## Abstract

Safe and secure carbon dioxide (CO<sub>2</sub>) storage is likely to be critical for mitigating some of the most dangerous effects of climate change. In the last decade, there has been a significant increase in activity associated with reservoir characterization and site selection for large-scale CO<sub>2</sub> storage projects across the globe. These prospective storage sites tend to be ~~terrestrial sites~~ selected for their optimal structural, petrophysical, and geochemical trapping potential. However, it has also been suggested that storing CO<sub>2</sub> in reservoirs within the ~~gas-CO<sub>2</sub>~~ hydrate stability zone (GHSZ), characterized by high pressures and low temperatures (e.g., Arctic or marine environments), could provide natural thermodynamic and solubility barriers to gas leakage. Evaluating the prospect of commercial-scale, long-term storage of CO<sub>2</sub> in the GHSZ requires reservoir-scale modelling capabilities designed to account for the unique physics and thermodynamics associated with these systems. We have developed the HYDRATE flow mode and accompanying fully implicit parallel well model in the massively parallel subsurface flow and reactive transport simulator PFLOTRAN to model CO<sub>2</sub> injection into the marine GHSZ. We have applied these capabilities to a set of CO<sub>2</sub> injection scenarios designed to reveal the challenges and opportunities for commercial-scale CO<sub>2</sub> storage in the GHSZ.

## 20 1 Introduction

Large-scale deployment of carbon capture and storage (CCS) projects is likely to be critical for constraining future global temperature increase due to climate change, yet major uncertainties exist regarding potential injectivity of CO<sub>2</sub> in subsurface reservoirs (Lane et al., 2021). Evaluating ~~terrestrial~~-CO<sub>2</sub> storage sites for long-term sequestration requires synthesizing sophisticated laboratory, field, and modelling tools to assess the CO<sub>2</sub> trapping potential of a prospective subsurface reservoir during a large-scale injection over a significant post-injection performance period. CO<sub>2</sub> trapping in ~~terrestrial~~-sequestration applications involves potentially both physical and chemical trapping mechanisms which include structural, solubility, capillary, and mineralization trapping (Al Hameli et al., 2022). Currently, large-scale carbon capture and storage (CCS) projects around the globe are each storing over 400,000 metric tons (Mt) of CO<sub>2</sub> annually (Snæbjörnsdóttir et al., 2020); the U.S. Department of Energy's CarbonSAFE initiative aims to develop CO<sub>2</sub> storage complexes across the U.S. that would be

30 capable of storing total volumes exceeding 50 million metric tons (MMt) of CO<sub>2</sub> each (Sullivan et al., 2020). To achieve this vision, a diverse set of potential reservoir host rocks and environments is being considered. This includes speculation about the feasibility of offshore CO<sub>2</sub> sequestration and mineralization, such as in Cascadia Basin basalts offshore the U.S. Pacific Northwest (Goldberg et al., 2018). Shallow sub-sea environments are not only isolated from the atmosphere by a large water body, but they can also exist in a unique pressure and temperature regime conducive for forming gas hydrate.

35

Gas hydrate is a solid-phase, non-stoichiometric mixture of low molecular weight gas molecules occupying free spaces in a solid water lattice. Hydrates of several different gases occur abundantly in nature, but since the hydrate phase is only stable at high pressures and low temperatures it is only found naturally on Earth in the pore space of soils in either permafrost or sub-sea environments. ~~Methane-CH<sub>4</sub>~~ hydrate is of interest for its potential as a natural gas energy resource (Collett, 2000; Oyama et al., 2017; Singh et al., 2022), for its potential role in global carbon cycling as the climate changes (Ruppel and Kessler, 2017), and for its role as a geohazard (Zander et al., 2018; Kaminski et al., 2020). On the other hand, ~~carbon dioxide (CO<sub>2</sub>)~~ hydrate, which ~~forms can form~~ at similar pressures and temperatures as ~~CH<sub>4</sub>methane~~ hydrate, is increasingly being explored as a potential means to permanently sequester CO<sub>2</sub> as a climate change mitigation solution that comes with additional safety factors beyond those typically encountered in ~~terrestrial more conventional~~ CO<sub>2</sub> sequestration scenarios. These include the fact 40 that ~~CO<sub>2</sub> hydrate~~ is immobile in sediment pore space, which adds a thermodynamic barrier to gas escape, and the ~~ability of the ocean to dissolve leaked CO<sub>2</sub>~~ ~~presence of a significant ocean sink~~ in marine environments which isolates CO<sub>2</sub> from release into the atmosphere (Tohidi et al., 2010). An added benefit of CO<sub>2</sub> injection into the ~~CH<sub>4</sub>methane~~ hydrate stability zone is that CO<sub>2</sub> hydrate ~~is typically can be~~ more thermodynamically favourable than ~~CH<sub>4</sub>methane~~ hydrate, meaning it could theoretically be possible to use CO<sub>2</sub> to ~~kick out replace CH<sub>4</sub>methane from in~~ the hydrate phase, thus sequestering CO<sub>2</sub> while producing 45 natural gas from a ~~CH<sub>4</sub>methane~~ hydrate deposit (Koh et al., 2016).

50

CO<sub>2</sub> sequestration in gas hydrate form can only occur in a finite bounded temperature and pressure range. In terms of a soil column, there exists a depth-bounded gas hydrate stability zone (GHSZ) in the subsurface in which ~~CO<sub>2</sub>~~ hydrate can form. In a marine environment, the ~~CO<sub>2</sub>~~ GHSZ typically begins several meters above the seafloor, but hydrate does not form freely in 55 the water column (except for, e.g., as a gas bubble crust [Fu et al., 2021]) because the guest molecule gas (e.g., CO<sub>2</sub>) typically cannot become concentrated enough in the water to do so. Therefore, the seafloor is typically the shallowest extent of hydrate formation in marine systems. ~~Relative to deeper sediments, this point usually represents a minimum temperature and pressure.~~ Working downward through the GHSZ, pressure increases roughly hydrostatically and temperature increases along a geothermal gradient. Increases in pressure stabilize hydrate, while increases in temperature destabilize hydrate. The geothermal 60 temperature change effect on hydrate stability outweighs the hydrostatic pressure change effect, so there exists a depth below the seafloor where the temperature is too high to form hydrate, known as the base of the gas hydrate stability zone (BHSZ). Overall, the specific thickness of the bulk GHSZ is dependent on pressure, temperature, porewater salinity and gas composition (Sloan and Koh, 2007).

65 For a potential host reservoir within the CO<sub>2</sub> GHSZ, the long-term CO<sub>2</sub> storage potential of the reservoir would consider the thermodynamic trapping mechanism of solid gas hydrate formation in addition to traditional trapping mechanisms. Several experimental studies have demonstrated the process of CO<sub>2</sub> trapping and hydrate conversion in the CO<sub>2</sub> GHSZ at the lab-scale, ~~demonstrating~~ showing how conversion of CO<sub>2</sub> into a solid phase adds an additional safety factor (Gauteplass et al., 2020; Rehman et al., 2021). An experimental study of layered sediments using different injection strategies demonstrated the need  
70 to consider thermal management when designing a CO<sub>2</sub> injection in the GHSZ and suggested multilateral perforated horizontal wells may achieve the most optimal CO<sub>2</sub> conversion efficiency (Pang et al., 2024). However, reservoir-scale modelling studies of the transport and thermodynamic phenomena associated with injection of CO<sub>2</sub> in commercial volumes into the GHSZ are lacking.

75 We present several new capabilities developed in the open source, massively parallel multiphase flow and reactive transport simulator PFLOTRAN (Hammond et al., 2014) to model reservoir-scale injection of CO<sub>2</sub> in the CO<sub>2</sub> GHSZ. We have extended PFLOTRAN's HYDRATE mode capabilities to model free-phase CO<sub>2</sub> flow properties and CO<sub>2</sub> hydrate phase behaviour. Additionally, we introduce a fully coupled parallel well model that can be used to model CO<sub>2</sub> injection into heterogeneous media and can adapt to changes in flow properties associated with hydrate formation in the vicinity of the wellbore. Finally,  
80 we add a new fully coupled salt mass balance to consider salinity and salt precipitation effects in the GHSZ. We demonstrate these capabilities on a series of test problems designed to elucidate the challenges and opportunities associated with commercial-scale injection of CO<sub>2</sub> into the GHSZ.

## 2 Methods

PFLOTRAN's HYDRATE mode was originally developed to model methaneCH<sub>4</sub> generation, transport, and structure 1 (SI)  
85 gas hydrate formation in deep marine and Arctic terrestrial reservoirs. PFLOTRAN's HYDRATE mode has been benchmarked against other reservoir simulators for modelling methaneCH<sub>4</sub> gas production from hydrate reservoirs (White et al., 2020). It has been used to predict shallow gas generation and gas hydrate formation offshore the eastern U.S. (Eymold et al., 2021), to study relationships between gas generation and slope stability along the U.S. Atlantic margin (Carty and Daigle, 2022), and to model gas hydrate accumulation offshore Norway (Frederick et al., 2021). An extension of HYDRATE mode to include  
90 salinity coupling was developed to investigate viscous fingering and convective mixing in layered marine sediments during methaneCH<sub>4</sub> hydrate formation over geologic time (Fukuyama et al., 2023). Here, we have redeveloped PFLOTRAN's HYDRATE mode to optionally consider CO<sub>2</sub> as the working gas; to couple fully implicitly with a new parallel well model; to include a new fully coupled salt mass balance; and to consider variable salinity effects on H<sub>2</sub>O-CO<sub>2</sub>-NaCl mixtures and the CO<sub>2</sub> hydrate phase boundary.

## 95 2.1 Governing Equations

A system of three mass balance equations, one energy balance, and one well equation is now solved fully implicitly in PFLOTRAN's HYDRATE mode. The mass conservation equations take the following form:

$$\frac{\partial}{\partial t} \phi \sum_{\alpha=l,g,h,i,s} (s_{\alpha} \rho_{\alpha} x_j^{\alpha}) + \nabla \cdot (\mathbf{q}_l \rho_l x_j^l + \mathbf{q}_g \rho_g x_j^g - \phi s_l D_l \rho_l \nabla x_j^l - \phi s_g D_g \rho_g \nabla x_j^g) = Q_j + Q_{w,j}, \quad (1)$$

100

where phase  $\alpha$  can be liquid (l), gas (g), hydrate (h), ice (i), or salt precipitate (s); component  $j$  includes water, gas (CO<sub>2</sub>, CH<sub>4</sub>, or air), and salt (NaCl);  $s_{\alpha}$  is the saturation of phase  $\alpha$ ;  $\rho_{\alpha}$  is the density of phase  $\alpha$ ;  $x_j^{\alpha}$  is the mole fraction of component  $j$  in phase  $\alpha$ ;  $q_l$  is the liquid Darcy flux vector;  $q_g$  is the gas Darcy flux vector;  $D_l$  is the liquid phase diffusivity;  $D_g$  is the gas phase diffusivity;  $\phi$  is the porosity; and  $Q_j$  includes any non-well sources/sinks of component  $j$ ; and  $Q_{w,j}$  is a source/sink of component  $j$  from a well. Solid phases are considered immobile and include the hydrate, ice, and salt precipitate phases. Mole fractions of components in the solid phases are fixed: by the hydration number in the hydrate phase, as pure water in the ice phase, and as pure salt in the salt precipitate phase. Formation of gas hydrate and ice therefore results in salt exclusion and aqueous dissolved salinity enhancement, which affects the hydrate phase boundary and gas solubility in the brine.

105

110 The energy conservation equation takes the form:

$$\sum_{\alpha=l,g,h,i,s} \left( \frac{\partial}{\partial t} (\phi s_{\alpha} \rho_{\alpha} U_{\alpha}) + \nabla \cdot (\mathbf{q}_{\alpha} \rho_{\alpha} H_{\alpha}) \right) + \frac{\partial}{\partial t} \left( (1 - \phi) \rho_r C_p T \right) - \nabla \cdot (\kappa \nabla T) = Q_e + Q_{w,e}, \quad (2)$$

115

where  $U_{\alpha}$  is the internal energy of phase  $\alpha$ ,  $H_{\alpha}$  is the enthalpy of phase  $\alpha$ ,  $\rho_r$  is the rock density,  $C_p$  is the heat capacity of the rock,  $\kappa$  is the composite thermal conductivity of the medium,  $T$  is the temperature,  $Q_e$  includes any non-well heat sources/sinks, and  $Q_{w,e}$  is a heat source/sink imposed by the well (e.g., a heater in addition to a fluid injection). Exothermic hydrate formation (and vice versa, i.e., endothermic hydrate dissociation) is captured here by a decrease in internal energy of the hydrate phase during formation; this typically results in either an increase in system temperature or a change in phase saturations in three-phase systems. As we will show later, this phenomenon is important during CO<sub>2</sub> injection in the short term and it can continue to buffer conversion between phases for hundreds of years; similar effects have been shown for natural CH<sub>4</sub> hydrate systems where the base of the gas hydrate stability zone is shifted due to climactic changes (Owulunmi et al., 2022).

120

## 2.2 Well Model

125 A fully implicit, parallel well model has also been incorporated into HYDRATE mode. A well model can more accurately  
represent the insertion of a (comparably) small cylindrical wellbore into a reservoir grid cell than a standard source/sink term.  
Given a prescribed surface injection rate of CO<sub>2</sub> into the well, the well model solves for pressure variation along a wellbore  
and dynamically adjusts flow rates into the reservoir in response to changes in reservoir physical properties like permeability.  
This phenomenon can be critical to capture in a horizontal well or injection into a heterogeneous reservoir in the gas hydrate  
130 stability zone, where near-wellbore formation (or dissociation) of gas hydrate can significantly alter reservoir permeability and  
thus injection behaviour. The well model developed for HYDRATE mode is a hydrostatic well model based off the design of  
White et al. (2013) but with key modifications including full parallelization to run flexibly on very large, unstructured grids  
and the addition of a thermal component; as we show here, injection temperature could be one of the most important design  
considerations for CO<sub>2</sub> storage in the gas hydrate stability zone. The well model developed here accounts for the enthalpy of  
135 the injected CO<sub>2</sub> at the prescribed temperature and wellbore pressure using the same equation of state (EOS) as the reservoir.

Solving a hydrostatic well model involves solving one extra conservation equation per well in addition to the reservoir mass  
and energy conservation equations. PFLOTTRAN uses a fully implicit Newton-Raphson nonlinear solution search method; for  
each distinct well. This means that for one well, only one extra row and one extra column are used in the fully implicit  
140 floware added to the Jacobian, ~~not an extra row and extra column for each reservoir cell associated with a well.~~ For each  
reservoir cell intersected by a well, well pressure is computed at the centroid of the well section crossing through the reservoir.  
All well pressures are determined from the bottom-hole pressure, a primary variable (see Section 2.34). The well model  
conservation equation is compact and reads as follows:

$$145 \quad \sum_i Q_{w,j}^i = q_{w,j} , \quad (3)$$

where  $i$  is the discrete reservoir cell index through which the wellbore passes,  $Q_{w,j}^i$  are the reservoir source/sink terms of phase  
 $j$  associated with a well in reservoir grid cell  $i$ , and  $q_{w,j}$  is the prescribed surface injection rate of phase  $j$ .

150 Well flux at each reservoir grid cell is computed as a function of the pressure difference between the well and the reservoir  
cell (free phase CO<sub>2</sub> pressure for gas injection) scaled by the well index as follows:

$$\underline{Q_{w,j} = -\frac{wI\rho_j}{\mu_j} (P_w - (P_r + \rho_j g \Delta z_{w-r}))} \quad (4)$$

155 where  $P_w$  is the well node pressure,  $P_r$  is the reservoir pressure of phase  $j$  in the grid cell associated with a given well node, and  $\Delta z_{w-r}$  is the vertical distance between well node centre and reservoir cell centre. The well can be oriented in any direction in 3D. To account for permeability anisotropy and arbitrary well orientations, the well index,  $WI$ , is calculated using a 3D extension of the Peaceman equation (White et al., 2013):

$$160 \quad WI = \sqrt{WI_x^2 + WI_y^2 + WI_z^2} \quad (5)$$

$$WI_x = \frac{2\pi\sqrt{k_y k_z L_x}}{\ln\left(\frac{r_{0,x}}{r_w}\right)+s}; \quad WI_y = \frac{2\pi\sqrt{k_x k_z L_y}}{\ln\left(\frac{r_{0,y}}{r_w}\right)+s}; \quad WI_z = \frac{2\pi\sqrt{k_x k_y L_z}}{\ln\left(\frac{r_{0,z}}{r_w}\right)+s} \quad (6)$$

$$r_{0,x} = 0.28 \frac{\left(\left(\frac{k_y}{k_z}\right)^{0.5} \Delta z^2 + \left(\frac{k_z}{k_y}\right)^{0.5} \Delta y^2\right)^{0.5}}{\left(\frac{k_y}{k_z}\right)^{0.25} + \left(\frac{k_z}{k_y}\right)^{0.25}}; \quad r_{0,y} = 0.28 \frac{\left(\left(\frac{k_x}{k_z}\right)^{0.5} \Delta z^2 + \left(\frac{k_z}{k_x}\right)^{0.5} \Delta x^2\right)^{0.5}}{\left(\frac{k_x}{k_z}\right)^{0.25} + \left(\frac{k_z}{k_x}\right)^{0.25}}; \quad r_{0,z} = 0.28 \frac{\left(\left(\frac{k_x}{k_y}\right)^{0.5} \Delta y^2 + \left(\frac{k_y}{k_x}\right)^{0.5} \Delta x^2\right)^{0.5}}{\left(\frac{k_x}{k_y}\right)^{0.25} + \left(\frac{k_y}{k_x}\right)^{0.25}} \quad (7)$$

165 where  $s$  is the well skin,  $r_w$  is the wellbore radius,  $WI_\alpha$  are well indices,  $k_\alpha$  are the absolute permeabilities of the medium,  $L_\alpha$  are the projections of each well leg, and  $r_{0,\alpha}$  are the Peaceman radii in each principal direction  $\alpha \in \{x, y, z\}$ .

170 The bottomhole pressure of the well is solved as a primary variable as part of a fully coupled system of equations (Section 2.4). Pressures of each well segment are then directly calculated as functions of the bottomhole pressure by a hydrostatic adjustment to the depth of each well segment centre, where the density of the gas phase is updated as a function of pressure and injection temperature.

### 2.32 Constitutive Relationships

175 Diffusive flux is modelled using Fick's Law with diffusivities computed as functions of temperature and salinity for CO<sub>2</sub> (Cadogan et al., 2014) and NaCl (Reid et al., 1987). Advective fluxes of mobile phases are computed by employing a two-phase Darcy's Equation:

$$q_\alpha = -\frac{k k_\alpha^r}{\mu_\alpha} \nabla(P_\alpha - \rho_\alpha \mathbf{g} z) \quad (48)$$

180 where  $k$  is the intrinsic medium permeability of the medium,  $k_\alpha^r$  is the relative permeability of phase  $\alpha$ ,  $\mu_\alpha$  is the viscosity of phase  $\alpha$ ,  $P_\alpha$  is the pressure of phase  $\alpha$ ,  $\mathbf{g}$  is the gravity vector, and  $z$  is depth. Relative permeability is computed as a function of phase saturations according to one of a suite of standard relative permeability relationships available in PFLOTTRAN. Phase densities and viscosities are computed as functions of temperature, pressure, and salinity according to several options in PFLOTTRAN; for CO<sub>2</sub>, (e.g., the Span-Wagner equation of state is recommended for CO<sub>2</sub>, and for pure water the IAP97 equation

of state ~~is typically used for water~~). Salt (~~NaCl~~) ~~is tracked only in the aqueous phase~~ mass can be distributed in either the aqueous  
 185 or solid salt precipitate phases, and aqueous dissolved salt mass affects brine flow properties like density (Haas, 1976),  
 viscosity (Phillips et al., 1981), enthalpy, and diffusivity (Cadogan et al., 2014; Belgodere et al., 2015).

Gas phase pressure and liquid phase pressure are related as a function of gas phase saturation through a choice of capillary  
 pressure functions available in PFLOTRAN. When the gas hydrate phase is present, a capillary pressure associated with the  
 190 hydrate phase is computed using the same capillary pressure function as the gas phase, scaled by the ratio of interfacial tension  
 vis-à-vis Leverett scaling (Leverett, 1941). This capillary pressure is used in the Gibbs-Thomson equation vis-à-vis the Young-  
 Laplace equation to determine the hydrate 3-phase equilibrium temperature depression required to precipitate hydrate in pores  
 as follows:

$$195 \quad \Delta T_m = -\frac{T_{mb}P_c}{\Delta H_m \rho_h} \quad (59)$$

where  $\Delta T_m$  is the change in the hydrate melting temperature,  $P_c$  is the hydrate phase capillary pressure,  $T_{mb}$  is the bulk melting  
 temperature,  $\Delta H_m$  is the specific enthalpy of the phase transition, and  $\rho_h$  is the density of solid hydrate. A similar method is  
 often used to compute ice freezing temperature depression vis-à-vis the Clausius-Clapeyron equation. This effect is typically  
 200 only significant in fine-grained sediments and/or at very high effective hydrate phase saturations (Anderson et al., 2003).

When both gas hydrate and free gas occupy significant fractions of the pore space, as would be common during CO<sub>2</sub> injection,  
 their combined presence in the pore system should be accounted for through an effective saturation that is passed to the  
 capillary pressure function. At three-phase (aqueous, free gas/CO<sub>2</sub> phase, gas hydrate) equilibrium, the chemical potential of  
 205 CO<sub>2</sub> in the gas hydrate phase at a given hydrate capillary pressure must equal that of CO<sub>2</sub> in the free gas phase at a different  
 free gas capillary pressure and dissolved CO<sub>2</sub>. At bulk thermodynamic equilibrium, free gas and gas hydrate are stable together  
 at a single pressure and temperature. In porous media, capillary effects on both the hydrate phase and gas phase lead to a  
 window of possible pressures and temperatures over which three-phase equilibrium can be maintained (Clennell et al., 1999).  
 To incorporate this effect and maintain thermodynamic reversibility, we adopt the approach of Liu and Flemings (2011) and  
 210 require free gas and gas hydrate to partition the large pore space equally when both are present (Nole et al., 2018). This  
 partitioning scheme results in the following effective saturations of free gas and gas hydrate:

$$s_{\alpha, \text{eff}} = \begin{cases} 2s_{\alpha}, & s_{\alpha} < s_{\beta} \\ s_{\alpha} + s_{\beta}, & \text{otherwise} \end{cases} \quad (610)$$

215 where  $s_{\alpha, \text{eff}}$  is the effective saturation of nonwetting phase  $\alpha$  and  $\beta$  is the other nonwetting phase in a 3-phase system where  
 liquid water is the wetting phase.

Well flux at each reservoir grid cell is computed as a function of the pressure difference between the well and the reservoir cell (free gas [CO<sub>2</sub>] phase pressure for gas injection) scaled by the well index as follows:

220

$$Q_{w,j} = \frac{WI\rho_j}{\mu_j} (P_w - (P_r + \rho_j g \Delta z_{w-r})) \quad (7)$$

225

where  $P_w$  is the well node pressure,  $P_r$  is the reservoir pressure of phase  $j$  in the grid cell associated with a given well node, and  $\Delta z_{w-r}$  is the vertical distance between well node centre and reservoir cell centre. The well index,  $WI$ , is calculated using a 3D extension of the Peaceman equation incorporating wellbore radius, well skin factor, reservoir directional permeability, and reservoir grid discretization (White et al., 2013).

230

The presence of gas hydrate in the pore space of a reservoir decreases the reservoir's permeability below its intrinsic (water-saturated) permeability. We model permeability reduction as a function of hydrate saturation as follows (Dai and Seol, 2014):

$$k_{\text{eff}} = \frac{(1-s_h)^3}{(1+2s_h)^2} \quad (811)$$

235

where  $k_{\text{eff}}$  is the effective permeability coefficient and is multiplied by intrinsic permeability to compute the effective absolute permeability.

240

Heat transfer occurs through mobile fluid phase flow, phase transitions, thermal conduction, and injection/production. Fluid phase enthalpies are computed using corresponding equations of state. For the CO<sub>2</sub> phase, the Span-Wagner equation of state is recommended (Span and Wagner, 1996), and for water the IF97 equation of state with salinity extensions are available in PFLOTRAN. Enthalpies of the solid gas hydrate (Handa, 1998) and salt (Lide and Kehiaian, 2020) phases are computed as functions of temperature. Several options for composite thermal conductivity can be used; the default thermal conductivity function is a linear scaling function of phase saturations:

$$\kappa = \kappa_{\text{dry}} + \phi \sum_{\alpha=l,g,h,i,s} S_{\alpha} \kappa_{\alpha} \quad (912)$$

245

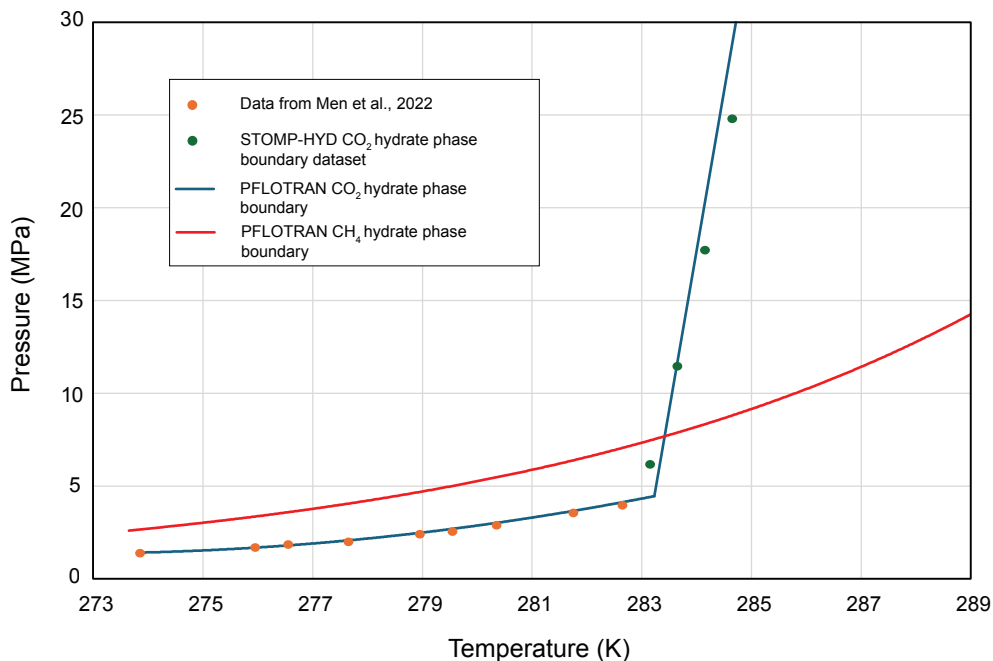

where  $\kappa_{\text{dry}}$  is the dry rock thermal conductivity and  $\kappa_{\alpha}$  is the thermal conductivity of phase  $\alpha$ .

The presence of salt has several impacts on system behaviour. If present, solid salt precipitation can occur due to near-wellbore dry-out (water evaporating into the free CO<sub>2</sub> phase) during the injection period or due to rapid hydrate formation.

250 whereby water and CO<sub>2</sub> forming a hydrate excludes salt and thus increases dissolved salt concentrations. Salt precipitation  
reduces permeability, which affects CO<sub>2</sub> injectivity, gas flow, and liquid imbibition ~~during injection and very far into the~~  
future. This occurs either at the injection site if enough CO<sub>2</sub> is injected to dry out the water or far into the future when free  
phase CO<sub>2</sub> has undergone conversion to very high hydrate saturations (though at this point, permeability reduction due to salt  
precipitation is dwarfed by the presence of solid hydrate at high saturations). Aqueous dissolved salt concentration affects the  
density of the aqueous phase; the presence of gradients in salt concentration drives convective mixing. Salt exclusion during  
255 hydrate formation locally increases salt concentrations, which can produce this phenomenon (Fukuyama et al., 2023).  
Dissolved salt also affects gas solubility and shifts the three-phase equilibrium pressure of gas hydrate.

Carbon dioxideCO<sub>2</sub> equilibrium phase partitioning is computed using the method of Spycher and Pruess (2010); the CO<sub>2</sub>  
hydrate – free phase CO<sub>2</sub> – water three-phase equilibrium curve is determined from a polynomial fit of data from Men et al.  
260 (2022) up to the upper quadruple point (283.2K), beyond which point a steep line was used to preserve differentiability of the  
phase boundary and then a linear function at higher temperatures (Figure 1). This 3-phase equilibrium boundary is consistent  
with the CO<sub>2</sub> hydrate phase boundary used in STOMP-HYD up to 100 MPa (McGrail et al., 2007) and is similar to the phase  
boundary proposed by Garapati et al. (2011) with the exception that here the phase boundary is monotonically increasing.

265 Figure 1: CO<sub>2</sub> hydrate phase boundary implemented in PFLOTRAN. At temperatures below 283.2 K, a curve fit of experimental data is  
used. Above 283.2 K, a line is used that is consistent with STOMP-HYD. The CH<sub>4</sub> hydrate phase boundary is plotted for reference (Moridis,  
2003)

### 2.4.3 Phase States and Primary Variables

PFLOTTRAN's HYDRATE mode solves mass conservation, energy conservation, and well flux conservation equations for a set of three components ( $\text{CH}_4/\text{CO}_2/\text{air}$ ,  $\text{H}_2\text{O}$ ,  $\text{NaCl}$ ) over five phases (aqueous, gas component-rich/gas, gas hydrate, ice, salt precipitate). This results in solving a set of four partial differential equations for all cells in the domain plus one coupled well equation per cell containing the bottom segment of a well. Therefore, PFLOTTRAN's fully implicit solution solves for four primary variables everywhere plus one extra primary variable per well in the domain.

The reservoir (non-well) equations use primary variable switching depending on the thermodynamic state of a grid cell. HYDRATE mode contains 13 phase states with four primary variables per phase state (Table 1). For example, cells in the fully liquid (aqueous) saturated state solve for liquid pressure, dissolved gas mass fraction, temperature, and total salt mass per unit liquid mass as primary variables. Secondary variables like phase densities, viscosities, and enthalpies are computed at equilibrium from the primary variables through use of various equations of state. Precipitated salt saturation is computed by determining whether bulk salt concentration (total salt mass per mass of liquid phase) exceeds dissolved salt solubility and converting the excess salt mass into a solid phase (permeability updates according to Verma & Pruess, [1988]). If dissolved gas mass fraction exceeds solubility and aqueous pressure, temperature, and dissolved salt mass fraction lie within the GHSZ (i.e., at pressures and temperatures above the 3-phase equilibrium boundary), the cell will transition into the hydrate-aqueous state and primary variables will update accordingly. Upon entering the hydrate-aqueous state, PFLOTTRAN then switches primary variables and solves for gas pressure, hydrate saturation, temperature, and salt concentration.

**Table 1: Phase states and primary variable combinations in PFLOTTRAN's HYDRATE mode**

Phase State	Primary Variables	Phase State	Primary Variables
L (aqueous)	$P_l, x_l^g, T, m_l^s$	AI (aqueous-ice)	$P_l, x_l^g, S_l, m_l^s$
G (gas component-rich)	$P_g, P_a, T, m_b^s$	HGA (hydrate-gas-aqueous)	$S_l, S_h, T, m_l^s$
GA (two-phase gas-aqueous)	$P_g, S_g, T, m_l^s$	HAI (hydrate-aqueous-ice)	$P_g, S_l, S_i, m_l^s$
HG (hydrate-gas)	$P_g, P_a, T, m_b^s$	HGI (hydrate-gas-ice)	$S_l, S_h, T, m_b^s$

300 For the well equation, the bottom-hole pressure (~~BHP~~) of the well is solved as a primary variable. Given a user-defined well  
flow rate, each well's bottomhole pressureBHP is solved fully implicitly as part of the full reservoir flow solution. At a given  
bottomhole pressureBHP, the well model solves for all other pressures in the well by working upward and iteratively solving  
hydrostatic pressure of the injection fluid where variable fluid density in the well is updated as a function of pressure and  
temperature. Once the hydrostatic pressures are determined, mass and energy fluxes between well and reservoir at the well  
segment centroids are computed by adding a hydrostatic adjustment to reservoir pressures to align reservoir pressures with  
305 well segment centroids and then employing Equation 74. Fluxes between coupled wells and reservoir cells are therefore  
functions of the well primary variable (bottomhole pressureBHP) and reservoir cell primary variables (e.g., gas/liquid  
pressure).

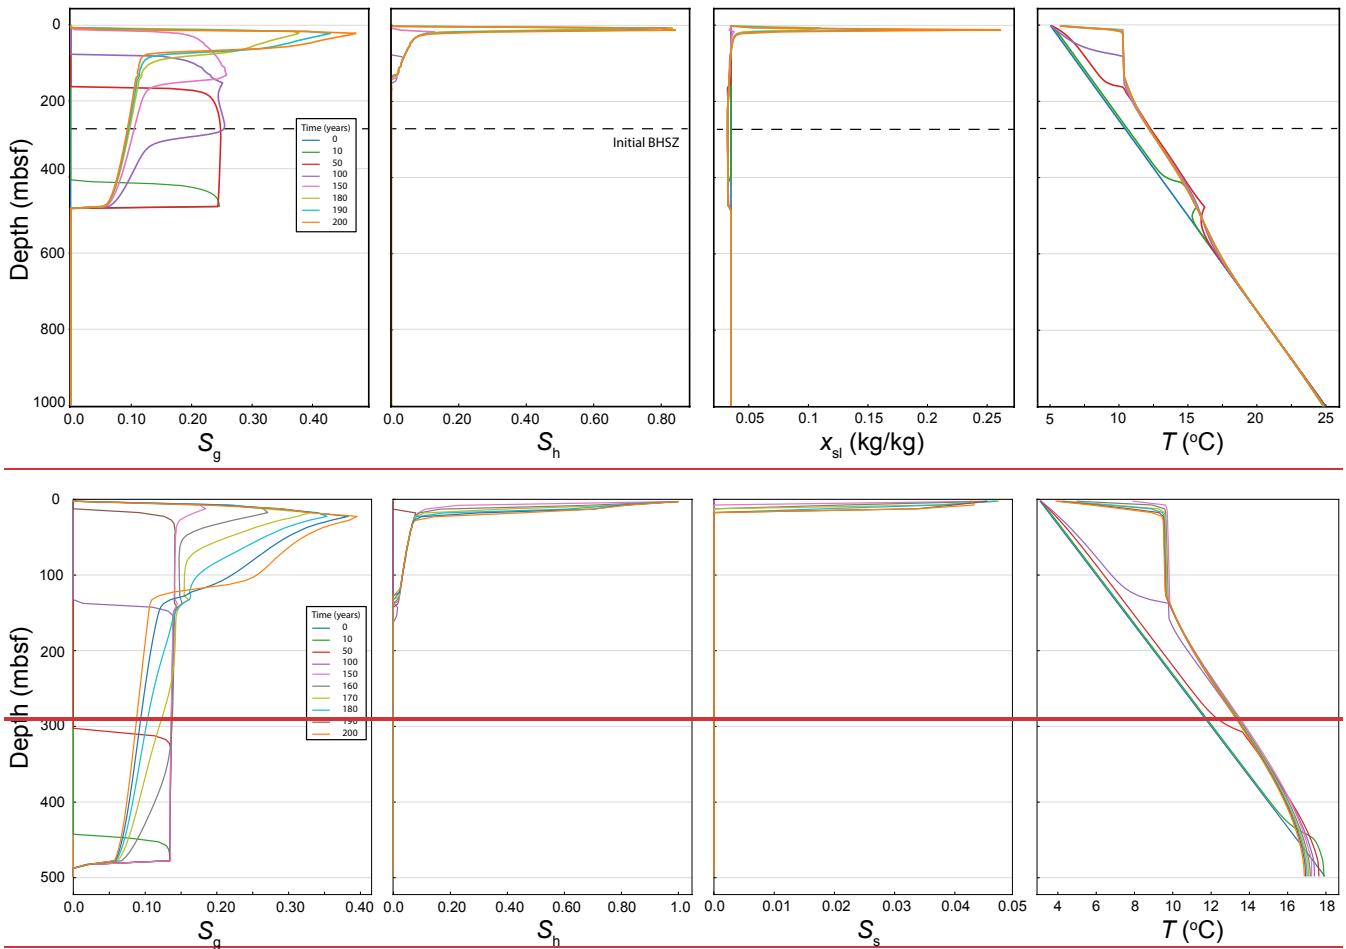

Using fully implicit coupling and a Newton-Raphson solution search method, insertion of a coupled well into the domain  
~~therefore~~ adds additional fill to the Jacobian matrix used to compute solution updates. Critically, the well model adds extra  
310 connectivity beyond the typical stencil for two-point flux calculations. Thus, the structure of the Jacobian matrix is altered by  
introducing wells. This alteration is typically minimal, but it would likely become more severe-computationally demanding as  
the number of wells in the domain is increased or as the number of ~~unceased (i.e., screened)~~ segments per well is increased. The  
number of wells, the extent to which each well increases the fill of the Jacobian, and the strength of the coupling between well  
and reservoir are all likely to affect the overall performance of simulations using the coupled well model. PFLOTRAN uses  
315 neighbour cell ghosting to parallelize computations: for a given subset of grid cells in the model domain that are owned by a  
particular process, say, Process "N", all of the off-process grid cells that border these cells are "ghosted" onto Process "N",  
meaning copies of state variables for those cells are kept up to date for computing updated flux terms at processor boundaries.  
Cell ghosting is determined by the numerical stencil and the distribution of cells on processors in parallel. Since adding a well  
introduces connectivity beyond the original ; the fully coupled well model updates the stencil, PFLOTRAN updates the  
320 ghosting stencil to include all off-process reservoir cells connected by a given well, allowing for consistent-full incorporation  
of well terms in the Jacobian ~~both in parallel and in serial~~. When a well is turned off (or well flow rates are set to 0), that well  
equation is not solved.

### 3 Results

We demonstrate our developments by applying the software to a set of two hypothetical CO<sub>2</sub> injection scenarios in marine environments within the GHSZ. In the first example, liquid CO<sub>2</sub> is injected slowly into a simple 1D homogeneous sediment column through a partially screened well beneath the GHSZ. The second example simulates commercial-scale injection of supercritical CO<sub>2</sub> into a 2D radial domain with heterogeneous layering, where a well is screened within and beneath the GHSZ. The CO<sub>2</sub> plume in this model is tracked for 10,000 years as it transitions from a supercritical phase to a dense liquid phase and then into the gas hydrate phase.

#### 3.1 1D Liquid CO<sub>2</sub> Injection into a Homogeneous Reservoir

In this scenario, a relatively slow ~~trickle~~-injection is designed to illustrate the multiphase and thermodynamic processes associated with injecting CO<sub>2</sub> into the GHSZ. A 1D, ~~500-1,000~~-m homogeneous domain is initialized to hydrostatic conditions where the top of the domain is held at seafloor pressure of 10 MPa, ~~seafloor temperature~~~~bottom water temperature~~ of ~~3°-5°~~ C, and geothermal gradient of ~~30°-20°~~ C/km. The top Dirichlet boundary condition is set to the initial ~~seafloor temperature~~~~bottom water temperature~~, pressure, zero gas mass fraction, and constant salinity (0.035 kg/kg). The bottom boundary at ~~500-1,000~~ mbsf is a Neumann zero flux boundary. The domain is discretized into ~~100-200~~ grid cells in the vertical dimension; individual grid cells measure 25 m in the horizontal x-dimension by 1 m in the horizontal y-dimension by 5 m in the vertical z-dimension. A well ~~penetrates the entire domain and is~~extends to 500 meters below seafloor (mbsf) and is ~~uncased (i.e., screened)~~ for ~~20~~ 25 m from 475 ~~meters below seafloor (mbsf)~~ to ~~495-500~~ mbsf. Dense liquid phase CO<sub>2</sub> is injected at 20° C at an injection rate of 15,000 kg/yr for ~~150~~ years. Pressure of the injection varies along the well depending on the ~~BHP~~bottomhole pressure, but CO<sub>2</sub> remains in the liquid phase for the entirety of the injection. Use of the well model will lead to variable CO<sub>2</sub> injection rates in each of the ~~uncased-screened~~ well segments and correspondingly variable injection enthalpy as a function of well segment pressure; this effect is less noticeable in this homogeneous case than in the heterogeneous case. This simulation is run for 200 years. While it is likely that bottom water temperature would fluctuate over 200 years, bottom water temperature variation is site specific; PFLOTRAN can apply time-dependent bottom water temperature as a boundary condition, but for this study a constant temperature was used for simplicity. A constant reservoir porosity is set to 0.35, and constant isotropic permeability is set to  $1 \times 10^{-13} \text{ m}^2$ . A Van Genuchten capillary pressure function is used, where Van Genuchten ~~n-m~~ is set to ~~1.841620.5~~,  $\alpha = 0.51 \times 10^{-4} \text{ mPa}^{-1}$ , and  $S_{lr} = 0.05$ . Corey relative permeability functions are used, where  $m = 0.4575$ ,  $S_{lr} = 0.3$  and  $S_{gr} = 0.05$ .

**Figure 1-Figure 2:** Gas saturation, hydrate saturation, dissolved salt precipitate saturation mass fraction, and temperature during and after a CO<sub>2</sub> injection beneath the GHSZ. Dashed line indicates the initial (pre-injection) BHSZ, though this is perturbed by upward migration of warm gas.

355

During the ~~first~~ 50 years of injection, the injected CO<sub>2</sub> remains beneath the base of the CO<sub>2</sub> hydrate stability zone (Figure 1-Figure 2). Therefore, it can only exist as free-phase CO<sub>2</sub>. ~~CO<sub>2</sub>~~ Thus, it migrates upward in characteristic fashion: buoyancy and pressure forces drive gas (free-phase CO<sub>2</sub>) saturations exceeding the residual gas saturation to migrate upward in the sediment column. By 100 years, the free-phase CO<sub>2</sub> front has reached the base of the GHSZ. At this point, some free-phase CO<sub>2</sub> converts to CO<sub>2</sub> hydrate. Exothermic hydrate formation keeps the reservoir temperature at the three-phase equilibrium temperature while free-phase CO<sub>2</sub> and hydrate coexist. As the gas plume migrates upward over time, more gas converts into gas hydrate. While the gas supply is strong and hydrate is still forming, the temperature of the reservoir is pushed well above the background (initial) geothermal temperature. The CO<sub>2</sub> hydrate 3-phase equilibrium temperature is cannot form past

360

365 approximately 10° C at this depth, which is why the temperature throughout the three-phase zone ~~is fixed to~~remains at roughly 10° C.

After the injection period ends, hydrate accumulates in high saturations near the top of the domain due to the ~~seafloor temperature~~bottom water temperature and pressure being fixed; the resulting permeability reduction causes gas to pool and salt to concentrate where hydrate is forming, leading to salt precipitation. This kind of scenario is unlikely to occur in a more realistic reservoir in 2D and 3D where permeability reduction would cause gas to migrate laterally and therefore not cause such significant pooling effects. But this model illustrates how exothermic hydrate formation can lead to a thick (albeit transient) three-phase stability zone throughout which free-phase CO<sub>2</sub> can remain mobile. Therefore, the fact that CO<sub>2</sub> hydrate is stable in the upper hundred meters of sediments at a particular hydrostatic pressure and geothermal temperature is an insufficient condition for ensuring CO<sub>2</sub> trapping by hydrate formation, merely relying on conversion of CO<sub>2</sub> to gas hydrate alone as a CO<sub>2</sub>-trapping mechanism is likely insufficient due to the thermal buffering effect of exothermic hydrate formation.

370

375

Permeability reduction associated with gas hydrate formation can act to slow free-phase CO<sub>2</sub> migration, but, at least at early time, a combination of thermodynamic and other structural trapping mechanisms is likely necessary to ensure the long-term sequestration of most of the injected CO<sub>2</sub> in the subsurface GHSZ.

### 380 3.2 Supercritical CO<sub>2</sub> Injection into a 2D Heterogeneous Reservoir

In this scenario, a commercial-scale CO<sub>2</sub> injection is modelled under more realistic reservoir and injection conditions (~~Figure 2~~Figure 3). A 2D, heterogeneous cylindrical domain extends from the seafloor down to 600 mbsf with a radius of 3.765 km. The model domain consists of 40 grid cells in the horizontal dimension increasing in thickness from 7.38 m at the model centre to 364.36 m at the far edge. The model contains 55 cells in the vertical dimension with varying thickness, each corresponding to a different layer in the model. The model consists of interbedded sand and mud units as might be found within the marine GHSZ. High and low permeability layers alternate with synthetic heterogeneity; similarly, the model contains heterogeneous porosity and capillary entry pressure. All other physical properties are kept constant between layers. A Brooks-Corey capillary pressure function along with Burdine relative permeability functions for liquid and gas phases are used for all layers. For all layers, Brooks-Corey  $\lambda = 0.8311$  and  $S_{rl} = S_{rg} = 0.0597$ . The capillary entry pressure (the inverse of which is expressed by the Brooks-Corey  $\alpha$  parameter) varies between reservoir layers (~~Figure 3~~Figure 4). Rock density is set to 2,650 kg/m<sup>3</sup>, dry rock thermal conductivity is set at 2.0 W/m-C, and soil compressibility is modelled with a linear compressibility function using a soil compressibility of 1.0E-8 Pa<sup>-1</sup> and a reference pressure of 10 MPa. Seafloor pressure is set to 10 MPa, ~~seafloor temperature~~bottom water temperature is 5° C, and seafloor salinity is 0.035 kg/kg. The model is initialized at hydrostatic pressure, constant salinity, and a geothermal gradient of 20° C/km. The top and outer edges of the domain are kept at the initial conditions. The bottom boundary condition is set to no liquid or gas flux, constant salinity, and a constant heat flux to preserve the geothermal gradient.

385

390

395

The well used in this scenario extends from the seafloor to 300 mbsf and is cased for the first 100 m. The rest of the well is ~~uncased~~screened; flow from well to reservoir is possible only in the ~~uncased~~screened interval. Given the conditions outlined above, the ~~bulk BHSZ~~initial BHSZ for CO<sub>2</sub> hydrate is at approximately 250 mbsf. Therefore, the well in this scenario extends through the GHSZ and 50 m below the ~~bulk BHSZ~~initial BHSZ. Care was taken to ensure that the required well pressures to achieve the specified CO<sub>2</sub> injection rate were realistic; the 100 m depth of well casing was chosen so that the well pressures resulting from our prescribed injection rate did not exceed the lithostatic pressure. This calculation is approximate and does not consider the fracture gradient; the fact that well pressures can easily approach the lithostatic gradient in these settings means that reservoir integrity should be rigorously evaluated when performing site-specific evaluations of CO<sub>2</sub> injectivity in the shallow subsurface.

~~Figure 2~~Figure 3: Schematic of the illustration of a heterogeneous layered 2D cylindrical model, with specific model parameters labeled injection scenario

410

The model is run for 10,000 years. ~~The injection is designed as if the reservoir were a prospective DOE CarbonSAFE storage complex. Therefore,~~ CO<sub>2</sub> is injected continuously at a rate of 1 million metric tons (MMT) per year for 50 years to meet a storage target of 50 MMT of CO<sub>2</sub>. The CO<sub>2</sub> is injected at a constant temperature of 45° C; injection pressure will vary along the wellbore depending on the hydrostatic pressure of the well, and this in turn will affect the enthalpy of the injected gas.

415 After 50 years, the well is shut off; over time, warm supercritical CO<sub>2</sub> will cool into a dense liquid CO<sub>2</sub> phase and then eventually a gas hydrate phase.

420 **Figure 4: Depth-varying physical properties (permeability, porosity, and inverse capillary entry pressure  $\alpha$ ) of the heterogeneous 2D injection scenario, zoomed-in near the injection interval. Physical properties held constant above and below these snapshots.**

425 During the 50-year injection interval, gas flows predominantly into the high-permeability reservoir intervals (Figure 45, Figure 56). This is because the well model adjusts how the mass of injected CO<sub>2</sub> is distributed to each interval in the injection region (Figure 7) given the total gas flow-injection rate, (Figure 6) into individual intervals as a function of hydrostatic well pressure, reservoir pressure, and well index, where well index is a function of reservoir permeability. Since early hydrate formation in the reservoir units elicits a permeability and pressure response, the well flow rate into individual units evolves over time during the injection. In some units, well flow rate drops, and these drops are then compensated by increases in flow rates in other units. Likewise, the pressure in the well evolves over time in response to hydrate formation and relative permeability of the mobile fluids.

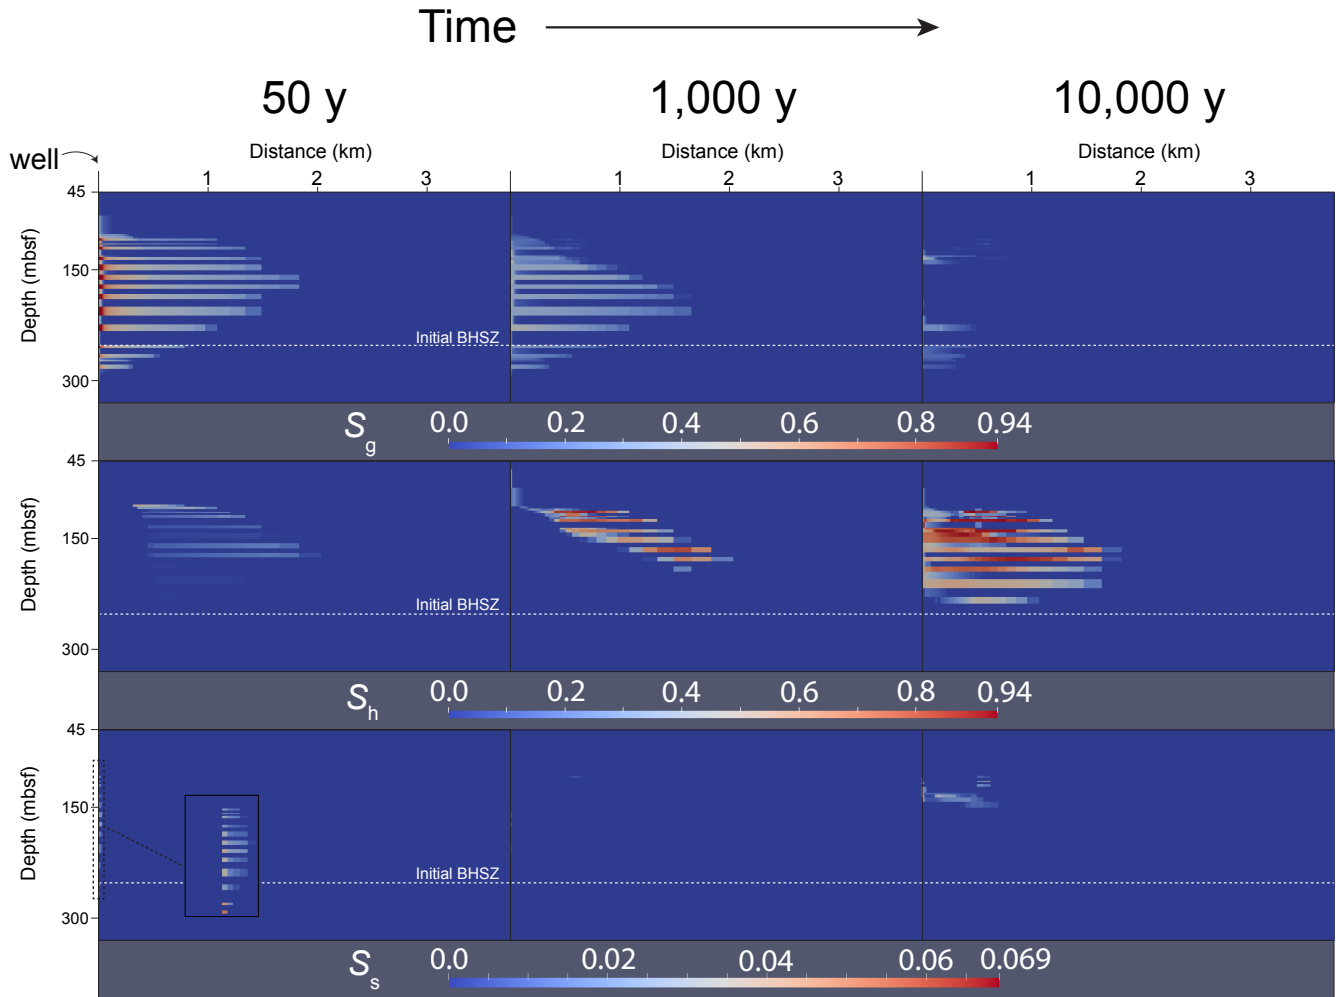

430

By the end of the injection period, gas has flowed preferentially in the radial direction along high permeability flow paths. On the outer edges of the gas plume, free phase CO<sub>2</sub> combines with water to form a gas hydrate phase where pressures and temperatures are within the gas hydrate stability zone. Since pure CO<sub>2</sub> is being injected through the well and since water is miscible in the CO<sub>2</sub> phase, high gas saturations in the near-wellbore cells cause salt concentrations in those cells to increase

435

above salt solubility. This salting out effect results in small amounts of salt precipitate saturation in the pore space at the end of the injection.

440 **Figure 45:** Snapshots of saturations over time in the vicinity of the wellbore. Depth is represented by the vertical axis, and radial distance from the well is represented by the horizontal axis. Gas (free-phase  $\text{CO}_2$ ) saturation ( $S_g$ ), hydrate saturation ( $S_h$ ), and salt precipitate saturation ( $S_s$ ) distribution at 50 years, 1,000 years, and 10,000 years of simulation time. A zoomed-in cut-out shows near-wellbore salt precipitate saturations at 50 years.

445 As water imbibes back into the near-wellbore cells between 50 and 1,000 years, gas saturations in those cells drop and salt re-dissolves (salt precipitate saturations near the wellbore drop toward 0). During this time, the temperature of the injected fluid is dropping toward the **background temperature field** **initial geothermal temperature**. As this happens, free phase  $\text{CO}_2$  combines with available water to form gas hydrate. Exothermic hydrate formation props up temperatures during hydrate formation and

slows the process of CO<sub>2</sub> conversion into gas hydrate. In some areas at the upper edges of the CO<sub>2</sub> plume, where the system is  
 450 furthest into the GHSZ, very high conversion of CO<sub>2</sub> to gas hydrate is achieved in a relatively short amount of time. Since  
 hydrate formation only involves water and CO<sub>2</sub> components, salt exclusion during rapid hydrate formation results in local  
 buildup of salt concentrations. Some cells in the model associated with rapid hydrate formation therefore exhibit some solid  
 salt precipitation by 1,000 years.

455 **Figure 56:** Permeability ( $k$ ) and temperature ( $T$ ) distribution at 50 years, 1,000 years, and 10,000 years of simulation time. Depth is  
 represented by the vertical axis, and radial distance from the well is represented by the horizontal axis.

After 10,000 years, most of the injected CO<sub>2</sub> has converted into gas hydrate. High gas hydrate saturations have built up in the  
 near-wellbore area since the initial temperature of the injection has decayed away toward the steady-state geothermal  
 460 temperature profile. Hydrate formation has significantly decreased the permeability of the host reservoir, and gas has migrated  
 into the other layers to form hydrate. A region of three-phase coexistence (liquid water, free phase CO<sub>2</sub>, and gas hydrate) is  
 still present after 10,000 years because of a combination of exothermic hydrate formation and slow imbibition rates of cool  
 liquid water due to significant permeability reduction.

Figure 67: CO<sub>2</sub> mass flow rate in each well segment (solid lines) and supercritical CO<sub>2</sub> phase pressure in the well (dashed lines) during the 50-year injection period.

### Discussion

470 The two models presented here were selected to demonstrate some of the key dynamic coupled processes associated with CO<sub>2</sub> injection into the gas hydrate stability zone. In the 1D homogeneous model, CO<sub>2</sub> is injected beneath the GHSZ and forms a free phase which migrates upward due to buoyancy and pressure forces. Once it enters the GHSZ, conversion of CO<sub>2</sub> into an immobile hydrate phase is limited by the rate at which heat can diffuse away and availability of water. When thermal conduction and liquid water flow are limited, the system can maintain 3-phase equilibrium temperature for decades (or  
475 thousands of years as is shown in the 2D model). This thermal buffering phenomenon has been observed in models of natural

methane $\text{CH}_4$  hydrate formation and dissociation in marine sediments and can occur on geologic timescales depending on free gas phase flow rate or rate of environmental change (You and Flemings, 2018; Oluwunmi et al., 2022). Clearly, such a scenario would not be ideal for permanent  $\text{CO}_2$  sequestration as much of the  $\text{CO}_2$  remains in a free phase and accumulates very close to the seafloor. Permeability reduction due to hydrate formation adds a physical trapping mechanism analogous to a low permeability sealing facies. The fact that this permeability reduction is the primary mechanism for preventing  $\text{CO}_2$  flow to the surface in the 1D model suggests that physical/structural trapping should be considered just as important or more important than thermodynamic trapping when evaluating a reservoir within the GHSZ for long-term  $\text{CO}_2$  storage.

The 2D cylindrical model was designed to incorporate more realistic reservoir physical properties and include an injection rate more viable for commercial-scale  $\text{CO}_2$  storage in the GHSZ. In this scenario,  $\text{CO}_2$  was injected into a layered reservoir that is bounded by low permeability facies that inhibit direct flow of  $\text{CO}_2$  to the seafloor. Instead of injecting beneath the GHSZ, a high-temperature supercritical  $\text{CO}_2$  phase is injected directly into and directly beneath the GHSZ. Near-wellbore gas hydrate formation is prevented by the high temperature of the injection during the injection period. Hydrate formation does occur during the injection period at the edges of the  $\text{CO}_2$  plume; the associated changes in fluid mobility and permeability alter the pressure in the well and cause well flow rates to fluctuate layer-by-layer. Therefore, even if the  $\text{CO}_2$  injection temperature is designed to prevent near-wellbore hydrate formation, hydrate formation in the far-field should be considered when designing a  $\text{CO}_2$  injection insofar as it could appreciably affect wellbore pressure. Salt precipitation can occur near the wellbore during injection due to “salting out” effects of dry  $\text{CO}_2$  injection. Salt can also precipitate later in time as  $\text{CO}_2$  converts to hydrate faster than the pore water can freshen through either aqueous imbibition or salt diffusion. In either case, salt precipitate saturations appear to be minimal for the scenario modelled here, but salt precipitation could appreciably decrease permeability under a configuration with either more rapid  $\text{CO}_2$  injection or more rapid conversion of  $\text{CO}_2$  to hydrate. In some regions of this model, hydrate saturations become very high at late times and lower the permeability of host reservoir units by several orders of magnitude. This makes for effective sealing of  $\text{CO}_2$  by conversion to an immobile phase and by impeding flow of the free  $\text{CO}_2$  phase. This phenomenon also has the effect of pushing gas into less intrinsically permeable layers and ultimately smoothing the distribution of gas hydrate throughout the model domain.

Potential leakage of  $\text{CO}_2$  into the ocean at the seafloor is clearly a risk when injecting  $\text{CO}_2$  into shallow marine reservoirs. In this model, advective leakage of  $\text{CO}_2$  is prevented by the low permeability of the top facies, but  $\text{CO}_2$  still migrates upward diffusively and thus there is some diffusive leakage of  $\text{CO}_2$  at the seafloor. Beyond just considering the bulk permeability of the top facies, however, care should also be taken to inject  $\text{CO}_2$  at pressures that remain below the fracture pressure of the overburden. While we do not model permeability evolution due to fracturing in this model, we designed our model scenarios to avoid fracturing (well model pressures in the injection interval were designed to remain below the lithostatic pressure). In a site-specific scenario, the fracture gradient should be well characterized and incorporated into  $\text{CO}_2$  injection design.

510 Although the models presented here only consider injection of CO<sub>2</sub> into reservoirs without naturally occurring gas hydrate  
deposits, the presence of other hydrates (e.g., CH<sub>4</sub> hydrate) in a reservoir could affect the injectivity of CO<sub>2</sub> by altering the  
physical properties (e.g., permeability) of the reservoir. The stability of all potential hydrates could be altered by injection of  
CO<sub>2</sub>, so site characterization should consider whether and what kinds of hydrates might exist in a potential subsea host  
515 reservoir. This information could be used to parameterize heterogeneous initial physical properties of a model, modify phase  
behaviour as a function of gas mixtures, or to develop a more sophisticated model of the interactions between multiple gases  
forming/dissolving multiple hydrates, but such models are beyond the scope of this work.

## Conclusions

We present several new developments in PFLOTRAN's HYDRATE mode including a new option to model CO<sub>2</sub> as the working gas, a new salt mass balance for considering effects of salinity gradients and salt precipitation, and a new fully coupled  
520 hydrostatic well model. We demonstrate these new capabilities on ~~a series of two~~ test problems designed to explore the coupled processes relevant to CO<sub>2</sub> injection into the marine gas hydrate stability zone for the purpose of permanently sequestering CO<sub>2</sub>. CO<sub>2</sub> sequestration in the gas hydrate stability zone is a potentially promising technique for secure storage of CO<sub>2</sub> because of the associated favourable conditions for converting injected CO<sub>2</sub> into solid gas hydrate form, which is immobile in the pore space. However, no reservoir modelling studies to date have demonstrated what commercial-scale CO<sub>2</sub> injection into the gas  
525 hydrate stability zone might look like. We show through a 1D homogeneous model that it is critical to consider multiple trapping mechanisms in addition to the thermodynamic trapping accompanied by conversion of CO<sub>2</sub> into hydrate form. We then expand to a 2D heterogeneous cylindrical model with a commercial-scale 1 MMT/yr CO<sub>2</sub> injection rate to underscore the interplay between structural trapping, thermodynamics, and permeability alteration on the migration and conversion of CO<sub>2</sub>. We demonstrate how our fully implicit well model adapts to changes in flow properties during CO<sub>2</sub> injection, and how injection  
530 of a warm supercritical CO<sub>2</sub> phase can facilitate near-wellbore injectivity but can lead to pressure change in the well. In the future, this capability could be used to more rigorously evaluate the potential for secure CO<sub>2</sub> storage in greater volumes, at larger (3D) scales, with more site-specific inputs, and with more exotic well designs including multiple wells or horizontal wells.

## Code and Data Availability

535 The software developments described here were released on August 23, 2024 with PFLOTRAN version 6.0 ([www.pflotran.org](http://www.pflotran.org)). PFLOTRAN is open source and freely available under a GNU LGPL Version 3 license at <https://bitbucket.org/pflotran/pflotran>. Software inputs and a snapshot of the PFLOTRAN v6.0 Bitbucket repository are available on Zenodo at <https://zenodo.org/records/13619874>. The files on Zenodo include PFLOTRAN input decks for both model scenarios and associated Span-Wagner EOS database files referenced by those input decks.
