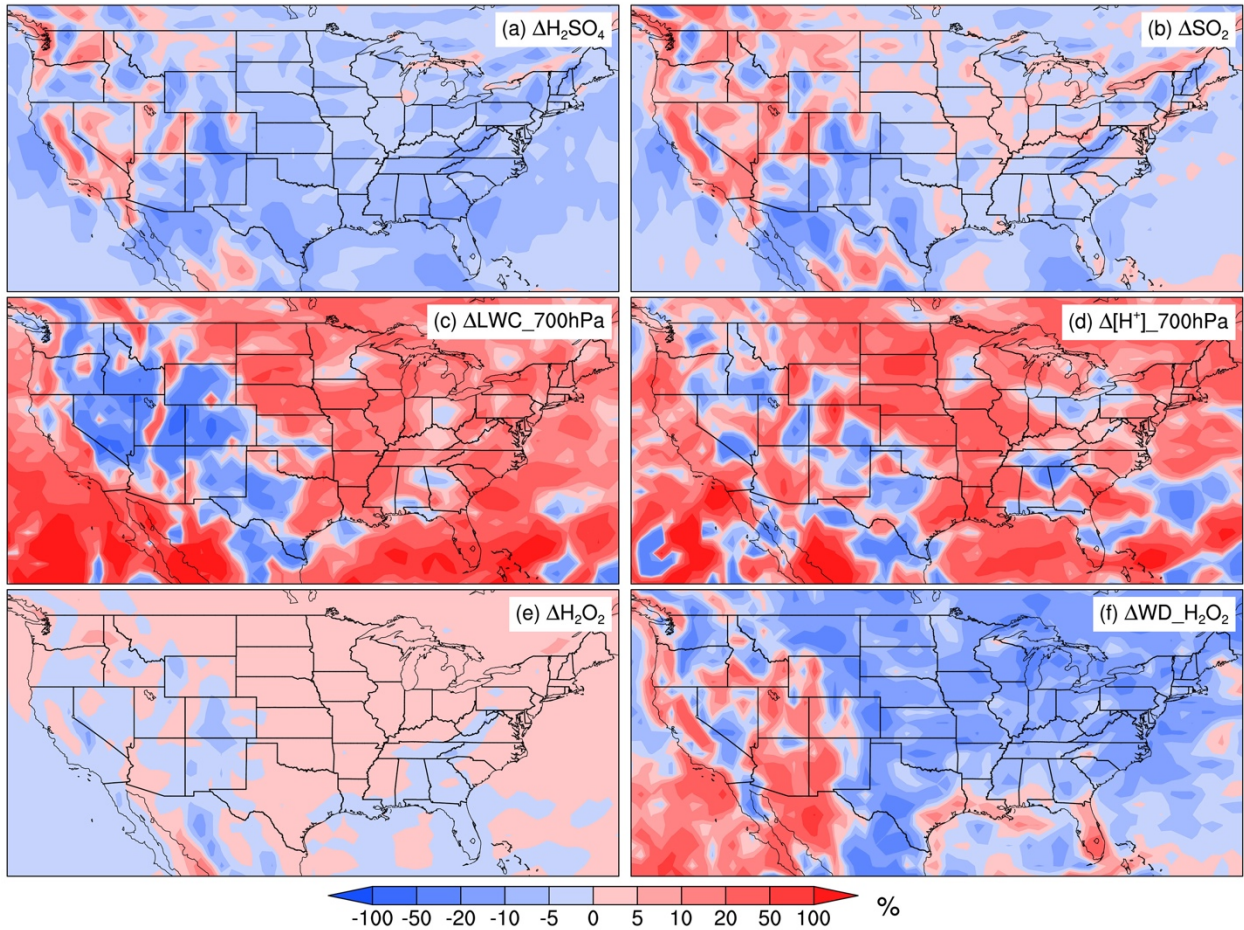

41 are used to calculate monthly means, which are then used to select coincident model monthly results.
42 Notably, we use the regridded (1°× 1°) LR and RRM simulation results to match observational sites to
43 make the comparisons fair to both simulations. Each dot in the figure denotes one observational site. “N”
44 refers to the number of observational sites; “r” is the Pearson correlation coefficient; “RMSE” is the root
45 mean square error; and “NMB” indicates the normalized mean bias.
46 We apply the following equations to calculate the model fine BC, OC, and SO₄ to be compared with
47 observations.
48 SO₄(fine) = SO₄(accumulation mode) + SO₄(Aitken mode) + Sea salt(accumulation) + Sea salt(Aitken)
49 OC(fine) = (POM(primary carbon) + POM(accumulation) + SOA(accumulation) + SOA(Aitken))/1.4
50 BC(fine) = BC(accumulation) + BC(primary carbon)
