Abstract. Models are simplified descriptions of reality and are intrinsically limited by the assumptions that have been introduced in their formulation. With the development of automatic calibration toolboxes, finding optimal parameters that suit the environmental system has become more convenient. Here, we explore how optimization toolboxes can be applied innovatively to uncover flaws in the physical formulations of models. We illustrate this approach by evaluating the effect of simplifications embedded in the formulation of a widely used hydro-thermodynamic model. We calibrate a Delft3D model based on temperature profiles for a case study, Lake Morat (Switzerland), through the DYNO-PODS optimization tool. The results show that higher values of the light extinction coefficient can compensate for neglecting the fraction β of short-wave radiation absorbed at the surface of the water. This leads to unrealistic values of the light extinction coefficient, as the optimization pushes its value towards the limit of no transparency, consistent with the need to reproduce a significant absorption at the surface. Although it is well known that β is significantly larger than zero, its absence from the model was never noticed as critical. Automatic calibration tools provide valuable diagnostic insights into the physical robustness of models, enabling more precise evaluation of their structural integrity and performance.

1 Introduction

Numerical models serve as powerful tools capable of embracing the complexity of intricate environmental dynamics. In many branches of environmental science, such as meteorology, climatology, hydrology, oceanography, and limnology, hydro-thermodynamic models have become standard tools to simulate and understand specific physical processes. These models are rooted on the numerical solution of physical first principles, e.g. the mass, momentum, and heat equations. Although first principles are well established, modeling the physics of fluid systems remains complicated for two reasons. First, the grid size limits the range of applicability of models based on first principles (e.g., Direct Numerical Simulations, DNS) and poses

20 the challenge to properly parameterize associated sub-grid scale processes. This implies that models that were developed for a specific environment, where the parametrization was adequate, may not be optimized for other contexts characterized by different spatial scales. Second, imposing the boundary conditions is a complicated task as the forcing acting at the boundaries of the computational domain is often only partially known. For instance, the estimation of the surface heat fluxes is based on parametrizations that have to cope with both the complex physics and the uncertainties associated with the forcing. Contrary
25 to the first principles solved by the model, such boundary conditions often lack universality. In the specific case of models widely adopted to simulate three-dimensional lake dynamics, many were originally developed for marine, riverine or estuarine environments. This is the case of, e.g., Delft3D (Lesser et al., 2004), MITgcm (Marshall et al., 1997), ROMS (Shchepetkin and McWilliams, 2005), FVCOM (Chen et al., 2003), NEMO (Madec et al., 2023), POM (Blumberg and Mellor, 1987), among a few others. Therefore, some processes that are crucial in lakes, but not for the original environment, may be correctly repro-
30 duced. Scientists thus must critically evaluate model performances, as even some of the most used models may have unexpected flaws.

The first step of any model setup and performance evaluation is calibration. Tools for the automatic calibration of the model parameters have recently been introduced, enabling a broader and more efficient search for the optimal parameters. Analyses of how these tools can provide support and foster a better understanding of the numerical results are becoming increasingly
35 frequent. For instance, examples are numerous for the Delft3D model (in particular, the FLOW module), one of the most popular models for simulating hydrodynamics of natural environments. Garcia et al. (2015) and Baracchini et al. (2020b) adopted a derivative-free algorithm for non-linear least squares (DUD from Ralston and Jennrich (1978)) within OpenDA (El Serafy et al., 2007) to optimize calibration and data assimilation in their lake models; Schwindt et al. (2022) assessed the uncertainty of mixing-related model parameters through a Bayesian calibrator combined with a Gaussian process emulator;
40 Xia et al. (2021, 2022) developed the PODS tool (Parallel Optimization with Dynamic coordinate search using Surrogates) and showed the potential of using surrogate models to accelerate global optimization. A surrogate model, also known as emulator, is a simplified and computationally efficient empirical model (Castelletti et al., 2010) that mimics the behavior of a computationally expensive model based on real model training data. In the search for the optimal parameters, the largest computation cost is indeed related to the real model runs. Thus, fast surrogate model runs are alternated with real model runs
45 such that a lower number of real model evaluations is needed. Surrogate models can be included in traditional optimization tools such as Bayesian calibration (Ma et al., 2024) and are highly effective in speeding up the calibration process.

Many opportunities are offered by automated calibrators, saving time and finding global optimal solutions, and many other optimization algorithms have been applied for the calibration of hydrodynamic models. We refer to Xia et al. (2021) for a review of all these aspects. However, much care must be taken when model parameters are calibrated, either manually or automatically.
50 The literature reports examples where calibration has guided modelers in regions of the parameter space that hold no physical meaning (e.g. Baar et al. (2019), well discussed by Tritthart et al. (2024)). Such unrealistic parameters are often justified as those giving the best model performance, but it is well known that (i) a different combination of parameters might give the same result and (ii) the performance of the model heavily depends on what metric is adopted. This is particularly true for hydro-thermodynamic models calibrated on a single variable, e.g. temperature profiles only (Amadori et al., 2021; Xia et al., 2022).

55 The objective of this work is to show how the use of automatic calibration can help identify flaws in the structure of even state-of-the-art models. Analyses of how these tools can foster a better understanding of the numerical results have started to appear in the literature. In the previously cited work by Schwindt et al. (2022), the authors were able to identify unrealistic model setups from the high uncertainty of the a posteriori distribution of mixing-related parameters. With a similar philosophy, here we evaluate the parameterization of the heat distribution along the water column as coded in Delft3D. In particular, we focus on the depth of the Secchi disk (Secchi, 1864, hereafter denoted as D_s or simply "Secchi depth"), as a parameter representing the transparency of the water. Considering water transparency in hydro-thermodynamic models has long been recognized as fundamental to enhance the prediction of water temperature (e.g. Henderson-Sellers, 1986; Zolfaghari et al., 2017; Shatwell et al., 2019), as it allows the inclusion of biologically driven mechanisms, even when they are not explicitly parameterized. D_s is used to model the distribution of the incoming solar short-wave radiation from the surface to deeper layers depending on how deep it can penetrate the water column. Although it is often considered a calibration parameter in models (e.g. Wahl and Peeters, 2014; Soulignac et al., 2017; Piccioni et al., 2021; Xia et al., 2021), D_s is actually a measurable quantity that can vary significantly over time and, in some cases, in space. In large lakes, differences between onshore and offshore D_s measurements can be of the same order of magnitude as seasonal variations (e.g. Pothoven and Vanderploeg (2020) found up to 4 times lower transparency in coastal waters compared to pelagic areas of Lake Michigan). Massive algal blooms, combined with basin-scale circulation, can also drive complex spatial patterns of water transparency as those observed by Rahaghi et al. (2024) in Lake Geneva, with D_s ranging between < 2 and $6 >$ m on the same day.

However, experience from previous Delft3D applications in various lakes shows that the calibrated value of D_s generally resides in the lower range of measured values (Wahl and Peeters, 2014; Soulignac et al., 2018), or it is even lower than the observed values (for example, Amadori et al. (2020) and Piccolroaz et al. (2019) rescaled the observed Secchi depth by a factor of 0.5). Through the DYNO-PODS automatic calibrator (Xia et al., 2022), we extend the search for the optimal D_s in a broader parameter space and explore uncharted regions for manual calibration. We demonstrate how this sheds light on a flaw in the heat flux parametrization of Delft3D and let us improve the physics behind such a widely used model with a small, yet significant, modification to its source code.

In the following sections, we first formulate the problem (Section 2). Here we summarize how Secchi depth is used in Delft3D (2.1), how surface warming is generally simulated in models (2.2), what are the physical implications of the current Delft3D parametrization (2.3) and of the modified version we implemented (2.4). In Section 3, we introduce the calibration strategy and numerical experiments. In Section 4, we first show the results of the original formulation of the Delft3D heat flux scheme (4.1). We then present the results of the calibration tests that point out the model's unexpected behavior (4.2). Finally, we show the gain in physical reliability achieved after our modification of the Delft3D source code (4.3).

85 2 Formulation of the problem

2.1 Use of Secchi depth in models

The three-dimensional model Delft3D-FLOW (Lesser et al., 2004) numerically solves the Reynolds Averaged Navier Stokes equations (RANS) under the Boussinesq and shallow-water assumptions. The horizontal velocity components and the water surface are solved by integrating the continuity and horizontal momentum equations, while the vertical velocities are computed from the continuity equation. The transport of heat is modeled by an advection-diffusion equation, assuming that there is no heat exchange at the lake bed.

In the heat equation module of the model, all the heat flux terms are estimated with empirical formulas. Here, we focus on the penetration of solar short-wave radiation, which is modeled with a reduction of the energy flux per unit area (Wm^{-2}) along the water column, as in the commonly used Beer law:

$$95 \quad H_{\text{sw}}(z) = H_{\text{sw}0} \exp(-\gamma z), \quad (1)$$

where $H_{\text{sw}0}$ is the downward short-wave radiation at the water surface (already considering the effect of albedo), $H_{\text{sw}}(z)$ is the energy flux that reaches the depth z , and γ is the extinction coefficient (m^{-1}). This simplified model refers to the light attenuation coefficient, which can be easily measured in situ, and is appropriate for the region of the visible spectrum (380-750 nm). Accordingly, the extinction coefficient γ is defined based on the depth D_s (m) at which the Secchi disk remains visible, through the simple relation:

$$100 \quad \gamma = \frac{c_\gamma}{D_s}, \quad (2)$$

where the value $c_\gamma = 1.7$ is used as standard in Delft3D (Deltares, 2023) and was originally proposed by Poole and Atkins (1929).

However, the actual penetration of the short-wave radiation depends on the different wavelengths that make up its spectrum. In principle, each wavelength has a different extinction coefficient (Zaneveld and Spinrad, 1980). Much of the short-wave radiation energy, in particular longer wavelengths in the near-infrared to short-wave-infrared region (750-2500 nm), is absorbed at the water surface regardless of its optical properties. The latter are indeed related to the concentration of constituents and mainly affect the extinction coefficient in the visible region (400-700 nm).

Among many formulations available to properly describe the penetration of downward solar radiation in the water column (Morel and Antoine, 1994), the simplified version reported in Henderson-Sellers (1986) is commonly applied in many numerical models:

$$H_{\text{sw}}(z) = (1 - \beta) H_{\text{sw}0} \exp(-\gamma z). \quad (3)$$

In such a formulation, β is the fraction of the short-wave radiation absorbed in a region close to the surface.

As a consequence, the surface layer is warmed up by a localized total heat flux,

$$115 \quad H_{\text{surf}} = H_{\text{np}} + \beta H_{\text{sw}0}, \quad (4)$$

Figure 1. a) Heat transfer at water surface. Non-penetrative terms H_{np} are lost at the air-water interface (blue line, representative of the skin layer), while a sub-layer at the surface retains a fraction β of incoming solar radiation H_{sw0} , and only the fraction $(1 - \beta) H_{sw0}$ of the solar short-wave radiation penetrates along the water column. The two grey lines represent the exponential decay of incoming heat flux in the surface sub-layer (above the horizontal dashed line) and beneath it. b) Conceptual illustration of how the process in a) evolves along the water column, with orange representing heat penetrating from the surface to the deeper layers; c) schematic of how a) is then parameterized in a vertically layered computational grid.

which is the sum of the absorbed short-wave radiation βH_{sw0} and of the other non-penetrative fluxes H_{np} (see Figure 1). The non-penetrative heat flux,

$$H_{np} = H_{lw}^{\downarrow} - H_{lw}^{\uparrow} \pm H_{sens} \pm H_{lat}, \quad (5)$$

is the result of the net downward long-wave radiative flux H_{lw}^{\downarrow} (from the sky to the lake), the upward long-wave radiation H_{lw}^{\uparrow} (emitted by the lake surface), and the sensible and latent heat fluxes, H_{sens} and H_{lat} respectively. All these terms are associated with a generic surface heat flux H_{surf} , but it is worth noting that non-penetrative terms act just at the interface between water and air, while βH_{sw0} is absorbed in a layer of the order of tens of centimeters (Henderson-Sellers, 1986) (Fig. 1b). From the viewpoint of numerical modeling (Fig. 1c), the fraction β of the incoming solar radiation represents a source of heat in a shallow layer of water, while non-penetrative terms (usually negative) represent a sink of heat, as will be shown later. All these fluxes are normally parameterized in only one computational cell, i.e. the one immediately below the water surface, where the contributions of both equations 3 and 4 should be accounted for.

Modified versions of the Beer law were introduced in some lake-dedicated models to account for the different absorption of heat depending on the spectral bands of solar radiation. This is the case of the General Lake Model (Hipsey et al., 2019), where the authors attribute 55% of the incident solar radiation to near-infrared (NIR) and ultraviolet (UVA, UVB) radiation heating the surface directly. A default value of 45% for β is implemented in CE-QUAL-W2 (Cole and Wells, 2015), but different values of 24 to 69% are recommended depending on the type of environment, with higher values attributed to pure waters (63%) and coastal waters (69%) and lower values (24 to 58%) to lake waters. A similar approach with different proportions (35% for NIR, 65% for PAR, UVA, UVB) was adopted by Thiery et al. (2014) to simulate Lake Kivu thermal structure with an ensemble of different lake models. Among these, models explicitly including β are SimStrat (Goudsmit et al., 2002), LAKEoneD (Joehnk and Umlauf, 2001), LAKE (Stepanenko and Lykossov, 2005), MINLAKE96 (Fang and Stefan, 1996).

Although accounting for this fraction of heat at the surface is important in lakes, to the best of our knowledge, the absence of this term in Delft3D never raised any concern in its previous applications to lacustrine environments. The reason is that the extinction coefficient γ estimated with equation (2), or equivalently the depth of the Secchi disk D_s , is considered a calibration parameter, even if D_s is a measurable quantity.

2.2 General formulation of surface layer warming

Hydro-thermodynamic models such as Delft3D solve a thermal energy balance, where the heat source is usually dominated by the heat exchanged at the air-water interface. The relevant terms in the equation for the transport of heat can be represented as follows:

$$\frac{\partial T}{\partial t} + \text{advection} + \text{diffusion} = -\frac{\partial \phi}{\partial z}, \quad (6)$$

where T is water temperature and ϕ is the vertical heat flux. We assume that the vertical coordinate z is pointing downwards, such that the heat flux is positive downwards (consistent with the direction of solar radiation). The source term on the right-hand side of the equation represents the local heating, which depends on the absorption of the radiative heat flux. Without this source term, the advection and diffusion terms can only redistribute the heat in the domain, so that the total heat content of the lake is conserved if no flux is exchanged at the boundaries.

In equation (6), we have simplified the notation by introducing the flux (units Ks^{-1}m)

$$\phi = \frac{H}{\rho c_p}, \quad (7)$$

which scales the total heat flux H with water density ρ (units kgm^{-3}) and specific heat capacity at constant pressure c_p (units $\text{Jkg}^{-1}\text{K}^{-1}$), assuming them to be constant, as a first approximation. Hereafter, the definition of ϕ_x based on equation (7) is adopted for all heat fluxes H_x , where the subscript x indicates the component.

The net heat flux at the air-water interface is

$$\phi_{\text{net}} = \frac{H_{\text{net}}}{\rho c_p} = \phi_{\text{sw0}} + \phi_{\text{np}} = (1 - \beta) \phi_{\text{sw0}} + \phi_{\text{surf}}. \quad (8)$$

In a depth-averaged model, the net heat flux is responsible for the change of the whole-lake temperature. Neglecting the sub-daily variability, the warming of the lake is related to the total heat exchanged during a day:

$$\int_{\text{diel}} \phi_{\text{net}} dt = \int_{\text{diel}} \phi_{\text{np}} dt + \int_{\text{sunlight}} \phi_{\text{sw0}} dt, \quad (9)$$

160 where the integrals are defined on a 24-hour period (covering the periods of sunlight, with $\phi_{\text{sw0}} > 0$, and night, with $\phi_{\text{sw0}} = 0$). The total exchanged heat, $\int_{\text{diel}} \phi_{\text{net}} dt$, is typically much smaller than the two individual components on the right-hand side of equation (9), as can be seen in Figure 2a. Under these conditions, and to illustrate the behavior of the system, it can be assumed that $\int_{\text{diel}} \phi_{\text{net}} dt \simeq 0$. Therefore, the non-penetrative heat lost through the surface must approximately balance the solar heating, i.e. $\int_{\text{diel}} \phi_{\text{np}} dt \simeq - \int_{\text{sunlight}} \phi_{\text{sw0}} dt$, so that the non-penetrative components of the heat flux have a cooling effect in most cases.

165 In terms of diel averaged values (indicated using angle brackets), the condition can be written as

$$\langle \phi_{\text{np}} \rangle \simeq - \frac{1}{\tau_{\text{day}}} \int_{\text{sunlight}} \phi_{\text{sw0}} dt < 0, \quad (10)$$

where τ_{day} is 24 hours. Since the sub-daily variability of the non-penetrative fluxes is small compared to the solar radiation flux, it follows that $\phi_{\text{np}} \simeq \langle \phi_{\text{np}} \rangle$ (see, e.g., the example in Figure 2), and equation (8) implies that lakes are typically subject to (relative) cooling during night and to (relative) warming during sunlight.

170 The numerical model solves the discretized form of the heat equation (6) in a i -th layer of thickness Δz_i . If the advective and diffusive fluxes are neglected, the variation in time of the temperature T_i^* (where $*$ denotes the idealized case of no advection and diffusion) can be written as:

$$\frac{\Delta T_i^*}{\Delta t} = \frac{\phi_{i-1/2} - \phi_{i+1/2}}{\Delta z_i} = \sigma_i, \quad (11)$$

whereby we define the warming rate σ_i (units Ks^{-1}). In fact, assuming that the horizontal dimensions of the grid remain 175 vertically constant and in the absence of advection and diffusion, the temperature T_i^* of the computational cell i increases only if the heat flux entering the cell exceeds the flux leaving the cell. When the heat source comes from above, this means that warming occurs if the heat flux entering from the upper face ($i - 1/2$, for a staggered Arakawa C-grid) is larger than the flux leaving the cell from the lower face ($i + 1/2$).

Indicating with $i = 1$ the computational cell at the top of the water column (see also Figure 1c), the flux at the upper 180 boundary condition of the model is $\phi_{1/2} = \phi_{\text{net}}$, while the flux at the bottom of the first computational cell is $\phi_{3/2} = (1 - \beta) \phi_{\text{sw0}} \exp(-\gamma \Delta z_1)$. Hence, the warming rate in the uppermost computational layer can be obtained by combining equations (3),(4), (7),(8) into equation (11):

$$\begin{aligned} \sigma_1 \Delta z_1 &= (\phi_{\text{sw0}} + \phi_{\text{np}}) - (1 - \beta) \phi_{\text{sw0}} \exp(-\gamma \Delta z_1) \\ &= \beta \phi_{\text{sw0}} + \phi_{\text{np}} + (1 - \beta) \phi_{\text{sw0}} [1 - \exp(-\gamma \Delta z_1)]. \end{aligned} \quad (12)$$

185 Extending the same approach to the layers below the one at the surface, we can express the warming rate in layer $i = 2$ as

$$\begin{aligned} \sigma_2 \Delta z_2 &= (1 - \beta) \phi_{\text{sw0}} \exp(-\gamma \Delta z_1) - (1 - \beta) \phi_{\text{sw0}} \exp[-\gamma (\Delta z_1 + \Delta z_2)] \\ &= (1 - \beta) \phi_{\text{sw0}} \exp(-\gamma \Delta z_1) [1 - \exp(-\gamma \Delta z_2)]. \end{aligned} \quad (13)$$

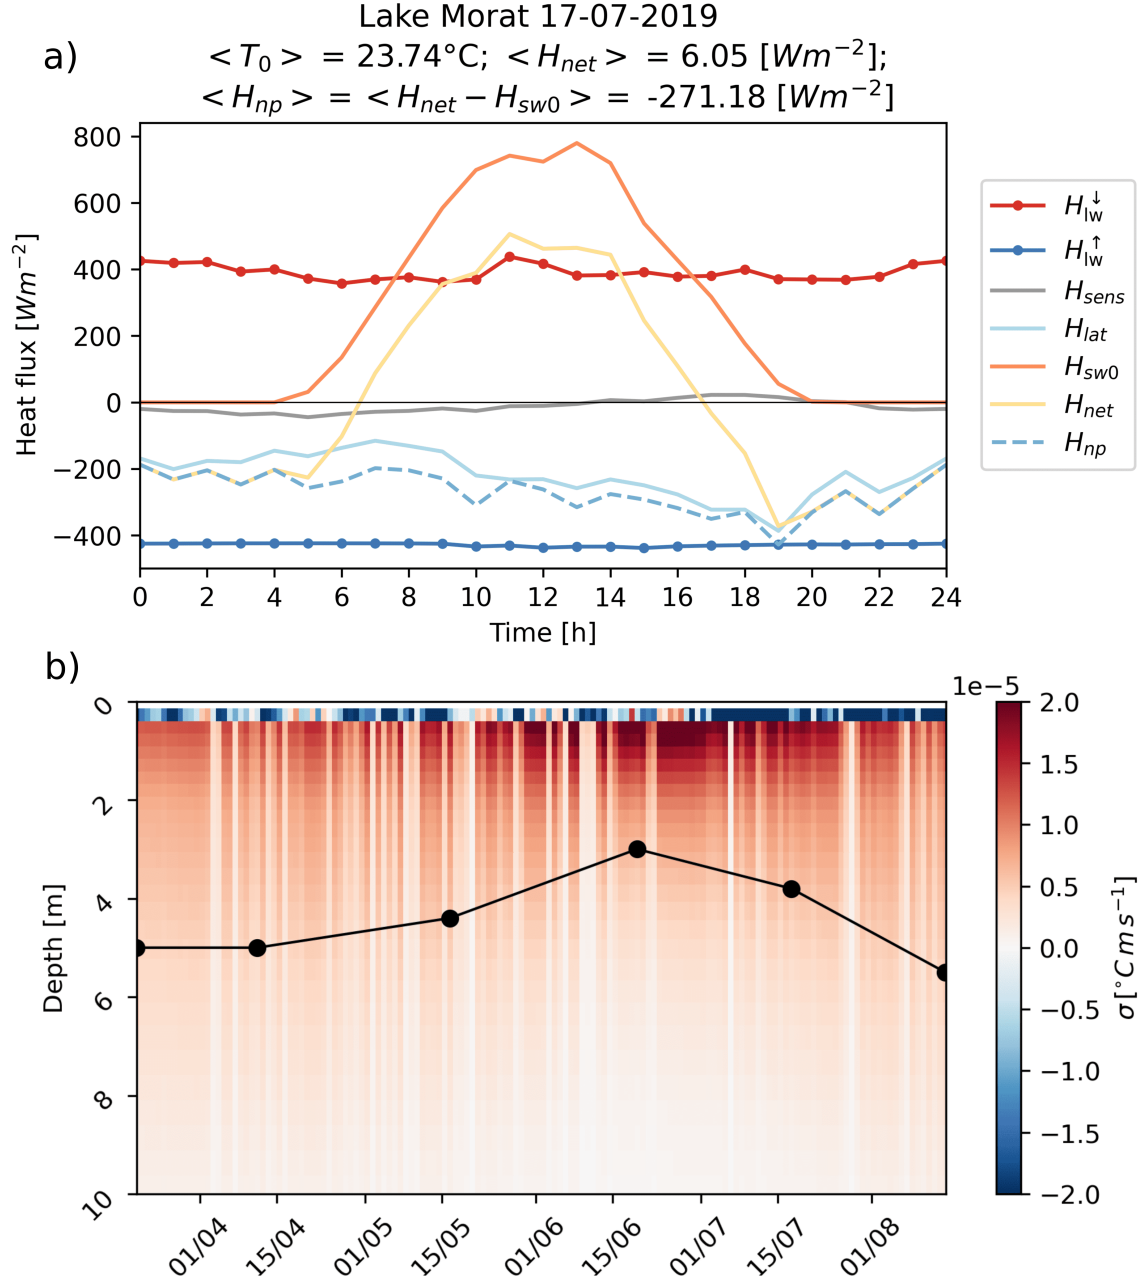

Figure 2. a) Heat fluxes computed using the meteorological forcing and the simulated surface water temperature from the base setup model (\mathcal{O} in Table 1) for Lake Morat on a sample summer day, i.e. 17 July 2019. b) Warming rates simulated along the water column calculated according to equations (14)-(15) using the flux calculated by model \mathcal{O} . Profiles are displayed at 12:00 UTC. The black line represents the measured Secchi depth (D_s) considered in the simulation, with black dots indicating the exact measurement day. Depths are limited to 10 m to improve visibility of the surface layer.

During sunlight ($\phi_{\text{sw}0} > 0$), the second term on the right hand side of equation (13) (first line) is smaller than the first one, ($\Delta z_1 + \Delta z_2 > \Delta z_1$). Hence, the layer $i = 2$ is always warmed. Similar considerations apply to all the other layers with $i > 1$.
 190 In contrast, σ_1 may be negative (producing local cooling of the surface layer) even during warming periods, depending on the value of β and ϕ_{np} .

The difference in the warming rates of layers 1 and 2 as predicted by equations (12) and (13) may produce a vertical temperature gradient, which tends to be balanced by the vertical diffusive flux in equation (6). The effectiveness of such a flux in balancing the differential warming highly depends on the intensity of the turbulence. In particular, increasing the
 195 eddy diffusivity could make the entire profile more homogeneous. As discussed in the following sections, turbulence might compensate the effect of different schemes for the penetration of solar radiation, for instance if $\beta = 0$, as in the original version of the Delft3D heat equation module.

2.3 Case with $\beta = 0$

The original version of Delft3D, which adopts the Beer law as in equation (1), can be described as a particular case of the
 200 scheme described above in which $\beta = 0$. In this case the warming rate of the top layer ($i = 1$) expressed by equation (12) can be simplified as in (14):

$$\sigma_1 \Delta z_1 = \phi_{\text{np}} + \phi_{\text{sw}0} [1 - \exp(-\gamma \Delta z_1)] . \quad (14)$$

When γ is small (very large D_s , i.e., very transparent water), the last term within square brackets becomes less important and non-penetrative terms prevail. As discussed in section 2.2, $\phi_{\text{np}} \simeq \langle \phi_{\text{np}} \rangle < 0$ (see also Figure 2a). Therefore, the layer $i = 1$
 205 may cool down also when sunlight is present ($\phi_{\text{sw}0} > 0$). The lower layers instead always receive heat, despite being maybe small in very transparent conditions, as the warming rate σ_2 only depends on penetrative short-wave radiation as implied by equation (15), which is obtained by setting $\beta = 0$ in equation 13.

$$\sigma_2 \Delta z_2 = \phi_{\text{sw}0} \exp(-\gamma \Delta z_1) [1 - \exp(-\gamma \Delta z_2)] . \quad (15)$$

2.4 Case with $\beta > 0$

We modified the Delft3D source code by substituting the Beer law (1) with the complete version (3), as reported in Appendix A. Hence, the scheme reported in equations (12) and (13) with $\beta > 0$ applies. Focusing on the warming of the top layer and repeating the same argument as for equation (14), in case of small γ the last term of equation (12) vanishes and $\sigma_1 \simeq (\beta \phi_{\text{sw}0} + \phi_{\text{np}}) / \Delta z_1$. Now, the sum of the two terms is not necessarily negative, as $\beta \phi_{\text{sw}0}$ can balance the negative contribution of ϕ_{np} , and the surface layer is not forced to cool down (or not so much) during sunlight. A proper choice of the coefficient β
 215 can improve the physical consistency of the calibrated model.

3 Material and methods

Lake Morat, Switzerland, is the test site for our study. This is one of the alpine lakes included in the AlpLakes network¹ for which a calibrated setup of the Delft3D model is available. The details of the case study and the base Delft3D setup have been explained in Appendix B.

220 3.1 Calibration strategy

For the calibration of the Delft3D model we adapted to our needs the procedure DYNO-PODS based on a parallel surrogate global optimization method (Xia et al., 2021, 2022), which allows for calibrating multiple parameters simultaneously. DYNO-PODS runs parallel simulations and finds the best result at each iteration based on a cost function ε_k to be minimized. We refer to the DYNO-PODS documentation and in particular to Xia et al. (2022) for an exhaustive description of the surrogate model
225 implemented in DYNO-PODS.

The purpose of optimization is to correctly reproduce measured water temperature in one single station. We therefore tested two objective functions: (i) an error function ε_T based on the temperatures measured throughout the profile, as in equation (16); (ii) an error function ε_{T0} based on the temperatures measured only at the lake surface, as in equation (17).

The distributed error ε_T is estimated by the average root mean square deviation

$$230 \quad \varepsilon_T = \sqrt{\frac{1}{N_t} \sum_{j=1}^{N_t} \frac{1}{N_z} \sum_{i=1}^{N_z} \left(T_{i,j} - \widehat{T}_{i,j} \right)^2}, \quad (16)$$

where N_t is the number of temporal profiles, N_z is the number of measuring points along the vertical, $T_{i,j}$ is the observed temperature at the depth z_i and time t_j , and $\widehat{T}_{i,j}$ is the corresponding value simulated by the model. If ε_T is chosen as objective function, the model is optimized towards the best representation of both surface and deep water temperatures.

The error at the surface ε_{T0} is estimated via the root mean square deviation of the surface temperature T_0 :

$$235 \quad \varepsilon_{T0} = \sqrt{\frac{1}{N_t} \sum_{j=1}^{N_t} \left(T_{0,j} - \widehat{T}_{0,j} \right)^2}. \quad (17)$$

If ε_{T0} is chosen instead as objective function, the calibrated model provides the best representation of surface temperature, regardless of the performance on water temperature below.

3.2 Calibration tests

Starting from a base setup (\mathcal{O} in Table 1, for more details, see Appendix B), we tested how the performance of the model
240 could be improved by calibrating the Secchi depth. To preserve the time-dependence of measured values of Secchi depth we introduced a parameter δ defined as follows:

$$\widehat{D_s} = \delta D_s, \quad (18)$$

¹<https://www.alplakes.eawag.ch>

Table 1. Calibration tests setups with values of the main parameters (wind drag corrective coefficient α , free convection coefficient (CFrcon), horizontal eddy diffusivity and viscosity coefficients (Dicouv, Vicouv) and Ozmidov length scale (Xlo), scaling of Secchi depth (δ) and fraction of short-wave solar radiation absorbed in the first layer (β). \mathcal{O} identifies the original Delft3D model, while \mathcal{M} the modified version including β . Numbers are reported only when calibrated in the test, and “n.c.” stands for “not calibrated”. For \mathcal{M}_{cal} test, not calibrated parameters are the same as in \mathcal{O} . “n.a.” stands for “not applicable” and only refers to the β parameter which does not exist in \mathcal{O} model version.

Model	Test	α	Cfrcon	Dicouv	Vicouv	Xlo	δ	β	ε_T
		-	-	m^2s^{-1}	m^2s^{-1}	mm	-	-	$^{\circ}\text{C}$
Original	\mathcal{O}	0.94	0.019	2.36	1.65	0.338	n.c.	n.a.	0.57
Original	\mathcal{O}_{cal}	n.c.	n.c.	n.c.	n.c.	n.c.	0.84	n.a.	0.49
Modified	\mathcal{M}_{cal}	n.c.	n.c.	n.c.	n.c.	n.c.	1.00	0.32	0.47
Modified	\mathcal{M}	0.98	0.004	1.84	1.28	0.118	n.c.	0.33	0.45

where $\widehat{D_s}$ is the Secchi depth value used in the model and D_s refers to the original value measured on-site.

We first calibrated δ with the original model (\mathcal{O}_{cal} in Table 1). Two separate calibration tests were performed considering the two objective functions defined in equations (16)-(17). Since the error along the entire water column (ε_T) is a standard objective function, only the details of these results are reported in Table 1. However, we also show and discuss the relevant results of tests with ε_{T0} below in Table 2 in Section 4.2).

As a second step, we tested the effect of introducing the coefficient β in a modified version of the model, \mathcal{M}_{cal} , where all other parameters were maintained as in \mathcal{O} , and δ and β were calibrated.

Finally, we run a new base calibration for the modified model \mathcal{M} , where the full set of parameters was optimized, including β .

All calibration tests were performed in those months when water transparency prominently influences the formation of a stratified thermal structure in dimictic lakes, i.e. the spring and summer months after winter mixing. The simulated period was 20 March to 14 August 2019. Sensitivity tests on the model response to variations in Secchi depth during the cooling season (from August onward) confirmed the assumption that it is possible to effectively determine the optimal value of δ limiting the calibration to the period when stratification occurs (not shown).

In order to gather a satisfactory convergence of the automated calibration tests, we run 10 iterations of 12 parallel simulations, for a maximum value of 120 evaluations for each calibration test. This aligns with Xia et al. (2021), who found that 120 model evaluations were necessary to achieve a solution similar (in performance) to manual calibration in their case study. The simulation time for 5 months was about 11 hours on a High Performance Computing Cluster. Each simulation utilized 6 cores on a single node, resulting in 72 CPU cores being used per iteration.

4 Results

4.1 Base setup model

In this section, we present the results of the calibration of the original model \mathcal{O} (without β , see Table 1) and without any modification of the Secchi depth. This setup implicitly corresponds to $\beta = 0$ and $\delta = 1$. Figure 2a shows the heat balance terms computed on an hourly time scale at the lake-atmosphere interface on a summer day (17 July 2019), for which in situ measurements of water temperature are available. As expected from the theoretical considerations in Section 2.2, the net heat flux is heavily affected by the short-wave solar radiation H_{sw0} , which however vanishes at night, producing a strong sub-daily variability that is extremely large compared to the other terms. Moreover, if short-wave radiation is excluded from the overall balance H_{net} , the resulting net heat flux accounting only for the non-penetrative terms (H_{np} , dashed line) is also negative during daylight hours.

By using the heat fluxes internally computed in the calibrated Delft3D model, we estimated the local warming rate of the surface layer according to equation (14), i.e. neglecting advection and diffusion. In this simplified scheme, the heat flux at the surface resulted in an almost always negative value indicating a predominantly heat loss term in the heat equation of the surface layer. As shown in Figure 2b, where the warming rate σ is plotted everyday at noon, this happens even in the warming periods (spring-summer), with a few exceptions during extremely calm (i.e. low wind) and sunny days. In layers beneath the surface, σ (estimated locally with equation (15)) instead has a positive sign. In fact, short-wave radiation penetrates the water column with a decreasing warming rate as depth approaches the Secchi depth D_s . Hence, excluding advective and diffusive terms from the simulation as in equation (11), would result in continuous cooling of the surface layer and slight warming of deeper layers. Although this is not the case in the Delft3D model, which accounts for advective and diffusive fluxes, the tendency can also be noted in the numerical results, as will be shown below (Figure 4).

4.2 Optimal scaling of Secchi depth

The results of the calibration tests \mathcal{O}_{cal} and \mathcal{M}_{cal} to assess the optimal scaling of the Secchi depth are reported in Table 2. The search for the optimal value of δ depends on the objective function used in the calibration tests.

In the original model \mathcal{O}_{cal} (Figure 3 a-b), if the calibration target is the surface water temperature (ε_{T_0} in equation (17)), the optimal scaling for the Secchi depth unrealistically converges to $\delta = 0.12$. Smaller values of δ lead to warmer surface temperature because γ becomes very large (low transparency; see equation (2)) and a large portion of the short-wave solar radiation is absorbed in the top surface layer. If the target is the temperature of the water throughout the water column (ε_T in equation (16)), the optimal value is $\delta = 0.84$.

The same plots from the tests \mathcal{M}_{cal} (Figure 3 d-f), suggest that the water temperature can be simulated without the need to drastically minimize δ . The optimal δ converges to 0.57 and 1 for the two objective functions ε_{T_0} and ε_T , respectively. The first value (0.57) will be commented on in the discussion section. Interestingly, Figure 3e-f show that the value of β converges in a physically meaningful range and the optimal value is 0.32 for both objective functions (Table 2), fully consistent with the range of literature values (20-60%) presented in Section 2.1.

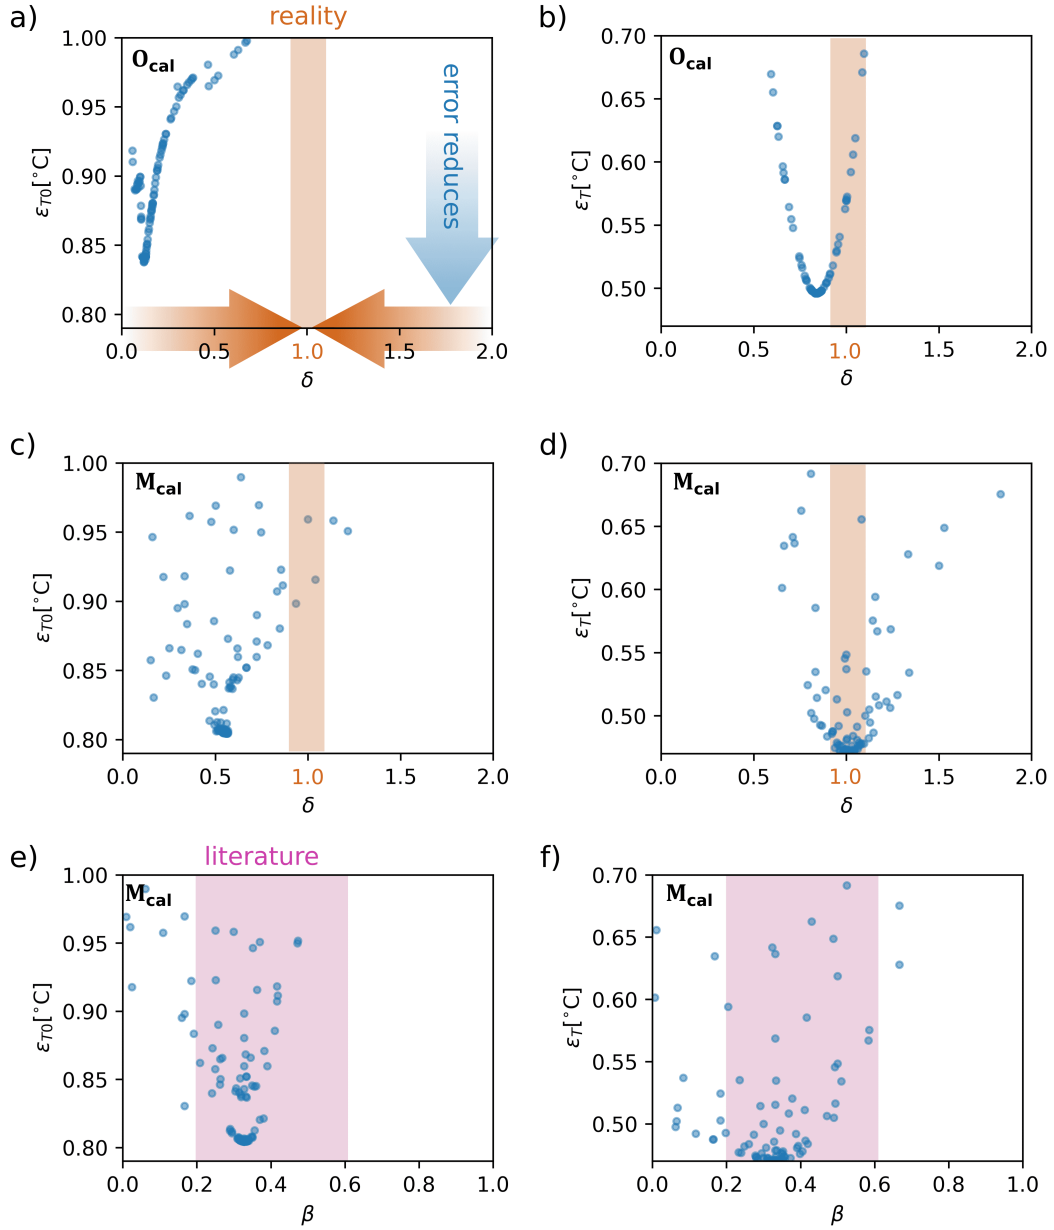

Figure 3. Convergence of different calibration tests and objective functions (a, c, e: ε_{T_0} , error on surface temperature; b, d, f: ε_T , error on temperature along the water column). a-b): Calibration test \mathcal{O}_{cal} for optimal δ in the original model \mathcal{O} (β implicitly equals 0); c-f) calibration of both δ (c,d) and β (e,f) in \mathcal{M}_{cal} tests with the modified model. The blue and orange arrows in panel a) show the main expected directions of the optimization problem in the calibration of δ (a-d). The orange shaded rectangle in panels a-d highlights the range of realistic values of δ , i.e. around 1. The pink shaded rectangle in panels e-f highlights the range of values reported for β in the literature, i.e. 0.2-0.6.

Table 2. Calibrated parameters δ and β and corresponding objective functions. “n.a.” stands for “not applicable”.

Test	parameter		objective function	
	name	value	name	value
\mathcal{O}_{cal}	δ	0.12	ε_{T0}	0.83 °C
	β	n.a.		
	δ	0.84	ε_T	0.49 °C
	β	n.a.		
\mathcal{M}_{cal}	δ	0.57	ε_{T0}	0.8 °C
	β	0.32		
	δ	1.00	ε_T	0.47 °C
	β	0.32		

295 4.3 Effect of β

To understand what actually changes when the parameter β is introduced in the parameterization of the heat flux, Figure 4 shows the comparison between the fully calibrated models \mathcal{O} and \mathcal{M} (Table 1). Panels a,b show the simulated temperature profiles on a sample summer day in the two optimal simulations that minimize ε_T , with and without β . The two thermal profiles appear to be very similar to each other and are both consistent with the measurements. Both simulations correctly capture the thermocline depth and the temperature of the surface well-mixed layer (about 7 m thick). However, in the model \mathcal{O} (panel a) the temperature of the surface layer (23.27 °C) is slightly colder than that of the layers below (23.35°C), while the surface in-situ temperature (24.15°C) is the warmest. In contrast, the model with calibrated β , i.e. \mathcal{M} (panel b), returns 24.50°C on the surface.

Although the difference in temperature is relatively small between the two versions of the models, the physics behind such thermal profiles is actually different. In Figure 4c-e we compare the eddy diffusivity D_z as simulated by the k - ε model in \mathcal{O} and \mathcal{M} on three selected days. In the original model version, stronger turbulent vertical diffusion is simulated in the epilimnion. The largest difference is visible during daylight hours, when the model \mathcal{O} (panel c) simulates homogeneous diffusivity of the order of $10^{-4} \text{ m}^2\text{s}^{-1}$ in the upper 2 m, while surface mixing is strongly inhibited in the model \mathcal{M} (panel d), with D_z generally lower than $10^{-6} \text{ m}^2\text{s}^{-1}$. Thus, the enhanced mixing in the epilimnion simulated by the model \mathcal{O} compensates for the unrealistic distribution of the warming rate caused by the absence of β , which would produce cooling of the surface layer (as Figure 2a shows). This effect is visible throughout the simulated period (panel e), with an overestimation of D_z of the order of $10^{-4} \text{ m}^2\text{s}^{-1}$ during daylight hours and higher differences during the stratified period.

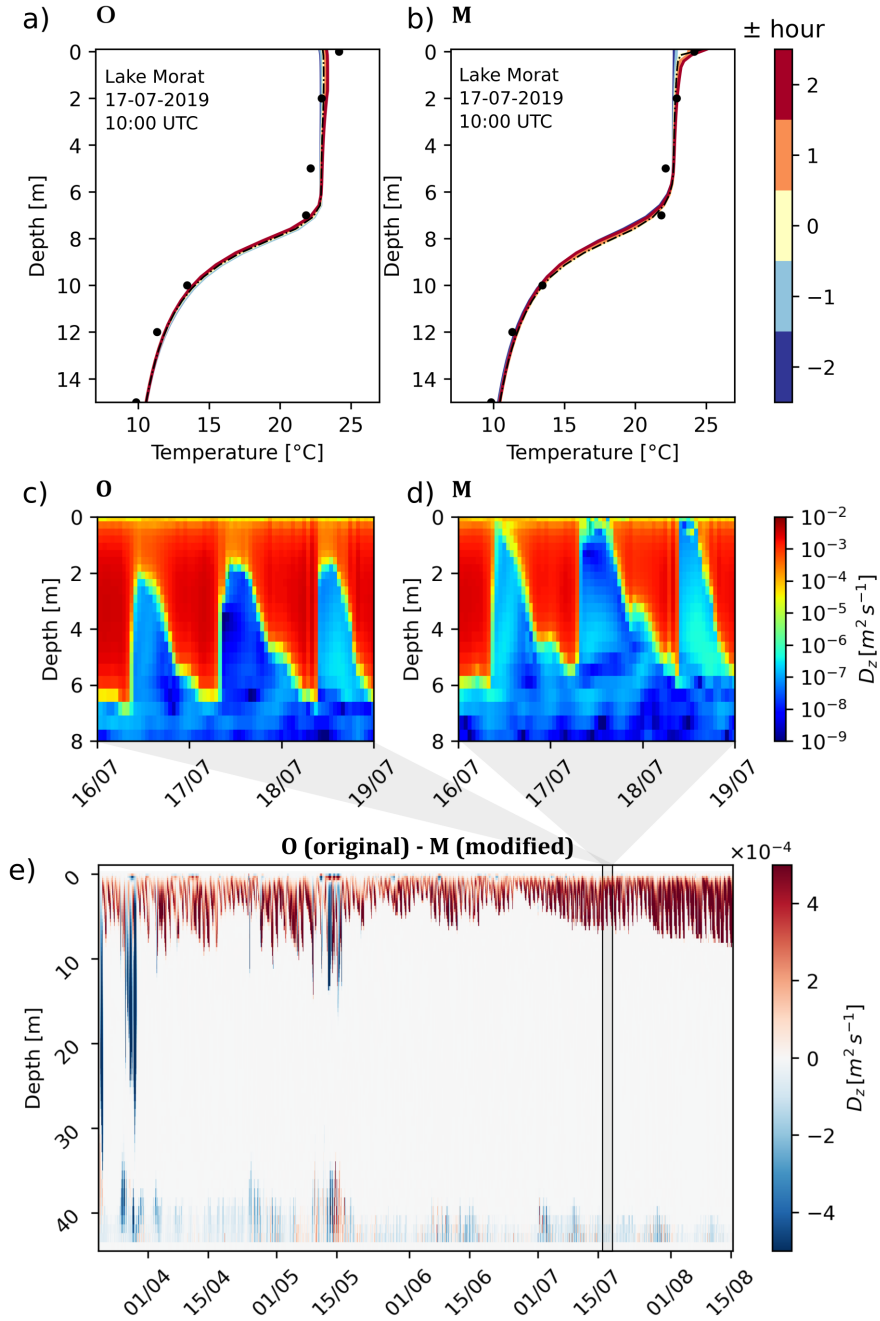

Figure 4. a-b) Temperature profiles simulated (lines) and measured (black dots) on a summer day (17 July 2019) in Lake Morat implementing the \mathcal{O} and \mathcal{M} model configurations with target ε_T . Model results are displayed at the measurement time (10:00 am, black dashed line) and in a time range of ± 2 hours around 10:00 am. c-d) Vertical eddy diffusivity simulated in the two model setups as in a-b) ± 2 days around 17 July 2019 (black straight line in panel e). d) Difference in simulated eddy diffusivity between the two models shown on an hourly basis.

5 Discussion

The comparison between the model outputs obtained with the original (\mathcal{O}) and modified (\mathcal{M}) versions of Delft3D clearly highlights that accounting for short-wave absorption in a shallow layer close to the water surface improves the performance of the model and, more importantly, provides a more realistic description of the physical processes driving surface warming in lakes. The best value of the scaling parameter δ obtained with the modified model is 1 (see Table 1), which implies that the measured value of the Secchi depth in Lake Morat is a reliable input parameter for the model and does not necessarily require calibration. The fact that the measured Secchi depth can be assumed as a physically measurable quantity is a significant advantage in the model setup compared to the common expectation of several Delft3D users that the Secchi depth must be calibrated (Wahl and Peeters, 2014; Soulignac et al., 2017; Piccioni et al., 2021; Xia et al., 2021).

Systematic calibration of model parameters, including Secchi depth, is essential not only for more accurately representing the physics of the system, but also for addressing the imperfections inherent in the model (e.g., neglected baroclinic mixing, imperfect turbulent schemes, unaccounted effects of tributary intrusions, inaccurate atmospheric forcing). Among all the calibration parameters, the Secchi depth is perhaps the most frequently monitored and is one of the easiest to measure, both in situ and through remote sensing. However, several previous modeling studies have highlighted significant deviations of this parameter in Delft3D from the measured values. Here, we demonstrate that this discrepancy is due to a misimplementation of certain physical phenomena in the Delft3D model, which is supported by the deviation of calibrated Secchi depths after correcting for it. However, there may still be a need to calibrate Secchi depth to account for potential errors in measurements or the sparse resolution of Secchi depth data in both time and space. Meanwhile, calibration of other parameters (e.g., wind drag, background eddy coefficients) will remain necessary to compensate for unresolved processes in the model. We believe that it is good modeling practice to avoid compensating for inaccuracies in one process by adjusting the parameters of others. We therefore suggest focusing on improving model deficiencies and promoting the correct use of parameters to ensure more reliable and physically sound results.

To what extent the modification of the heat fluxes scheme was necessary to improve the performance of the model can be discussed based on the objective functions reported in Tables 1 and 2. Our results indicate that the base calibration of the original model \mathcal{O} (Table 1) already gives satisfactory results, with an error $\varepsilon_T = 0.57^\circ\text{C}$ along the water column. This result is possible due to the automated calibration, which allows us to explore a wider range of parameter combinations compared to the manual procedure. The relatively low error also confirms the general reliability of the model with its original formulation, as demonstrated by the numerous successful lake applications in different lakes (e.g. Amadori et al., 2021; Baracchini et al., 2020a; Soulignac et al., 2017, 2018; Wahl and Peeters, 2014; Chanudet et al., 2012; Dissanayake et al., 2019, among many others). By rescaling D_s (i.e. by calibrating δ in the \mathcal{O}_{cal} test), the error reduced to 0.49°C . This result is in line with the observations of Amadori et al. (2020); Piccolroaz et al. (2019), who reduced the measured Secchi depth to improve the performance of the original Delft3D model in Lake Garda. An improvement of 0.08°C in the model error along the water column is considerable (14%), but it is achieved at the expense of the physical meaning of the Secchi depth information. If β is introduced and calibrated (\mathcal{M}_{cal} test), we see that the final error $\varepsilon_T = 0.47^\circ\text{C}$ is only slightly smaller than in the previous

case, but a significant gain is obtained in the physical consistency of all inputs ($\delta = 1.0$, $\beta = 0.32$). The value of β estimated by automatic calibration falls conveniently within the range $\beta \in (0.2, 0.6)$ observed in different lake environments (e.g., 0.4 in Dake and Harleman, 1969) and suggested in previous modeling applications (Thiery et al., 2014; Cole and Wells, 2015; Schmid and Köster, 2016).

The interesting element of our analysis is that the parameter calibration allows the original model to get close to reality despite the faulty parametrization of the heat absorption at the surface. However, the price of such an optimization is the alteration of other physical processes that compensate for the flaw in the model formulation. This is evident from the enhanced diffusivity at the surface in the original model formulation (Figure 4), which derived from an unrealistic instability between the upper layer and those below due to surface cooling. This overestimation of surface mixing was also observed by Biemond et al. (2021), who compared the results of the Delft3D model in Lake Garda with in situ turbulent kinetic energy dissipation profiles. In particular, such overestimation was stronger in stratified conditions and was present also when temperature profiles were appropriately simulated.

We have shown in Figure 4 that the largest difference between the two model configurations is at the surface, and in particular during daylight hours in the stratified period. In the temperature profiles shown, a strong gradient is present between the near-surface temperature (i.e. 0 m) and the layer immediately below (2 m). On other days, when the measured surface temperature is relatively well mixed with the layers below, the difference between the two model versions is not that relevant. In fact, if enough mixing is physically provided by, for example, strong wind-induced turbulence, the model does not need to generate artificial convection to compensate for the negative buoyancy at the surface caused by the incorrect parametrization.

The thickness of the model layers also plays a role in the optimal scaling of δ . When the surface water temperature is the calibration target (ε_{T_0} as an objective function), the optimal value of δ is 0.57 (Figure 3c) even if β is included in the parametrization and is calibrated. Although 0.57 is definitely more acceptable than 0.12, which was obtained in the case without β (3a), it is still significantly smaller than the desirable value, i.e. $\delta = 1$. We speculate that this behavior can be interpreted by recalling that the layer in which the β fraction is absorbed is generally considered to be ~ 60 cm thick (Henderson-Sellers, 1986). This thickness is used by several models as the reference depth where the exponential decay starts (Zaneveld and Spinrad, 1980; Piccolroaz et al., 2024). Since the thickness of the surface layer in our model is 0.26 m (Table B1), it is possible that the value of δ lower than 1 again compensates for trapping the fraction β in a layer too thin. It is therefore likely that if we used a thicker surface layer (e.g. 60 cm thick), the value of the parameter would be closer to 1.

Using automated tools to identify existing flaws could also help improve the representation of other simulated processes. For instance, the impact of density stratification on vertical turbulent fluxes is poorly represented in turbulent schemes, and internal wave breaking is accounted for in only a few lake models, for example Simstrat by Goudsmit et al. (2002). Models like $k-\varepsilon$ could benefit from supervised automated calibration of parameters that are traditionally fixed based on "standard" experiments and generally poorly understood. Similarly, refining horizontal turbulent models through tuning could provide insights into whether the adopted scheme (e.g. constant coefficients or sub-grid scaling following Smagorinsky, 1963) and grid resolution are sufficient to capture the timing and location of horizontal and vertical transport processes, such as up/downwellings and gyres.

6 Conclusions

Automatic calibration tools are powerful for optimizing parameter selection in complex models, helping modelers achieve realistic simulations of the environment studied. Here, we demonstrated that such tools can also be utilized by developers to assess whether their implementations of models align with the physics, and by users to identify potential improvements needed in the modeling framework. Unlike manual calibration, which is often user-sensitive and prone to bias, automatic calibration is objective and allows one to more effectively highlight inherent flaws in model formulations. Although lake modeling issues often arise from inadequate meteorological input, automatic calibration can help users and developers detect code-related issues, offering a more unbiased and systematic approach. We tested the response of a hydrodynamic model, Delft3D, which is widely used by the limnological community, to the task of simulating the vertical distribution of heat in lakes. The process is regulated by the well-known Beer law describing the absorption rate of short-wave radiation along the water column, but its incomplete implementation in the numerical model requires a compensation mechanism to optimally simulate surface water temperature. Such a mechanism is the nonphysical adjustment of the Secchi depth to compensate for the exclusion of the absorption of a fraction of solar short-wave radiation at the surface. By exploiting a recently developed calibration tool (DYNO-PODS), based on surrogate models, we were able to unveil such a limitation of the Delft3D parametrization that was never explicitly discussed and to fix it with a small modification of the source code.

In conclusion, we recommend caution when blindly applying automatic tools, emphasizing the importance of evaluating the physical significance of the calibration parameters obtained. This calibration approach combined with detailed analysis of optimization results should yield comparable benefits in various applications, including computationally intensive simulations.

Appendix A: Source code

We report here the parts of the Delft3D code which were modified to include the effect of β according to equation (3). Such modification is made in the subroutine `heatu.f90`.

At surface layer, the original source code lists:

```
qink = corr * qsn * (1.0_fp - exp(extinc*zdown)) / extinc
```

We modified as:

```
qink = corr * (1.0_fp-beta_sw) * qsn * (1.0_fp - exp(extinc*zdown)) / extinc  
      + qsn * beta_sw
```

At deeper layers, the original source code lists:

```
qink = corr * qsn * (exp(extinc*ztop) - exp(extinc*zdown))
```

We modified as:

```
qink = corr * (1.0_fp-beta_sw) * qsn * (exp(extinc*ztop) - exp(extinc*zdown))
```

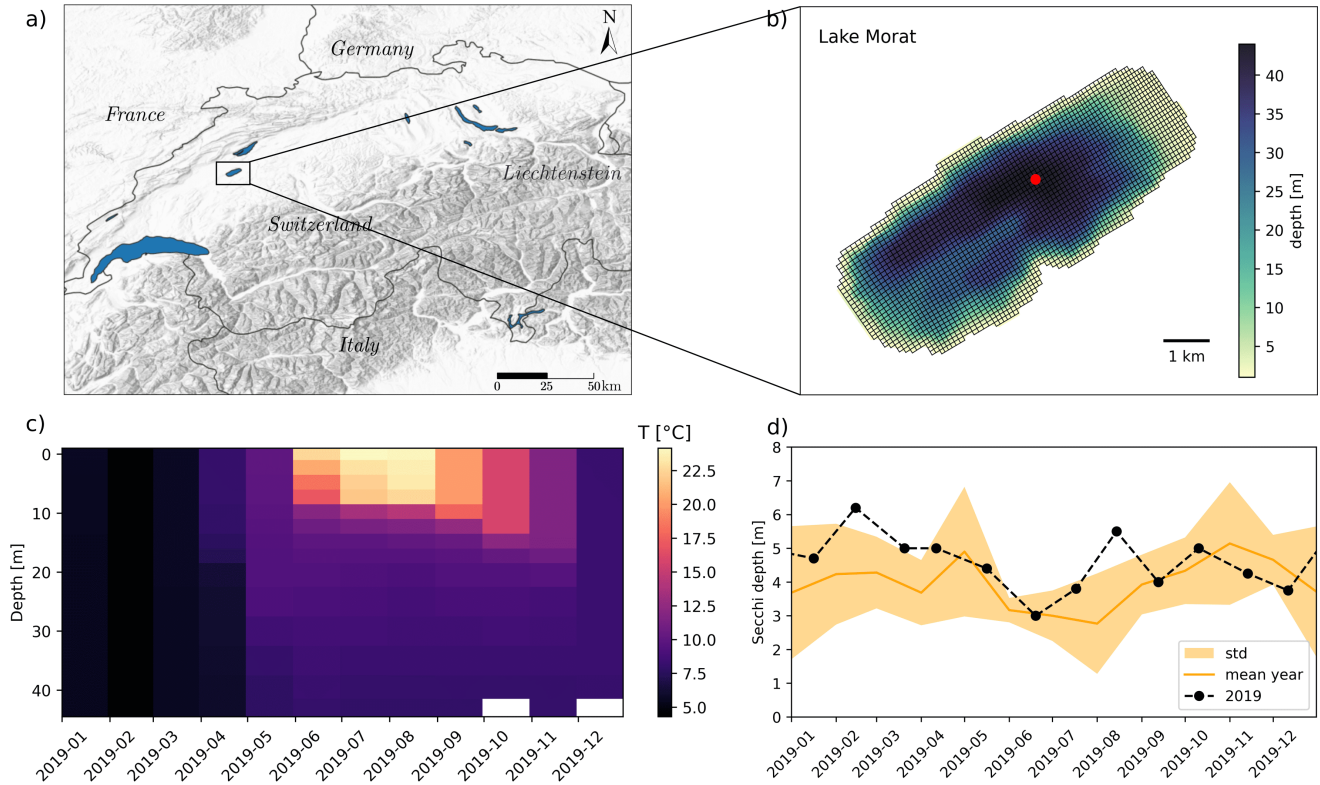

Figure B1. a) Location of Lake Morat in the alpine area; b) computational grid, bathymetry and location of in-situ monitoring station (red dot); c) heatmap of the monthly in-situ water temperature profiles for the year 2019 measured in the monitoring point; d) Time series of in-situ water transparency for 2019 (black dots) and mean year computed from the 2016-2021 time series (mean: orange thick line; standard deviation: orange shaded area).

Appendix B: Test site and base model calibration

Lake Morat (Lake Murten in German) (Fig. B1a,b) is a Swiss lake situated at 429 m above sea level with a surface area of 22.8 km², an average depth of 24 m and a maximum depth of 45 m. In-situ water temperature profiles are sampled monthly in the middle of the lake (Fig. B1 b, c) over irregular depth intervals: 0 (just below the surface), 2, 5, 7, 10, 12, 15, 17, 20, 25, 30, 35, 40 and 43. Monthly measurements of water transparency (expressed as Secchi depth, Fig. B1d) are also recorded at the same observation point.

The details on the size of the model grid and the time spacing of the Delft3D model for this lake are reported in Table B1. As atmospheric forcing at the surface boundary of the lake we used COSMO-1 space and time varying meteorological variables (air temperature, relative humidity, wind speed, cloud cover, short-wave radiation and air pressure) provided by MeteoSwiss

Table B1. Base setup for the Delft3D model of Lake Morat.

Nmax	Mmax	Kmax	$\Delta x, y$	Δz	Δt
-	-	-	m	m	s
41	88	77	73-110	0.26-1	60

at hourly time resolution and 1.1 km spatial resolution. The assimilated outputs, i.e., reanalysis data, based on observational measurements (Voudouri et al., 2017) were used for this purpose.

The base setup for this lake model was obtained from a year-long automated calibration implementing DYNO-PODS (Xia et al., 2022). The full set of parameters are reported in Table 1 in the main text and include the background horizontal viscosity and diffusivity coefficients (indicated as Vicouv, Dicouv in Delft3D, see Deltares 2023), the Ozmidov length scale (Xlo), the free convection coefficient (Cfrcon), and a corrective coefficient on wind drag coefficient α . For the wind drag coefficient, as in recent applications of the Delft3D model to peri-alpine lakes (e.g. Amadori et al., 2021), we took as a reference the parametrization proposed by Wüest and Lorke (2003) to set the coefficients of the piecewise function implemented in Delft3D: $C_{dA}^0 = 0.0044$ for wind speed lower than $U_A = 0.5 \text{ ms}^{-1}$, $C_{dC}^0 = 0.002$ for values higher than $U_C = 10 \text{ ms}^{-1}$, and linear interpolations between $C_{dB}^0 = 0.001$ and C_{dA}^0 and C_{dC}^0 , respectively for wind speed between $U_B = 4.5 \text{ ms}^{-1}$ and U_A and U_C . The wind effect is also taken into account in the parametrization of forced latent and sensitive heat fluxes. Instead of calibrating parameters like the “Stanton” and “Dalton” numbers, respectively for the sensible and latent heat fluxes (Deltares, 2023), we set the model to use C_d also in calculating these heat fluxes.

To account for the uncertainties related to the input wind speed and to calibrate the wind function for the forced heat fluxes, the drag coefficient was adjusted by introducing the corrective parameter α as follows:

$$C_{di} = \alpha C_{di}^0. \quad (\text{B1})$$

Background values of the vertical eddy viscosity and diffusivity (Vicoww, Dicoww) were set as equal to molecular values (i.e. 10^{-6} and $10^{-9} \text{ m}^2\text{s}^{-1}$, respectively), while all the other calibration parameters (e.g. bottom roughness) were set as default values.

The Secchi depth D_s was provided as time series with approximately monthly frequency, as obtained from in-situ measurements. These values were not modified. As objective function for this base calibration, we used the error along the entire water column ε_T .

Code availability. The current version of the model is available at https://github.com/eawag-surface-waters-research/Delft3D/tree/d3d4/research/surface_heat_transfer under the GPLv3 licence. The exact version of the model used to produce the results used in this paper is archived on Zenodo (Amadori et al., 2024) as are input data and scripts to run the model and produce the plots for all the simulations presented in this paper.
