Abstract

Secondary Inorganic Aerosol (SIA) makes up a considerable fraction of the total particulate matter exposure and, thus, is an important product from any forecasting system of atmospheric composition and air quality. The subsequent loss to the surface of SIA via dry and wet deposition determines the duration of the exposure time for humans and the extent of acidification imposed on sensitive ecosystems. Here we provide a description and evaluation of the most recent updates made towards aerosol production, aerosol scavenging and wet deposition components of the global IFS-COMPO chemical forecasting system, which is used as part of the Copernicus Atmosphere Monitoring Service. The application of the EQSAM4Clim simplified thermodynamic module in IFS-COMPO cycle 49R1 changes the efficacy of phase transfer of SIA precursor gases (Sulphur dioxide, Nitric Acid and Ammonia) which significantly impacts the concentrations of the respective SIA particulate concentrations by changing the fraction converted into SIA. Comparisons made against observational composites at the surface for Europe, the U. S. and South-East Asia during 2018 show reductions in the global annual mean bias statistics for both sulphates and nitrates. Updating the IFS-COMPO model towards cycle 49r1 increases both the burden and lifetime of sulphate and ammonium particles by one third. Coupling EQSAM4Clim into IFS-COMPO provides a better description of the partitioning between state phases involving ammonia and ammonium across regions, whereas changes for sulphate are minimal. For nitric acid and nitrates, the partitioning changes significantly, Jeading to lower particulate concentrations and a corresponding increase in gas-phase nitric acid with an associated improvement in surface nitrate. There is also a shift in the size of particles towards the fine mode nitrate away from the coarse mode. The impact on the total regional wet deposition values is generally positive, except for sulphates in the U.S. and ammonium particles in South-East Asia which are strongly influenced by the precursor emission estimates. This provides confidence that cycle 49rl IFS-COMPO has the ability to provide accurate deposition fluxes of S and N at global scale.

1 Introduction

٩n

The SIA occurs throughout the troposphere, where resident concentrations are dependant on Temperature (T), Relative Humidity (RH) and the concentrations of inorganic precursor gases, namely water vapour (H2O), Sulphur Dioxide (SO₂) Ammonia (NH₃) and Nitric Acid (HNO₃). High concentrations of SIA contribute to total Particulate Matter concentrations that accumulate in various size bins of 1.0µm (PM1.0), 2.5µm (PM2.5) and 10µm (PM10) (Liu et al. 2022), and have detrimental effects on both human health and visibility (Sharma et al. 2020; Ting et al., 2021). The main types of SIA are ammonium sulphate ((NH₄)₂SO₄), ammonium bisulphate (NH₄HSO₄) and ammonium nitrate (NH4NO3). Once formed, the sulphates are very stable and deposit to the surface, whereas NH₄NO₃ is more unstable and can decompose back to the precursor gases (Feick and Hainer, 1954) depending on T and RH. These particles can be transported out of source regions subsequently influencing air quality in neighboring countries (e.g., Vieno et al., 2014; Chang et al., 2022). Anthropogenic activity makes a significant contribution to SIA formation via the emission of NO_x (oxidised nitrogen in the form NO and NO₂), NH_x (reduced nitrogen) and SO₂, where there has been a general trend of decreasing Sulphur (S) and Nitrogen (N) emissions in the EU, US and China (Tørseth et al., 2012; Aas et al., 2019; Benish et al., 2022; Jiang et al., 2022) resulting in an increasing fraction of SIA being from NH4NO3. This results in a decrease in the lifetime of SIA, due to the increased meteorological instability of NH₄NO₃ (e.g. Williams et al., 2015; Metzger et al., 2002; 2006), reducing the potential for reduced long-range transport out of the source regions (He et al., 2018).

At RH values above 50%, most SIA take up water and exist in a deliquescent state. At high RH values SIA formation is enhanced (Gao et al., 2020) therefore, under constant or changing emissions, SIA is likely to become more ubiquitous in a warming atmosphere. The hygroscopic growth of SIA alters both the optical properties (in terms of scattering and absorption) and interactions with gas-phase trace species via changes in pH (e.g. Jayne et al., 1990; Shi et al, 2018). The concentrated salt solution produced typically has higher ionic strength than cloud droplets with pH values ranging between -1 to 6 (Ault, 2020). The high solubility of SIA results in the scavenging into aquated aerosols and clouds being a dominant loss term. This has impacts in terms of the acidification of sensitive ecosystems and an increase in eutrophication due to high nitrogen loading in inland water bodies, which can result in the exceedance of critical loads for vegetation (e.g. Sun et al., 2020). The uptake of carbon to land is also enhanced with an increase in N loading (Holland et al., 1997; Reary et al., 2008). Once dissolved in solution, SIA dissociates efficiently into the respective ionic constituents (e.g. nitrate (NO₃⁻), ammonium (NH₄⁺) and sulphate (SO₄⁻)) whereas these anions/cations are deposited on land during precipitation events.

A distinct difference exists with respect to the main source terms for the various SIA species. For NO_x and NH_x species, particle formation is sensitive to the resident gas-phase precursor species, temperature and RH, in the absence of aqueous phase droplets. For SO_4^{2-} , production occurs almost exclusively in the aqueous phase after SO_2 is scavenged into cloud and fog, whose cumulative oxidation rate is dependent on the prescribed pH in solution. Recent studies have shown that the correct prescription of cloud pH is necessary to account for changes in SO_4^{2-} efficacy over long time scales for the determination of trends (Thurock et al., 2019; Myriokefalitakis et al., 2022). The representation of acidity in tropospheric aerosols and clouds ranges significantly across large-scale atmospheric models. The most simplistic representation is to use a fixed cloud water pH of between 5.0-5.6, thus effectively representing the impact of dissolved carbon dioxide (CO₂). A more accurate representation includes the influence of other dissolved species which either acidify (e.g. HNO₃, H₂SO₄) or buffer (e.g. NH₃) solution pH once scavenged via irreversible uptake. This is the approach adopted in the Integrated Forecasting System with atmospheric composition extension (IFS-COMPO) for both cloud and precipitation. Other SO_4^{2-} production terms involving e.g. methyl-hydroperoxide (CH₃OOH) have been shown to be of secondary importance towards the total SO_4^{2-} production (Myriokefalitakis et al., 2022). The more buffering of solution by NH₃, the faster the conversion rate as dictated by the reaction of HSO₃ being less than that for SO_3^{--} (Warneck, 1991).

One dominant loss term for SIA is wet deposition in precipitation to the surface. Previous global tropospheric modelling studies have been performed focusing on the temporal accuracy and annual deposition totals at continental scale for NH_x and SO_x (Zhang et al., 2012; Kanikadou et al., 2016; Ge et al., 2021), as well as multimodel intercomparison studies to examine the variability across different models and the main assumptions causing such differences (Dentener et al., 2006; Bain et al., 2017; Tan et al., 2018). The accuracy of any model towards capturing the correct wet deposition terms is a balance between the accuracy of the precursor emission inventory, the distribution of the cloud liquid water content (defining the cloud Surface Area Density, SAD), the representation of the formation and distribution of aerosol particles, the extent of phase-transfer and the parametrizations adopted for describing dry/wet deposition to the surface.

The IFS-COMPO model is a large-scale global model used for operational analyses and air quality forecasts (Peuch et al, 2022; Williams et al., 2022; Rémy et al., 2024) used in the Copernicus Atmosphere Monitoring Service (CAMS). This service provides forecasts and reanalysis of trace gases and aerosols for the purpose of informing

Deleted: aggregate

108 national service providers and policy makers. It currently provides chemical/aerosol forecast products, among them Ozone (O₃), Nitrogen Dioxide (NO₂), SO₂, PM2.5, PM10 and also Aerosol Optical Depth. One main focus 109 110 of the recent updates made to IFS-COMPO is the reduction of biases and increase in correlation for aerosol 111 products (Rémy et al., 2024). In that, acidic deposition and N-loading can also be output from the model means such that improving the deposition term via an improved distribution in PM will foster the development of this 112 113 IFS-COMPO future product.

In this paper we present an analysis of the regional performance of IFS-COMPO Cy48r1 and Cy49r1 towards the surface distributions N and S gaseous precursors for SIA and the associated particle concentrations and distributions as evaluated against ground based observation networks, with special focus on the application of latest update of EQSAM4Clim (Metzger et al., 2024) in the global chemical forecasting model IFS-COMPO Cy49r1. This work is complementary to the recent evaluation of the performance of IFS-COMPO Cy48r1 and Cy49rl and of the impact of using EQSAM4Clim with respect to regional PM2.5 distributions and Aerosol Optical Depth presented in Rémy et al (2024). The influence on regional wet and dry deposition terms are subsequently evaluated to assess upgrades to both EOSAM4Clim and the deposition schemes. In Sect. 2 we provide details of the IFS-COMPO simulations used, a brief description of the latest model updates and emissions used. In Sect 3 we describe the observational networks against which the surface evaluations are performed for the precursor gases and resulting SIA particulates. In Sect. 4 we provide details of the changes in regional surface concentrations of precursor gases and associated particulates and regional annual mean statistics and in Sect 5., we present the associated comparisons of the annual mean wet deposition fluxes for Europe, the U. S. and South-East Asia and discuss improvements. Finally, in Sect. 6 we present some further discussion and conclusions from our study. Additional information in support of the main findings are also given in the supplementary material.

The IFS-COMPO global composition model (previously known as C-IFS) is used for operational air quality analyses and forecasts as part of CAMS. The modelling and data assimilation framework is regularly updated. During 2023 IFS-COMPO was based on the Cy48rl version of IFS, and uses recently updated chemical and aerosol components for the near-real time simulations of atmospheric composition https://www.ecmwf.int/en/elibrary/81374-ifs-documentation-cy48r1-part-viii-atmospheric-composition; access; 20 February 2024; Rémy et al., 2022; Williams et al., 2022), but since end of 2024 has moved to the Cy49rl version, IFS-COMPO Cv49r1 has been shown to improve on the evaluated biases simulated in previous cycles for key products such as O₃ and NO₂ (Huijnen et al., 2016; Huijnen et al., 2019; Williams et al. 20 https://atmosphere.copernicus.eu/eqa-reports-global-services ,last access 17 February 2025). For this study we perform simulations with both Cy48r1 and a version of IFS-COMPO pertaining to Cy49r1, which is t operational. These updates were included to improve the aerosol component, the wet deposition scheme and the description of pH in clouds and aerosols by applying the EQSAM4Clim approach and other updates related to cloud scavenging (Metzger et al, 2016; Metzger et al., 2024; Remy et al, 2024). For brevity we only provide a brief description of the updates made to the IFS-COMPO aerosol/chemistry component, wet deposition parameterization and the implementation of EQSAM4Climinto IFS-COMPO which determines surface deposition fluxes here. A more comprehensive description of Cy49rl updates is provided in Rémy et al. (2024) and of the EQSAM4Clim thermodynamic module in Metzger et al. (2024), along with a schematic showing the interaction of these different models towards providing accurate air quality forecasts.

2.1 Updates in IFS-COMPO Cv49r1

JFS-COMPO Cy49r1 is built on the previous operational cycle (Cy48r1) and contains 8 distinct aerosol types with multiple bins for size segregation, namely sea salt, desert dust, organic carbon, black carbon, SO4=, fine and coarse NO₃⁺, NH₄⁺ and Secondary Organic Aerosol. For <u>Cy49r1</u> updates have been made to the aerosol component of the model in the form of modifying both the description and properties of Desert Dust and Sea-Salt. This impacts the resident lifetimes and long-range transport component for each aerosol species. Modifications to the description of the aerosol optics has also been implemented, which improves the simulation with respect to the Aerosol Optical Depth (AOD) and Ångström exponent when compared against regional observations (Rémy et al., 2024). The gasphase chemistry, photolysis and dry deposition are identical to that described in Williams et al. (2022).

For Cy49r1 there has been an integration of the aerosol and chemistry components in the code to make them more consistent, where both the sulfur and nitrogen cycles are now represented through the aerosol module (for particulate species) and the chemistry module (for gaseous species and aqueous SO4= production). The aerosol module also provides additional input to the chemistry module to better represent heterogeneous reactions (via Deleted: CY48r1 Deleted: CY49r1

Formatted: Header Surface Area Density (SAD)) and the effects of aerosols on photolysis rates. The extent of gas-particle partitioning and conversion via heterogeneous reactions on dust and sea-salt particles, are outlined in Rémy et al. (2019), as based on the work of Hauglustaine et al. (2014). In Cy48r1, the first version of the EQuilibrium Simplified Aerosol Model (EQSAM; Metzger et al., 2002) was implemented for the calculation of e.g. NH₄NO₃ concentrations. These parameterizations rely on meteorological data provided by IFS, as well as gaseous precursors such as nitric HNO3 and NH3 from the chemistry module. The gas-particle partitioning scheme estimates compound production through the neutralization of HNO3 by NH3 left over after sulfuric acid neutralization. It also accounts for the formation of specific compounds from heterogeneous reactions of HNO3 with calcite (found in dust aerosol) and In IFS-COMPO Cy49r1, EQSAM4Clim is used to estimate the gas/particle partitioning of the HNO₃-NO₃ and $\mathrm{NH_{3}\text{-}NH_{4}^{+}}$ couples and to provide an estimate of the aerosol pH. The pH of aqueous solutions, aquated aerosols and precipitation is now updated each time-step using the EQSAM4Clim approach accounting for additional cations (Ca²⁺, Mg²⁺, Na⁺, K⁺), anions (SO₄⁻, HSO₄, NO₃, CI) and their solute interactions, whose methodology is comprehensively described in Metzger et al. (2012, 2016, 2024). This replaces the original estimate of solution Deleted: anons pH determined by summing the contributions from dissolved CO2 and strong acids (HNO3, HSO3*, H2SO4, NO3* and Methane Sulfonic Acid) which is buffered by dissolved NH3. The contribution towards solution pH of dissolved Formic and Acetic acid (HCOOH and CH₃COOH, respectively) are also now accounted for in Cy49r1, Deleted: CY49R1 which has been shown to contribute to the pH in cloud droplets (Shah et al., 2020). This impacts the phase-transfer, speciation and subsequent aqueous-phase oxidation of SO₂ in cloud droplets (thus impacting SO₄=). Also the loss of gas-phase species such as e.g. H₂O₂ and the corresponding formation of SIA particles is affected. Note that both the original (Cy48r1) and updated (Cy49r1) approaches account for the most dominant gaseous contributions Deleted: CY48R1 towards solution pH, namely SO₂, HNO₃ and NH₃. This means that differences imposed in cloud pH are naturally Deleted: CY49R1 less than the associated changes in aerosol pH. Below cloud scavenging of gaseous precursors is also affected by the pH of solution (e.g. Seinfeld and Pandis, 2006). In Cy48r1 fixed values for cloud pH are used over land (pH=5.0) and ocean (pH=5.6), thus only providing Deleted: CY48R1 limited variability with respect to regions affected by both high and low emissions. In <u>Cy49r1</u> this has been updated Deleted: CY49R1 such that the calculator of the pH is coupled to resident trace gas and aerosol concentrations to improve consistency within IFS-COMPO and to provide variable scavenging rates dependent on tropospheric composition. In <u>Cy48r1</u>, the wet deposition routines for aerosols and chemistry in IFS-COMPO are distinct, though both utilise Deleted: CY48R1 a scheme adapted from Luo et al. (2019), which is used operationally. To ensure a consistent approach between aerosol and trace gases wet deposition, and to simplify code maintenance, these separate implementations have been merged into a unified routine. This new routine now represents the wet deposition processes for both aerosols and chemical species and is called with either chemical or aerosol tracers as input. Similar to Cy48r1 and previous Deleted: CY48R1 versions, the routine in Cy49rl is executed twice: once for large-scale precipitation and once for convective Deleted: CY49R1 precipitation. In the case of convective precipitation, the assumed precipitation fraction has been standardised to 0.05 (whereas in Cy48r1 a value of 0.1 was used for chemistry scavenging and 0.05 for aerosol scavenging). Deleted: CY48R1 Additional upgrades have been made for aerosol wet deposition as follows: (i) The aerosol activation parameterization of Verheggen et al. (2007) has been implemented. This parameterization estimates the fraction of aerosols that can be scavenged through in-cloud processes as a function of temperature. It is applied to mixed clouds, specifically for temperatures between the freezing point and 233K. For temperatures above 0°C, the consistency of the parameters determining the fraction of aerosols subject to in-cloud wet deposition with the results of the Verheggen parameterization has been verified. (ii) For below-cloud scavenging of aerosol species, the scavenging rates have been updated to more accurately reflect the particle size dependency as described by Croft et al. (2009). This update includes adjustments to the below-cloud scavenging parameters, which describe the efficiency with which aerosols are removed by rain and snow, depending on the species and the assumed size Deleted: formcycle 49R1 distribution. Additionally, a below-cloud scavenging model has been implemented. Deleted: CY48R1 Deleted: CY49R1 Deleted: CY49R1 Deleted: cycle 48R1 2.2 Setup of model simulations **Deleted:** proposed

the same between simulations and corresponds to Cy48r1. The simulations presented here are for the year 2018, with a one-month spin-up period. The vertical resolution uses 137 individual model levels and a horizontal resolution of TL511, corresponding to approx. 0.4° x 0.4° (with further details being given at https://confluence.ecmwf.int/display/UDOC/L137+model+level+definitions). The experiments do not include the data assimilation of observations, meaning that although the changes shown will not be directly visible in the final operational forecast they will influence the resulting skill scores for e.g. PM2.5. Meteorology is initialised every 24 hours based on ERA5 reanalysis data, i.e. IFS-COMPO is tropospheric chemistry (Williams et al., 2022), excluding active stratospheric chemistry for efficiency (with this study being focused on changes at the surface). Three-hourly 3D global output is used for the analysis and aggregated into weekly, monthly and annual mean values.

The details of the sensitivity experiments are summarised in Table 1. The Cy48r1 reference simulation pertains to the 48R1 version of IFS-COMPO while the Cy49r1 simulation is based on the version described in Rémy et al (2024). The Cy49r1 NOEQ4C simulation is identical to the Cy49r1 simulation, except the EQSAM4Clim module (Metzger et al., 2024) is deactivated. For future reference, the experiment identities on the ECMWF Multiversion Asynchronous Replicated Storage system (MARS) are hylm (Cy48r1), i3bw (Cy49r1 NOE4C) and i3ad (Cy49r1). These three simulations use a configuration similar to those simulations presented in Remy et al. (2024) for evaluating PM.

Table 1: Definitions of the IFS-COMPO simulations used in this study. The experiment ID's can be used to retrieve the original data from the MARS archiving system hosted at ECMWF.

Simulation	Experiment ID	Comments	
Cy48r1	<u>rd.</u> hylm	Reference Cy48r1 model version	ļ
Cy49r1 NOEQ4C	rd.i3bw	As <u>Cy48r1</u> but with all composition modeling updates for <u>Cy49r1</u> , except EQSAM4Clim.	
<u>Çy49r1</u>	<u>rd.</u> i3ad	As Cy48r1, but with all composition modeling updates for Cy49r1, particularly activating EQSAM4Clim in both aerosols and cloud droplets	

The emissions adopted in these configurations are taken from CAMS_GLOB_ANT v5.3 (Soulie et al., 2024), with biogenic emissions taken from the CAMS_GLOB_BIO v3.1 dataset (Sindelarova et al., 2022; http://eccad.aeris-data.fr/) and biomass burning emissions taken from GFAS v1.2 (Kaiser et al., 2012), all applied using the methodology as described in Ye et al. (2021), provided at 0.1 x 0.1 resolution on a monthly basis. Apart from Biomass Burning (BB) and SO₂, emissions are applied in the lowest model level. Volcanic outgassing of SO₂ is also included. Currently the emission of Di-Methyl Sulphide (DMS) is taken from a climatology, i.e. not coupled to sea surface temperature which controls biogenic activity (Deschaseaux et al., 2019). Moreover, direct production of SO₄⁼ and HNO₃ in hot shipping exhausts is not accounted for (e.g. von Glasow et al., 2003).

3 Observations

For SO₂(g)/SO₄², NH₃(g)/NH₄⁺ and HNO₃(g)/NO₃⁻ evaluation in Europe we compare model output against data from the EMEP measurement network as stored on the EBAS data archive (EMEP, Torseth et al., 2012; https://ebas.nilu.no/; last access 6 June 2025) using a composite of 49 individual stations located in 10 different countries, as shown in the top panel of Fig A1 in the Appendix. The sampling locations are mostly in Northern and Eastern Europe, but co-location of model output means the comparison is still valid. For the US we compare against model output aggregated on a weekly basis as derived from the in-situ measurements provided at locations included in the Clean Air Status and Trends Network (CASTNET; https://www.epa.gov/castnet, last access: 6 June 2025) using a composite of 92 individual stations distributed across the U. S., whose locations are shown in the middle panel of Fig. A1 in the Appendix. For NH₃(g) not direct measurements are available from the CASTNET database, therefore we compare against both weekly and yearly mean values as derived from the in-situ measurements taken from sites near CASTNET station locations (0.5 degrees radius) i.e. 92 of the current 106

Deleted:

Deleted: For the evaluation of the regional distribution and concentrations of SIA precursor gases and the associated particle concentrations and deposition fluxes we use data freely available from a variety of observational networks. Here we only provide a brief description of the chosen networks.

For the gas phase precursors, we use in-situ measurements of SO₂ from the AirBase (Europe, https://www.eea.europa.eu/, last access: 12 Aug 2024), AirNow (US,

https://www.airnow.gov/about-airnow/, last access: 12 Aug 2024) and the China National Environmental Monitoring Center (CNEMC, https://www.cnemc.cn/) networks. Only rural background stations have been chosen and filtering has been used on the AirNow data in order to remove spurious high values which are not representative of rural background conditions. For NH₃(g) in the US we compare against both weekly and yearly mean values as derived from the in-situ measurements taken from selected stations which participate

sites in the Ammonia Monitoring Network (AMoN, https://nadp.slh.wisc.edu/networks/ammonia-monitoring-network/, last access on & June 2025), with measurements being at the location of CASTNET sites. No filtering has been applied to these measurements due to the quality control adopted from the provider. These sites are distributed more evenly across the continent. Unfortunately for S. E. Asia measurements of both precursors and SIA at a weekly time frequency are not available which does not allow the same analysis for this region.

For evaluating the SIA particle concentrations in we use available data from the EMEP (Europe), CASTNET (US) and the Acid Deposition Monitoring Network in East Asia (EANET, https://www.eanet.asia/, last access: ¿ June 2025; S. E. Asia) networks for SO₄². NH₄¹ and NO₃⁻. The EANET network includes 41 individual stations covering a wide region, whose location is shown in the bottom panel of Fig A1 in the Appendix. Although we use all of the observations provided in each database, the distribution is non-homogeneous with those in EMEP being clustered towards Northern Europe and those in South-East Asia spanning a large area from Eastern China to Japan. The locations of the stations used for evaluation are shown on the corresponding figures associated with regional and spatial validation.

For the wet deposition totals we use data from the same measurement networks as those for the gaseous precursors, thus removing any differences potentially introduced by spatial sampling which would potentially complicate the comparisons discussed here. Specifically, these are: the EMEP network for Europe, the CASTNET network for the US data and the EANET, for South-East Asia. No filtering of the data was performed before making the comparisons. Although seasonal variability is of interest, the EANET wet deposition totals are only provided as annual mean values placing constraints on the sampling frequency used for the analysis. The averaging period chosen for the evaluation is predominantly constrained by the frequency and availability of the data from South-East Asia, which only provides annual mean values. For Europe and the U.S. data is provided on weekly intervals (EMEP, CASTNET).

All statistical metrics represent spatio-temporal averages unless otherwise noted, combining all station-time pairings into a single evaluation vector per region and species.

4 The influence of pH on SIA chemical precursors and particulates

The efficacy of SIA formation is strongly governed by the resident concentrations of the gaseous precursors. Therefore changes imposed with respect to the parameterizations used for the simulating particle formation also have an associated feedback effect on the precursors, due to changes in the fractional uptake governed by the solute pH. In this section, we evaluate the temporal and regional distribution and biases of the both gaseous precursors (SO₂, NH₃, HNO₃) and SIA (namely SO₄⁼, NH₄⁺, NO₃) simulated by IFS-COMPO for Europe, the U.S. and Asia. Mixing ratios and particle concentrations are strongly influenced by the description and distribution of the primary emission sources, meteorology, the deposition component, aerosol pH (for NHx and NOx) and atmospheric transport. To investigate the ability of IFS-COMPO towards capturing the observed distributions we show both weekly and annual mean comparisons for <u>Cy48r1</u> and <u>Cy49r1</u> as compared against the corresponding measurement composites. In that the differences between Cy48rl and Cy49rl NOE4C are much smaller as shown in the budget analysis of the gaseous precursors, for brevity we limit the selection of results shown. A direct link exists between [NH₄⁺] and [NO₃⁻] in that <u>fine mode nitrate</u> takes the form NH₄NO₃. All observational data is used for the calculation of the statistics thus they are representative of the mean across different chemical regimes. In that the location of the sampling sites is not homogenous throughout the analysis region, meaning that result can be weighted towards certain states/countries. For Mean Bias (MB) and Root Mean Square Error (RMSE), negative percentage differences are indicative of improvements in the bias statistics, whereas for Pearson's R it is a positive percentage difference.

To investigate the scale of such feedbacks we show monthly mean regional differences for July and December 2018 for the three selected regions below focusing on the gaseous distributions of SO₂, NH₃ and HNO₃. For evaluating the performance of IFS-COMPO we aggregate at a weekly frequency. For the corresponding distributions and concentrations of SIA we show annual mean values against observations.

Figure 1 shows the regional monthly mean distributions in surface SO₂ mixing ratios for July and December 2018 for Cy48r1, along with the percentage differences between Cy48r1, Cy49r1 NOEQ4C and Cy49r1. When comparing the spatial distributions across regions, Europe exhibits the lowest SO₂ mixing ratios in Cy48r1, where the region has undergone strong mitigation practices over the last decades (e.g. Vestreng et al, 2007). The maps for December show higher mixing ratios towards the East, with a significant contribution from shipping. For the US, a stark East-West gradient exists as governed by the continental distribution in anthropogenic emissions, with higher emissions towards the East Coast, again with a seasonal signature. Maximal surface mixing ratios are 5-10 times higher than those simulated for Europe distributed over a much larger area. As expected, China exhibits the highest mixing ratios of between 10-20 ppb over the entire country, which is approximately 20 times higher than those simulated for Europe for both months shown.

When comparing Cy48r1 against Cy49r1 NOE4C there are reductions in $[SO_2(g)]$ at the surface for all regions of between 0-10%, resulting in limited increases in SO_4^{2-} production of a few percent due to changes other than those related to updates to aerosol and solution pH. This small increase in the SO_4^{2-} production is reversed when applying the EQSAM4Clim pH methodology (Metzger et al., 2024), where the conversion efficacy of SO_2 is faster at a more alkalinic pH. The global budget terms show that in addition to primary emission, approximately one third of SO_2 in the troposphere, comes from the oxidation of DMS by the hydroxyl radical (OH), with DMS originating from biogenic activity in the oceans.

In $\c V48r1$, approximately 20% of SO₂ is oxidised in the gas-phase and 43% in the aqueous phase, with the remaining 37% being lost to surface via dry and wet deposition. This increase in gas-phase production via OH is linked to changes imposed by differences in O₃-NO_x reaction cycles near anthropogenic source regions which results in a small increase in O₃ of a few percent (not shown). The corresponding values for $\c V49r1$ NOE4C show changes in the order of a few percent across terms, increasing the global burden by 1.5% mostly in the lower troposphere. For $\c V49r1$ the application of EQSAM4Clim pH in cloud droplets reduces both the uptake and oxidation of SO₂ by reducing aquated sulphite ([SO₃²]_{aq}, pKa(HSO₃)=7.2) and an enhancement of the gas-phase oxidation due to increased OH, resulting in more gas-phase production of H₂SO₄ which is subsequently scavenged into solution further increasing solution acidity (lower pH values) in case of excess SO₄² (insufficient cations to completely neutralise all SO₄²).

Figure 1			

whows that the region with the highest surface SO_2 is the North-East of the U.S., with the other regions moderating the biases. Again little seasonality exists in the weekly observational composites. There is a positive bias for wintertime and a negative bias for summertime around 0.5-1.0 $\mu g/m^3$ across all simulations. There is an increase in the annual mean negative bias by around 0.1 $\mu g/m^3$ in CV49r1 with poor correlation with the observations. Finally for China, weekly SO_2 concentrations are an order of magnitude larger than those observed in the other regions reaching 15-20 $\mu g/m^3$ during wintertime. The simulated concentrations exhibit a very large positive bias of between 10-20 $\mu g/m^3$, suggesting that the regional SO_2 emissions are likely overestimated in the global inventory. Only a negligible improvement occurs in CV49r1 where no detectable correlation exists between the simulated and observed values.

Figure 2 shows a comparison of weekly $[SO_2(g)]$ and $[SO_4^2_\pi]$ surface composites as simulated in IFS-COMPO against weekly composites of measurements taken from the EMEP measurement network (top left panel). For $SO_2(g)$ a consistent positive bias exists for the entire year across all IFS-COMPO simulations suggesting emission estimates which are high, where surface concentrations exhibit around 100% positive bias, increasing to almost 200% during wintertime. The variability in the observational means (grey shaded area) does indicate that the simulated increase in surface $[SO_2(g)]$ during wintertime does occur at some of the measurement sites. The corresponding observational means of $[SO_4^{2^*}]$ show that there is higher weekly variability during wintertime than summertime, with concentrations ranging typically between 1.0-2.0 μ g/m³. This significant weekly variability is simulated well by IFS-COMPO across all simulations. For wintertime both Cy48r1 and Cy49r1 exhibit significant positive biases of 0.5-1.0 μ g/m³. Surprisingly, Cy49r1 NOE4C has the lowest bias during wintertime of around

Moved down [1]: Due to the primary source term of SO₂ being direct emissions indicates that estimates for Eastern Europe could be too high (c.f.

Moved down [2]: The annual mean bias (MB) value decreases by around 25%, with a moderate correlation. For the US the weekly mean SO_2 values in the observations are typically around $2.5~\mu g/m^3$, which is more than double that observed in Europe.

Deleted: Figure 1 shows weekly comparisons of surface $SO_2(g)$ concentrations $(\mu g/m^3)$ from the three different regions for 2018 against observational composites assembled using data from background/rural stations as selected from the relevant observational networks introduced in Sect. _____[1]

0.2-0.5 μg/m³. Comparing Cy49r1 against Cy48r1 shows an increase in surface [SO4²] by approximately 10-25% during wintertime in Cy49r1, albeit still with a significant negative bias of around 0.8-1.5 μg/m³. During summertime the weekly variability in the observed weekly means is much lower with monthly gradients being captured well in IFS-COMPO. All simulations capture the extent of this variability quite well. Differences across simulations is around 0.1-0.2 μg/m³, with Cy49r1 having a slightly higher bias. Due to the primary source term of SO₂ being direct emissions indicates that estimates for Eastern Europe could be too high (c.f. Fig. 1). The annual mean bias (MB) value decreases by around 25%, with a moderate correlation. For the US the weekly mean SO₂ values in the observations are typically around 2.5 μg/m³, which is more than double that observed in Europe. For 2018 there is generally a low annual MB in Cy48r1 (-0.41 μg/m³), which is subsequently reduced in Cy49r1 NOE4C (-0.20 μg/m³) and Cy49r1 (+0.01 μg/m³). The correlation coefficient also shows a marginal improvement from 0.37 (Cy48r1/Cy49r1 NOE4C) to 0.43 (Cy49r1).

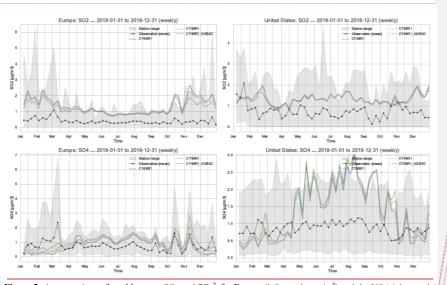

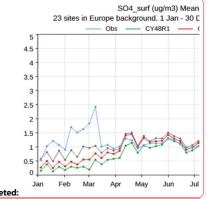

Figure 2: A comparison of weekly mean SO₂ and SO₄²⁻ for Europe (left panels; µg/m³) and the US (right panels) simulated in JFS-COMPO as compared against EMEP and CASTNET observational networks, respectively, for 2018. The sampling frequency of the data for SEAsia does not allow a corresponding weekly plot for this region.

In the right hand panels of Fig. 2 a similar comparison is made against weekly observational composites of surface [SO₂(g)] and [SO₄²] from the CASTNET measurement network. Similar to Europe, no seasonal cycle exists in the observations of either surface [SO₂(g)] and [SO₄²] with typical weekly mean values of around 0.7-1.0 µg/m³ even though the latitudinal range is large for the CASTNET measurement stations. For the wintertime lower, weekly MB occur for both Cy49r1 NOE4C and Cy49r1 as compared with Cy48r1, where the weekly variability is inverse of that seen in the observations. During the summertime much larger positive biases occur reaching between 200-300% across all JFS-COMPO simulations which exhibit a strong seasonal cycle in spite of no such increase in the simulated [SO₂(g)]. Although some smaller differences occur between simulations, there is no improvement in Cy49r1 with respect to the weekly MB. Considering the corresponding high summertime MB for SO₂ shows either a significant fraction is transported in IFS-COMPO, where a slower oxidation rate of SO₂ by OH and/or aqueous phase processing would be required to improve the performance of IFS-COMPO which would then lower the negative bias seen for [SO₂(g)].

Figure 3 shows the annual means of surface [SO₂(g)] and [SO₄²⁻] for Cy48r1 and Cy49r1 for Europe, and the US. The changes in surface [SO₄²-] here are somewhat unaffected by the changes in aerosol pH due to EQSAM4Clim that are shown in Rémy et al. (2024) for 2019 due to the dominant aqueous-phase production term (albeit with small increases due to the additional contribution from organic acids). One main difference for SO_x than either NH_x or NO_x is that the gas-particle partitioning is dependent on cloud pH, dissolved O3 and hydrogen peroxide (H2O2), where SO42 production

For Europe the sampling sites for this aerosol species in the EMEP network are located such that comparisons for southern european countries are not included in the regional mean statistics or discussed further. A sharp North-South gradient exists imposed by the variability in H2SO4 production between seasons, cloud cover for the wet production term and the distribution of the primary point sources for SO2 emissions, although mitigation measures remove the increase in the emitted flux during the cold winter months associated with domestic heating (Versteeg et al., 2007) Simulated concentrations in Cy48r1 are lower in Scandinavia as compared with e.g. France, which results in a low bias of around 1 μg/m³ in e.g. Finland and around the Baltic, here related to missing shipping emissions of SO₂, which quickly converts to SO₄² in the plume (Celik, et al., 2020). For the other sites in Europe agreement is better with the low bias decreasing to approx. 0.5 µg/m³. One outlier exists for the most easterly station, which exhibits a significant high bias of 1.5 μg/m³. Comparing Cy49r1 shows increases in the simulated surface [SO₄²⁻] of between 0.2-0.4 μg/m³. which leads to an improved bias. Only small improvements are made to the correlation coefficient due to identical emission estimates being used and EQSAM4Clim affecting SO_x the least, i.e., only indirectly through changes in pH

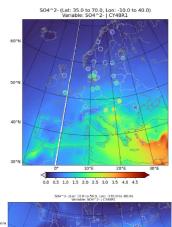

For the U.S. the CASTNET observations show an East-West continental gradient in surface [SO₄²-] exists as determined by the distribution in the primary SO2 emissions and transport (c.f. Figure 1). A significant transport component exists for SO₄²⁻, resulting in surface [SO₄²⁻] in the Marine Boundary Layer between 1.0-2.5 µg/m³, where transport dominates local surface [SO4²-] produced from DMS oxidation (Simpson et al., 2014). For Cy49r1 there is a reduction in surface [SO₄²⁻] at continental scale, with a decrease in the annual MB from 0.67 to 0.20 µg/m³, with a corresponding increase in the correlation coefficient to 0.43, albeit remaining only rather weakly correlated. For the West of the U.S. a positive, MB is introduced for the rural background in Cy49r1 of 0.5-0.7 μg/m³, with a contribution being transported from the East. Hence, reductions in the annual MB primarily stem from improved agreement at Eastern U.S. monitoring sifes That a positive MB of approx. 1-1.5 µg/m³ exists in the annual mean values around Kentucky/Tennessee suggests that the local SO₂ emission estimates are too high (see Discussion in Sect. 5).

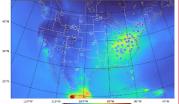

For South-East Asia, the scarcity of sampling sites in the EANET network results in a less robust evaluation. Also many sampling sites are located at coasts rather than inland, thus the influence of changes at coastal regions have a large influence on the regional statistics. Higher primary SO₂ emissions occur on the land. Therefore any positive MB near source regions are not included in the statistics; the results shown here for surface SO₄² should be considered lower limits. The long-range transport of SO₄²⁻ in Asia has been shown to somewhat neutralise national SO₂ mitigation measures taken in e.g. Taiwan and South Korea. This originates from changing trends in SO2 emission from mainland China as captured by EANET measurement sites (Chang et al, 2022). For <u>Cy48r1</u> the annual mean statistics show very low MB and a good correlation coefficient of 0.75. For <u>Cy49r1</u> there is a significant degradation, where the MB increases to 0.48 µg/m³ showing a trend in the performance for SO_x that is similar to the U.S. . Notably, the more remote sampling stations (e.g. oceanic) exhibit regional negative biases (approx. -0.7 μg/m³) whereas those situated near Mongolia and South Korea agree well with low MB values. For Thailand and Vietnam there are typically large MB values, suggesting regional SO₂ emission estimates are too high. Unfortunately there are no in-situ measurements available for better quantification. The correlation coefficient degrades in <u>Cy49r1</u> compared to <u>Cy48r1</u> towards 0.66. Overall, the improvements are mixed for the SO₂ - SO₄²⁻ couple and much less pronounced compared to the other Formatted: Header

4.2 NH₃ and NH₄⁺

The regional distribution of surface NH₃ for 2018 in the three chosen regions and the resulting changes which occur due to both the IFS cycle upgrades and the application of EQSAM4Clim are shown in Figure 4. Although there is a declining trend in European regional NH₃ emissions (Tichý et al, 2023), a strong seasonal cycle exists in Cy48rl. Maximal mixing ratios are situated around Benelux and Northern Italy, with local differences of 8-20 ppb between July and December across regions. The CAMS_GLOB_ANT v5.3 (Soulie et al, 2024) emission inventory has recently been validated for NH₃ against top-down estimates providing confidence in the quality of the estimates for Europe (Ding et al., 2024). For the US a similar seasonal signature exists especially for the North West and South East associated with agricultural emissions (Wang et al, 2020), with background mixing ratios of between 0.5-2.0 ppb remaining relatively constant. For China, whose NH₃ emissions have increased over the last decades (Liu et al., 2019; Chen et al. 2023), surface mixing ratios of between 5-20 ppb occur for July for large areas, again associated with agricultural practices. Likewise, high mixing ratios are found around Bangladesh (> 20 ppb). For December, mixing ratios are typically an order of magnitude lower, with the exception of the South-West, which again exhibits high mixing ratios (> 20 ppb). Measurements of NH_x over the ocean are rare, thus the large increase shown cannot be verified. Nevertheless, estimates range from 0.1-4.2 ppb depending on season and location (Sharma et al., 2012) indicating that Cy48rl has a significant negative bias which is somewhat improved in Cy49rl.

Figure 5 shows comparisons between weekly observational composites from EMEP of [NH₃(g)] against those extracted from the various IFS-COMPO simulations for 2018. The observational composite shows that there is a skewed seasonal cycle exhibiting a maxima in April/May from agricultural activity, with wintertime values being around 0.5 μg/m³ increasing to 0.8-1.5 μg/m³ during spring and summertime. This seasonal variability is captured across all simulations. For wintertime there is a low weekly bias of around 0.1μg/m³ and a positive summertime weekly bias of between 0.5-2 μg/m³ in Cy48r1 (annual MB 1.04 μg/m³), where a 20% increase in the bias is simulated for Cy49r1 (annual MB 1.21 μg/m³). There is a high correlation across simulations resulting in values from 0.71-0.73, where the occurrence of weekly increases in the observed values are typically captured in IFS-COMPO.

The bottom left panel of Fig. 5 shows that there is a reversed seasonality in [NH₄+] in the observational means, with higher [NH₄+] during wintertime due to the colder temperatures decreasing the volatility of the particles (e.g. Tang et al., 2021). Moreover, for Cy48r1 there is clearly a large positive bias of [NH₄+] with little change in Cy49r1 NOE4C. Table 4 provides the global budget terms for all three simulations, showing the large increase in deposition terms and tropospheric burden for NH₃(g). For Cy49r1, the improved gas/particle partitioning from EQSAM4Clim reduces the particle phase concentrations of the semi-volatile aerosol species which leads to an increase in the respective gas phase concentrations, also affecting aerosol pH. This determines the solubility of NH₃(g), also contributing to its reduced conversion into NH₄+ (see Table 4, approx. 44% reduction), which is an effect amplified by the inclusion of mineral cations (i.e. Ca²⁺, Na⁺, K⁺, Mg²⁺). The tropospheric lifetime of NH₃(g) more than doubles in Cy49r1 allowing more transport from strong source regions, in line with changes in the tropospheric burden. Both the associated loss due to dry and wet deposition increases (37% and 51%, respectively), due to lower NH₄+ particle production (see Sect. 4.2).

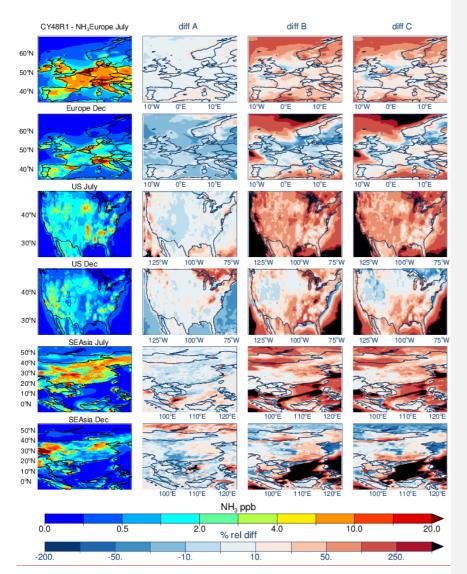

Figure 4: As for Fig. 1 except for NH₃. Panel definitions: Diff A=(Cy49r1_NOEQ4C - Cy48r1)/Cy48r1; Diff B=(Cy49r1-Cy48r1)/Cy48r1 and Diff C=(Cy49r1-Cy49r1_NOEQ4C)/Cy48r1.

Therefore, there is a modest degradation in performance as compared with Cy48r1. Comparing Cy48r1 and Cy49r1_NOE4C shows that there are typically decreases of [NH₃(g)] of between 5-20% over the land across the chosen regions, as a result of the changes to wet scavenging in the absence of decrease in pH (reducing 13% and increasing the burden by 20% c.f. Table 4).

Table 4. The tropospheric NH₃ budget in Tg N/year for 2018 as calculated by Cy48r1, Cy49r1_NOE4C and Cy49r1, with the associated percentage differences being provided in parentheses as e.g. ((Cy49r1-Cy48r1)/Cy48r1)*100.

<u>Process</u>	<u>Cy48r1</u>	Cy49r1_NOE4C	<u>Cy49r1</u>

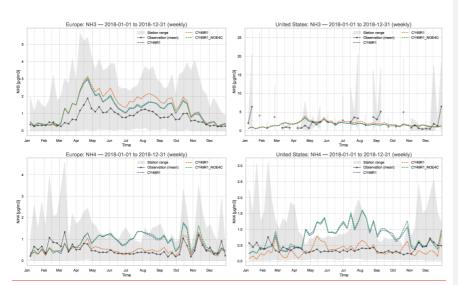

Figure 5: A comparison of weekly mean $[NH_3(g)]$ and $[NH_4^+]$ at the surface for Europe (left panels; $\mu g/m^3$) and the US (right panels) as simulated in IFS-COMPO as compared against the composites of measurements taken from EMEP and CASTNET for 2018. For the U.S. the data for $NH_3(g)$ is taken from the AMoN measurement network. The data frequency provided for the South-East Asia region does not allow a corresponding plot, although annual statistics are provided in Table 5.

Also shown in Fig. 5 are weekly comparisons of observational composites of [NH₄⁺] at the surface from the EMEP measurement network against those extracted from the various IFS-COMPO simulations for 2018 (bottom left panel). Although the maximum observed NH₃(g) shown in the top panel of Figure 5 occurs during April/May, higher [NH₄] are observed during the winter months. For both $\underline{Cy48rl}$ and $\underline{Cy49rl}$ NOE4C summertime mean biases of > 100% exist (0.5 μ g/m³) which are removed by the application of EQSAM4Clim in $\underline{Cy49rl}$ resulting in a very low bias < 0.1 μ g/m³. This potentially improves the accuracy of forecasting both PM2.5 and PM10 significantly by reducing the cumulative bias across aerosol types (where the definition of both aggregate quantities are given in Rémy et al., 2024).

Similar comparisons are shown in Fig. 5 for the US in the bottom right panel using weekly composites assembled from the CASTNET data in the bottom right panel. In contrast to the seasonal cycle for [NH₃(g)], which peaks during April/May, the corresponding seasonal cycle in the weekly [NH₄*] values peaks during July, being fairly consistent between 1.5-1.75 µg/m³ during summertime. This indicates that a saturation occurs with respect to NH₄* particle formation which is most likely linked to availability of HNO₃(g) (c.f. See sect 4.3. below). Again significant biases exist in Cy48r1 and Cy49r1 NOE4C, reaching around 1.5 µg/m³ during summertime (which is 600% of the summertime observational values). Applying EQSAM4Clim halves this positive bias in Cy49r1, resulting in fairly good agreement during the winter and summer months.

Figure 6 shows the distribution of the corresponding annual mean [NH₄⁺] for the three chosen regions for both Cy48r1 and Cy49r1 during 2018, with the associated regional annual mean statistics being given in Table 5. The location of the measurement sites are shown in each panel, with the respective annual mean values within each circle. Significant decreases in the conversion rate of NH₃ in Cy49r1 results in lower [NH₄⁺]. This is a result of the improved gas/aerosol partitioning and the subsequent increase in aerosol pH when applying EQSAM4Clim (see Table 4; Rémy et al., 2024). More direct depositional loss to the surface for NH₃(g) occurs in Cy49r1 due to increased residence time. There is a wide variability in the simulated aerosol pH between regions, with Europe exhibiting aerosol pH values of around 3-4, whereas the Southern U.S. and Northern China exhibit aerosol pH values in the range 2-3 (Pan et al., 2024; Rémy et al., 2024) which indirectly affects the temporal variability in NH₄⁺ production. Once formed, regional transport contributes to the continental distribution of NH₄⁺ away from strong source regions (e.g. Simpson et al., 2010; Renner and Wolke, 2010: Du et al., 2020).

For Europe (top panels), most observational annual mean values are between 0.2-1.2 μ g/m³ which are exceeded by > 50% in Cy48r1. In Cy49r1 the reductions in the annual mean $[NH_4^+]$ are of the order of 0.5-1.0 μ g/m³ and result in low annual mean $[NH_4^+]$ values for e.g. Spain/UK, whilst reducing maximal concentrations by approx. 50% in Northern Italy. This subsequently contributes to a reduction in the cumulative PM2.5 biases for this region as shown in Rémy et al. (2024) for 2019. The associated MB values in Table $\frac{1}{2}$ show a significant reduction in the bias (> 80%) along with an increase in the correlation coefficient, although the simulated NH₄⁺ distribution is still only moderately correlated (r=0.62). Unfortunately, the lack of available measurements means no quantification of the performance of IFS-COMPO around the mediterranean can be shown. It should be noted that with a more realistic distribution and seasonal variability in NH₃(g) emissions (e.g. Shepard et al, 2011; Dammers et al, 2019), the $[NH_4^+]$ distributions shown here will most likely not be affected as other SIA species determine the $NH_3 - NH_4^+$ gas/aerosol partitioning.

For the U.S. (middle panels) similar decreases in annual mean [NH₄⁺] values occur in Cy49r1 as compared to Cy48r1, with very low concentrations of between 0.1- $0.4 \,\mu g/m^3$ for the West of the U.S., which shows less bias when compared against the observational mean values. This causes a reduction in the annual mean regional bias of around $0.7 \,\mu g/m^3$ as shown in Table 5. A gradient exists in the aerosol pH from EQSAM4Clim ranging from annual mean values of pH=3.0 towards the North-West U. S. and becoming more acidic towards the South West U.S. with annual mean values of pH=2.0 (Rémy et al., 2024). This reduces the transfer of NH₃(g), thus moderating NH₄⁺ production (c.f. Table 5). For the North-East U.S. with high NO₃ emissions, there are reductions of between 0.5- $1.0 \,\mu g/m^3$. For the South-West U.S., with high [NH₃(g)] from agriculture (c.f. Fig. 5) there are reductions of between 0.3- $1.0 \,\mu g/m^3$. There is a degradation in the correlation coefficient exhibiting a moderate annual mean correlation with significant overestimates for the South-West U.S. as shown for the comparisons of [NH₃(g)] at selected sites in Figure 5.

Deleted: A comparison of the weekly variability in $[NH_3]_g$ between IFS-COMPO and measurements from a selection of rural sites which contribute to the AMON measurement network for 2018 is shown in Figure A5 in the Appendix, with the details of each site being provided in the figure legend and sites chosen to cover a wide area of the US. In general, the measurements indicate that wintertime [NH₃(g)] are lower than summertime concentrations across multiple sites, except in California which experiences less seasonal variability in temperature (and agricultural practices). Maximal concentrations are in the range of 1-6 µg/m³ occurring during either springtime (Alabama / New York) or summertime (Florida) depending on the extent and timing of agricultural activity in each respective state. In general differences between CY48R1 and CY49R1_NOE4C are negligible whereas the weekly bias is significantly reduced for CY49R1. An exception is Arizona where the large positive bias indicate a too high local emission flux. The incidence of high [NH₃(g)] in CY49R1 is also somewhat dependent on the local [HNO₃(g)] via NO_x, which is the other important precursor with respect to [NH₄(NO₃)] (contrast New York State versus Alabama). The seasonality derived from the weekly variability is captured to a large degree, with the amplitude of the cycle being substantially improved in CY49R1. .. [15]

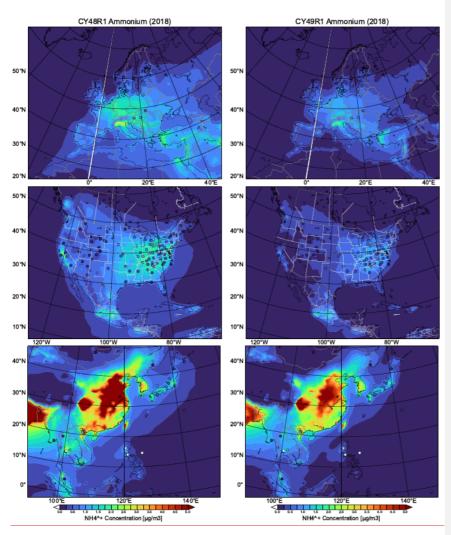

Figure 6 : Comparisons of annual mean $[NH_4^+]$ simulated at the surface in Cy48r1 and Cy49r1 when compared against measurements for the three selected regions during 2018 (μ g/m³). The corresponding regional statistics are provided in Table 5. The site locations used are shown in each pane and taken from the EMEP, CASTNET and EANET networks respectively.

For South-East Asia, (bottom panels), the simulated annual mean [NH₄+] over land are typically much higher than those simulated for either Europe or the U.S., with maximal values of between 7.0-9.0 $\mu g/m^3$ for Eastern China, inspite of the similar surface mixing ratios in NH₃(g) between Europe and China as shown in Fig. 5. This difference is predominantly driven by the relatively high HNO₃(g) in China due to the more polluted chemical regime (the availability of O₃(g), NO₂(g) and OH(g) determining gas-phase HNO₃(g) production). Applying EQSAM4Clim in $\frac{\text{Cy49-1}}{\text{Cy49-1}}$ results in significant decreases of between 1-2 $\frac{\mu g}{m^3}$ [NH₄+] as associated with the highest annual mean [NH₄+] > 6.0 $\frac{\mu g}{m^3}$. This reduces the associated annual mean regional bias by 0.4 $\frac{\mu g}{m^3}$, with a corresponding reduction in the correlation, due to less transport. Again the lack of sampling sites in the region with high primary

Deleted: ,

Deleted: Figure A3

Deleted: CY49R1

NH₃(g) emissions skews the associated annual mean biases. For the more remote locations (e.g. Mongolia/South China Sea) low values of $< 0.5 \mu \text{g/m}^3$ are captured well in both Cy48r1 and Cy49r1.

Figure 7 shows the monthly mean regional distribution of HNO₃(g) for July and December 2018 for the three chosen regions for Cy48r1, along with the relative differences when compared with Cy49r1 NOE4C and Cy49r1. The corresponding global chemical budget terms for HNO₃(g) are provided in Table 6. No direct emission of HNO₃ occurs in IFS-COMPO, which is often prescribed in global chemistry transport models to represent e.g chemistry in the plumes of ships (e.g. Vinken et al., 2011), with the main source being the oxidation of NO₂ by OH in the gasphase as shown in Table 6. This production term increases in Cy49r1 by approx. 14% as a result of the enhancements in OH via changes in O₃ (not shown). For heterogeneous conversion, the cumulative HNO₃ production term is approx 50% that of the gas-phase production term, remaining relatively constant between simulations. There is a shift between fine mode NO₃* (NH₄NO₃) and coarse mode NO₃* (CaNO₃/NaNO₃), strengthening the link between NH₄* and NO₃* in IFS-COMPO. Both dry and wet loss terms increase significantly due to the increase in the availability of HNO₃(g), which reduces the fraction converted to NO₃*. The temporal variability of HNO₃(g) is influenced by the magnitude and extent of regional NO_x emissions, photochemical activity (via OH formation), gas/acrosol partitioning (where particles with high SO₄* content having an associated low NO₃* content) and scavenging in clouds and aerosols.

For Europe very low surface mixing ratios occur over land for both months shown in Cy48r1 (< 0.1 ppb), which is surprising considering that the Benelux has been shown to have high NO_x levels (van der A, 2024) therefore likely to have correspondingly high HNO₃(g) mixing ratios. Higher mixing ratios of between 0.25-0.5 ppb occur around the Coasts and the Mediterranean originating from direct shipping emissions of NO₂. This can lead to elevated NO₃ concentration due to uptake of HNO₃(g) on sea salt, which might be too high as the current formulation of EQSAM4Clim only assumes thermodynamic equilibrium which is not dynamically limited. A coupling with a dynamical aerosol model is foreseen. In contrast, the application of EQSAM4Clim in Cy49r1 results in large increases in surface HNO₃(g) at continental scale during July. For December, a strong latitudinal variability in the relative differences imposed in Cy49r1 occurs, with decreases of between 25-75% in HNO₃(g) at latitudes higher than 60°N due to lower temperatures and lower RH under a relatively low NO_x environment.

For the U.S., the highest HNO₃(g) mixing ratios in <u>Cy48r1</u> occur for the Eastern states and California (1-2 ppb), with much lower values in the more remote Central U.S. (0.1-0.2 ppb), with a strong seasonal cycle in maximal values peaking in July. Comparing relative differences between simulations shows a significant increase of surface HNO₃(g) in <u>Cy49r1</u> (between <u>0.1-6 ppb</u>) at continental scale for both months, with the largest increases occurring in the Northern States. In contrast to Europe no seasonal decreases occur for any location.

Finally for South-East Asia, the surface mixing ratios are the highest across all regions, with maximal values being of the order of 4-5 ppb towards the Eastern Coast (July) and Central regions (December). Comparing the relative differences between simulations shows significant increases of between 50-5000%, with the exception of the more remote regions to the North. As for Europe, a strong seasonality can be seen with decreases above 30°N occurring regardless of the NO_x regime. As shown for NH₃ (c.f. Fig. 4), there are significant increases in HNO₃ over the ocean for both months shown, associated with lower [NO₃⁻¹] (as shown by the cumulative reduction in global conversion by 50%).

Deleted: Figure 6 shows the resulting changes in surface [HNO₃(g)] between simulations as compared against weekly composites assembled from a selection of background measurement sites in Europe which participate in the EMEP measurement network. The location of the sampling sites results in a significant bias in the evaluation towards Northern Europe (where seasonality is the largest). However, only a weak seasonal cycle is evident in the observations with weekly values in the range of 0.4-0.8 μg/m³, although many sites are located away from strong NOx sources. Both CY48R1 and CY49R1 NOE4C (Figure A7) exhibit negative biases resulting in under-estimations of around 100% during the summertime. There is a reduction in the bias of around $0.1\text{-}0.2 \mu g/m^3$ in CY49R1 NOE4C showing that the other changes made between IFS cycles cause changes in the gas phase production term in addition to the changes in NH_4NO_3 from EQSAM4Clim (c.f. Table 8). For CY49R1 there is a significant excess of [HNO₃(g)] due to enhanced production and less transfer into the particulate phase, in spite of an increase in the cumulative deposition terms. Such changes are associated with relatively low [HNO3(g)] IFS-COMPO values of around < 0.1 ppb (Figure A7). Figure A7 in the Appendix further

Figure 8 shows the resulting changes in surface [HNO₃(g)] across simulations for Europe when compared against weekly composites assembled from EMEP measurement sites (top left panel). The location of these sites is shown in Figure A1 in the Appendix, where the location of the sampling sites results in a significant bias in the evaluation towards Northern Europe. No obvious seasonal cycle is evident in the observational weekly means, with concentrations in the range of 0.3- $0.7 \,\mu g/m^3$, although many sites are located away from strong NO_x sources. Both Cy48r1 and Cy49r1 NOE4C exhibit negative weekly biases resulting in under-estimations of around 100% during the summertime, although the weekly variability is captured to a degree. There is a reduction in the bias of around $0.1 \,\mu g/m^3$ in Cy49r1 NOE4C showing that the other changes made between IFS cycles cause changes in the gasphase production term in addition to the changes in NH₄NO₃ from EQSAM4Clim (c.f. Table 8). For Cy49r1 there

Figure 8 also shows comparisons of weekly [HNO₃(g)] from the CASTNET measurement network in the US are shown in the top right panel. As for Europe both the concentrations and seasonal variability in the observations is low, with typical weekly concentrations being around $\pm 0.5 \,\mu \text{g/m}^3$. The rather equal distribution of measurement sites in the US means the evaluation presented does not have any significant regional bias. That the measured weekly mean concentrations are rather constant is surprising considering that variability in the gas-phase chemical production term involves OH, which has strong seasonality from the differences in day length. In contrast to Europe, both Cy48r1 and Cy49r1 NOE4C show good agreement against the measurements with weekly biases of the order of 0.2-0.25 μg/m³. However, for Cy49r1 a large positive bias is introduced by the use of EQSAM4Clim due to a limitation in the ability for HNO3 to condense on particle surfaces, such that condensed HNO3 does not $contribute \ to \ NH_4NO_3 \ formation \ (which \ requires \ a \ coupling \ of \ EQSAM4C lim \ with \ an \ aerosol \ dynamical \ model$ as e.g., described in Metzger et al., 2018). It also shows that although the cumulative global dry and wet deposition terms in Cy49r1 have increased markedly compared to Cy48r1 (c.f. Table 6), which is insufficient to compensate for the reduced aerosol formation.

The bottom left panel of Figure & shows the corresponding changes in surface [NO₃] as shown for HNO₃ for Europe. The observational composites show that [NO₃] is almost twice that of the corresponding [HNO₃(g)] during wintertime, with similar concentrations during summertime. Unlike for HNO₃(g), a shallow concave seasonal cycle exists in the weekly observational composites, related to seasonal differences in temperatures lifetime (Tang et al., 2021). Both Cy48rl and Cy49rl NOE4C fail to capture the correct seasonality and exhibit higher concentrations during summertime, resulting in substantial positive biases of 1-2 µg/m3. Considering the associated biases in [HNO₃(g)] shows that the HNO₃-NO₃ partitioning is not captured well. For Cy49r1 the description of the seasonal cycle is significantly improved due to the inclusion of EQSAM4Clim, resulting in much lower biases of $< 0.5 \mu g/m^3$ throughout the year, also pointing to the importance of a better representation of gas/particle partitioning. The right bottom panel of Fig. 8 shows the corresponding changes in [NO₃] against weekly composites from the CASTNET measurement network. A similar seasonal cycle exists as for Eu similar concentrations. For Cy48r1 and Cy49r1 NOE4C an inverse seasonal variability occurs in [NO₃] as compared with the observational weekly means, resulting in significant positive biases of around 1.0-1.5 μμg/m³. For Cy49r1 biases decrease by an order of magnitude and the seasonal variability is improved markedly, again showing improved particle distribution when using EQSAM4Clim.

Moved up [5]: Dry Deposition

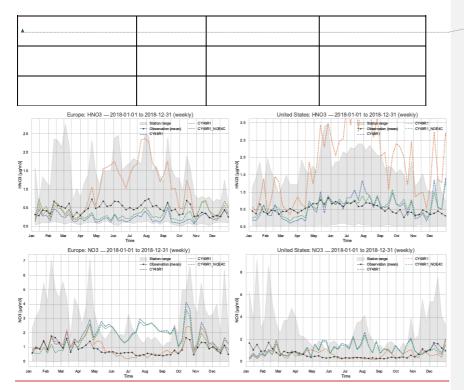

Figure 8: A comparison of weekly mean [HNO₃(g)] and [NO₃] for Europe (left panels; μg/m³) and the US (right panels) at the surface as simulated in IFS-COMPO as compared against measurement composites from EBAS (left) and CASTNET (right) stations for 2018. The various simulations are defined within the panels and the grey band represents the variability in the measurement values across stations.

In Figure 2 we show the corresponding regional distributions of the annual mean [NO₃] for Cy48r1 and Cy49r1 during 2018 for the three chosen regions, where the associated changes in the regional annual mean statistics are provided in Table 7. Some commonality exists between the changes shown for annual mean [NH₄†] and annual mean [NO₃], due to the speciation of the SIA involved. The cumulative sums of the smaller nitrate particle (fine mode NO₃ in Table 6 with the form NH₄(NO₃)) and the larger nitrate particle (coarse mode NO₃ in Table 6 with the form of CaNO₃ and NaNO₃) are both included in the plots. Therefore the changes evaluated here are a combination of changes to both the fine and coarse mode NO₃, rather than the changes associated with individual particle sizes. In contrast to the reduced N analysis provided above, which is impacted more directly due to changes in the fine mode NO₃, the [NO₃] is also indirectly affected by the coarse mode assumptions through the effect of cations on the neutralisation level that subsequently controls the gas/aerosol equilibrium partitioning. The change in the partitioning for HNO₃ shown above results in an associated reduction in the fraction of NO_x held in particulate form due to e.g. a higher dry deposition component.

For Europe, the simulated annual mean $[NO_3^-]$ in $\underline{Cy48r1}$ generally ranges between $0.2\underline{-2.0}$ $\mu g/m^3$ over Scandinavia/Spain and the surrounding seas and between $2\underline{.0}$ -6.3 $\mu g/m^3$ over North-Western/Central Europe and the Mediterranean, becoming lower towards the North-East and South-West. The highest European NO_x emissions occur around the South-East of the UK, Benelux, the Ruhr and Po valleys (e.g. Liu et al., 2021; van der A., 2024). This, and the rather homogeneous distribution within Central Europe shows that a significant degree of transport occurs once NO_3^- particles are formed. No such continental gradient in the annual mean $[NO_3^-]$ exists in the observational mean values indicating an overestimate in IFS-COMPO. Nevertheless, in $\underline{Cy49r1}$ decreases of $[NO_3^-]$

] of between 2-4 μ g/m³ occur for the Baltic states/France/Germany and over the Mediterranean Sea (from relatively high shipping NO_x emissions) compared to Cy48r1. This results in much better agreement with the annual mean observed values for the individual measurement stations. The annual regional MB is reduced by \cong 90%, decreasing to 0.1 μ g/m³ in Cy49r1 with an associated increase in the correlation coefficient due to lower transport of $[NO_3^*]$ out of the main source region. A large impact occurs due to the acidification of sea salt aerosols under relatively high NO_x emission from dense shipping lanes, which can be seen by similar $[NO_3^*]$ reductions over the sea, though difficult to evaluate due to the lack of sufficient measurements.

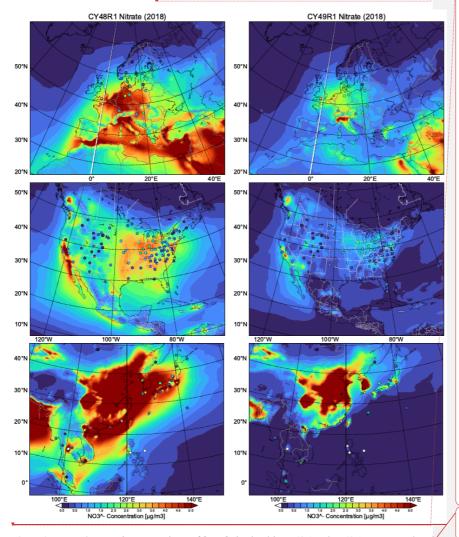

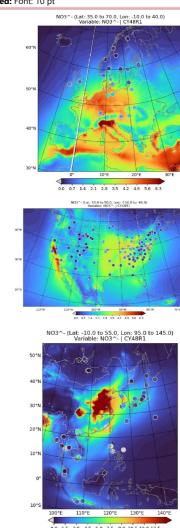

Figure 9: Comparisons surface comparisons of [NOs] simulated in Cy48r1 and Cy49r1 as compared against measurements for the three selected regions given in $\mu g/m^3$. The corresponding regional statistics are provided in

Table 7. The site locations used are shown in each pane and taken from the EMEP, CASTNET and EANET networks respectively.

For the U.S., there is a similar impact on $[NO_3^*]$ as shown for Europe, where the high annual MB in $[NO_3^*]$ decreases significantly (94%) from Cy48r1 to Cy49r1. For Cy48r1, $[NO_3^*]$ typically ranges between 2-4 $\mu g/m^3$ with medium-range transport resulting in appreciable concentrations over the surrounding oceans. Considering the precursors, there is surprisingly little variability in the observed annual mean $[NO_3^*]$ despite the large difference in the resident $[HNO_3(g)]$ across different states of the U.S. related to the distribution of the NO_3 emissions (Figure 7; Goldberg et al., 2021). Only in the southwest, around California, the annual mean $[NO_3^*] > 2.0 \ \mu g/m^3$, shows typical annual mean $[NO_3^*]$ being $\leq 1.0 \ \mu g/m^3$ in Cy49r1 for the majority of the U.S. This implies that the cations used as input for EQSAM4Clim imposes a limit concerning the phase-transfer of $HNO_3(g)$ into more acidic aerosols via neutralisation of the anions by cations in the particle phase.

5 The changes in regional wet deposition

In this section, we evaluate the temporal distribution and biases associated with the annual wet deposition terms of soluble trace gas species and particulates. All three SIA are lost to the surface by both dry and wet deposition processes. Over the last decades the main source of acidification has shifted from SO_x based to NO_x based in line with the reduction measures imposed for SO_x and the increase and associated emission changes from e.g. road transport. Here we evaluate whether the current version of IFS-COMPO captures the correct wet scavenging for the various dissolved precursors and SIA. Evaluations are made using comparisons of model output against annual wet deposition totals as taken from the observational networks, introduced in Sect. 3. The concentrations of the dissolved precursors (i.e. SO₂(aq), NH₃(aq) and HNO₃(aq)) also undergo wet deposition (in IFS-COMPO) and cannot be differentiated well in the observational networks but are included in the measured totals. The wet deposition term is also influenced by meteorological parameters such as the simulated large-scale and convective mixing, liquid and solid precipitation droplet size, SAD, and the frequency and intensity of precipitation as provided by the IFS model.

In Table $\[\frac{9}{8} \]$, the changes in the global tropospheric burden, lifetime, dry and wet deposition totals for $SO_4^{2^-}$, $NH_{\frac{1}{4^-}}$, NO_3^{-} (fine) and NO_3^{-} (coarse) during 2018 across all simulations are given. The corresponding statistics for the comparison with observations for the wet deposition annual means of SO_x , reduced N and oxidised N are provided for the three chosen global regions in Table $\[\frac{9}{4^-} \]$.

Table &: The global budget values for the burden, tropospheric lifetime, wet and dry deposition terms for SO₄², NH₄⁺ and NO₃⁻ for 2018. Totals are provided in Tg S/year and Tg N/year. Percentage difference changes are are calculated as ((Cy49r1-Cy48r1)/Cy48r1)*100 and given in parentheses.

Figure 10 shows the regional distribution of annual wet S deposition for Europe, the U.S. and South-East Asia in both Cy48r1 and Cy49r1 during 2018. To allow a direct comparison across regions we use a colour scale which covers values Jarger than 500 mgS/m²/year, in South-East Asia. The global budget terms for SO₄²- are presented in Table and show that, in spite of the global burden increasing by one third, only very small increases of a few percent occur in the annual wet SO₄²- totals (Rémy et al., 2024). However, the significant increase in the tropospheric SO₄²- lifetime means more remains in the aerosol phase will impact the degree of scattering in IFS-COMPO as shown for AOD comparisons in Remy et al. (2024). The most significant change is in the direct gasphase production term of H₂SO₄(g), where increases in [SO₂(g)] subsequently increase the total mass scavenged into aqueous cloud droplets. This results in an extent of acidification (slowing in-situ oxidation; c.f. Table 2), which is somewhat buffered by the increased phase transfer of NH₃(g) (c.f. Table 4). Although there is a 15% reduction in the total global SO₂(aq) wet deposition, the increases in [SO₄²-(aq)] results in an increase in the cumulative wet S deposition annual totals.

For Europe (top panels), the changes between model simulations are similar to the changes in the SO₂(g) and SO₄²-particle concentrations discussed in Sect. 4. Compared against the annual EMEP mean observational values, which range from 100-900 mgS/m²/year, there is generally an underestimation in Cy48rl of approx. 100-150 mgS/m²/year for North-West Europe, Poland and on the Iberian Peninsular. For other regions the agreement is quite good, capturing the observed deposition gradient from Germany into Austria/Northern Italy. A limited number of measurement stations exhibit very high localised values (e.g. South-West Ireland, Palma), indicating missing primary emission sources in the global inventory. For Cy49rl, strong similarity exists for Benelux, Denmark and Italy, where negative biases of around 50-100 mgS/m²/year occur. A significant negative annual MB exists in Europe, which decreases by around 10% in Cy49rl (c.f. Table 9) with a marginal increase in the correlation. This is impacted by the associated negative MB for SO₂(g) during summertime (c.f. Figure 2) and the large values observed at selected stations influencing the regional mean.

For the U.S. (middle panels) there is a stark contrast to the changes shown for Europe. Assessing the annual mean values from CASTNET shows that an observational gradient exists in the wet deposition annual totals, similar as that for the location of primary SO₂ emission sources (c.f. Fig. 1), with maximal values reaching 300-400 mgS/m²/year towards the East Coast. For Cy48rl, this gradient is captured well albeit with large positive biases of > 100 mgS/m²/year, resulting in a maximal range of 700-900 mgS/m²/year. There is a significant annual wet deposition in the Atlantic (250-300 mgS/m²/year) due to the oxidation of DMS (released from the ocean) and the long-range transport of SO₂(g)/SO₄²⁻ from the anthropogenic source regions. In Cy49rl the area of maximal wet S deposition increases around, e.g., New York State, resulting in an increase in the positive annual MB by nearly 40% to 190 mgS/m²/year. This is in contrast to the significant improvement in the annual MB for [SO₄²⁻] given in Table 3, indicating that there is an increase in the scavenging into the aqueous phase of SO₄²⁻ particles due to the other cumulative updates of IFS-COMPO (c.f. Table 8), in part due to the 10% increase in gas-phase SO₂ to H₂SO₄ (Table 8)

Finally for South-East Asia, (bottom panels), EANET annual wet depositional totals show that more than twice the amount of S deposition occurs as measured in either Europe or the U.S. over an identical timeframe, reaching 1200-1300 mgS/m²/year in Central China and Indonesia. The spatial distribution of stations shows that a positive gradient exists between deposition totals in China and those extending towards Indonesia (2000-2200 mgS/m²/year; not shown). This indicates the importance of the transport component of SO4² when considering the low regional SO2(g) precursor mixing ratios around the equator (c.f. Fig. 1), and that the primary sources are typically infrequent volcanic cruptions for the region between 5°N-5°S (Fioletov et al., 2020) that typically inject the SO2 above the boundary layer (thus with a limited impact on the surface values).

Towards the Coast of Eastern China the observations show annual totals of $250\text{-}350~\text{mgS/m}^2/\text{year}$, in contrast to high values near the middle of China. This is surprising, considering that high SO_2 emissions are defined in IFS-COMPO around South Korea rather than Central China. The implication is that the regional SO_2 emissions employed for this region are likely too high, considering the low regional deposition values. The regional annual MB improves markedly to $8.7~\text{mgS/m}^2/\text{year}$, which is very low considering the high values in the measurements. This is accompanied by a degradation in the correlation coefficient from 0.72 to 0.65.

In Figure 11 we show the corresponding changes in the total annual mean wet deposition of reduced N for both Cy48r1 and Cy49r1 during 2018. The location of the sampling stations is identical to those shown above for the wet S deposition evaluation. In Table 8, the global chemical budget terms for NH₄⁺ show that the cumulative updates to IFS-COMPO increase the tropospheric burden by one third (similar to SO₄², with (NH₄)₂SO₄ being a dominant SIA, Seinfeld and Pandis, 2006), which is subsequently reversed when applying EQSAM4Clim for the description of aerosol and cloud pH, as seen when comparing Cy48r1 and Cy49r1. This results in significant decreases in both the total annual global dry and wet deposition terms, as illustrated for the three select regions (> 50% from Table 8).

For Europe (top panels), where high summertime NH₃(g) mixing ratios are simulated (c.f. Figure 6 in Sect. 4), the EMEP observational annual wet deposition totals show that peak values exist in the Balkans and Northern Italy (Po valley), and that local regional variability exists in e.g. France (ranging between 250-350 mgN/m²/year). For regions with low NH₃ emissions, such as Scandinavia and the Iberian Peninsula, wet deposition totals have a lower range, of between 50-200 mgN/m²/year. For Cy48rl, the high resident surface mixing ratios of NH₃(g) (5-15 pph) results in a relatively high NH₃ annual total wet deposition values of between 350-500 mgN/m²/year for North-West and Central Europe at a country-wide scale (e.g. Benelux, Austria). Measured annual mean values are typically exceeded, which results in an annual MB of 61 mgN/m²/year, albeit with a high correlation of 0.69 (c.f. Table 2). The continental distribution is therefore represented well, although high values extend too far to both the East and West of Europe. Comparing the annual mean temporal distribution simulated in Cy49rl shows a reduction in the area with maximal values (> 450 mgN/m²/year). The reduction in [NH₄*] (c.f. Table 4) reduces the annual MB in wet deposition by nearly 60%, without any notable degradation in the correlation coefficient. Thus, the application of EQSAM4Clim significantly improves the simulation of reduced N wet deposition in IFS-COMPO for Europe.

For the U. S. (middle panels), the AMON observations show that there is a similar East-West gradient in the total reduced N wet deposition totals as that for NH₃(g) surface mixing ratios and [NH₄*] distributions. The range in observed total wet deposition values is between 30-400 mgN/m²/year showing that, in the absence of local NH₃ emission sources, that levels of deposition are rather low (lower than that observed for Europe). Comparing the temporal distribution of reduced N wet deposition in Cy48rl shows that the continental gradient is captured, although maximal values which occur towards Iowa are not seen in the measurements (>100% MB) being influenced by the high local NH₃ emission flux, For the East-Coast, where most primary NH₃ sources are located, there is generally an overestimation in the wet deposition simulated in Cy48rl. Compared to Europe, the annual MB for the U. S. is low at 9 mgN/m²/year. This low annual MB is a result of a large positive bias towards the East that is moderated by underestimates in other parts of the U.S. . However, a high degree of correlation (R=0.72) is achieved for Cy49rl. Although the spatial distribution of NH₄* is similar between model cycles, the reduction in [NH₄*] results in associated reduction of 21% in the annual MB and a slight degradation in the correlation coefficient.

For South-East Asia, the EANET observational annual mean wet deposition totals show that much higher values occur than for the other two regions presented. Similar to that shown for wet S, values range between 200-2400 mgN/m²/year (not shown), with the highest measured values in Indonesia and Vietnam. The simulated temporal distribution in wet reduced N deposition does capture the variability across individual strations quite well across a wide area. In Cy48r1, the annual MB is 12 mgN/m²/year on high annual totals resulting in it being the lowest for all the regions, with a high correlation coefficient of 0.75. For Cy49r1, there is a larger negative MB (although still relatively small compared to the large totals), in-spite of the lower (positive) MB simulated for the [NH4] comparisons as compared to Cy48r1 (c.f. Table 5).

excess remaining in the gas phase, which impacts the results shown in this section. Note that the particulate NO_3° takes various chemical forms in IFS-COMPO ($Ca(NO_3)_2$, $NaNO_3$, KNO_3 , NH_4NO_3), therefore there is only partial commonality between the changes shown for NH_4^+ and NO_3° . With the application of EQSAM4Clim, the surface concentration and burden of NH_4^+ decreases strongly, while the gas phase concentration of HNO3 increases (c.f Table \mathcal{L} and Figure \mathcal{L}).

For Europe (top panels), the EMEP observational annual total wet deposition values show that there is a rather constrained range in total oxidised N deposition (150-275 mgN/m²/year). This correlates with a rather homogeneous distribution of [NO3⁻] shown in Sect. 4.3; a few high outliers are most likely affected by strong local NO₂ emission sources. Although there are rather modest differences in cumulative wet deposition of [NO3⁻] between Cy48rl and Cy49rl, there is a marked improvement in the regional bias in the oxidised N wet deposition term, which decreases by 80% turning from positive to negative, albeit with no significant improvement in the (time-sensitive) correlation.

For the U.S. (middle panels), higher values of oxidised N deposition occur towards the East Coast as defined by the distribution of NO_x emissions (Figure 12). The range in CASTNET observational total wet deposition values is between 50-500 mgN/m²/year, exhibiting a strong longitudinal gradient. Although this gradient is captured rather well, there is typically an overestimation of between 100-200 mgN/m²/year for e.g. New York state and the surrounding regions in Cy48r1. For the Western U.S., observations provide the range of between 0-100 mgN/m²/year, with positive model biases of 100 mgN/m²/year for the North-Western states in both model versions. For the Southern U.S., Cy48r1 exhibits overestimates of 50-70 mgN/m²/year, which decreases noticeably in Cy49r1. There is a large positive bias in Cy48r1 of 130 mgN/m²/year which is improved in Cy49r1 decreasing by 23%. Again the Pearsons R value remains relatively unaffected showing the governing influence of the spatial distribution of the main point sources and a little effect on the forecasts itself (since IFS-COMPO is not employed here as a fully coupled forecasting system using data assimilation).

For South-East Asia, (bottom panels), the range in the EANET observational total wet deposition values is between 50-800 mgN/m²/year, with the highest values of >2000 mgN/m²/year occurring on the Malaysian Coast. For Northern China, total wet deposition values of up to 400 mgN/m²/year occur, which is approximately half that observed near the Southern Coast and towards the East. The highest simulated wet deposition totals occur towards the South-West of China, correlating with high NO_x emissions. Comparing _Cy48r1 and _Cy49r1 shows that a marked decrease of 31% occurs between cycles, again with limited changes to the correlation.

6 Conclusions

In this paper we build on the previous evaluations of the performance of IFS-COMPO Cy49r1 presented in Rémy et al. (2024), which evaluates the impact of EQSAM4Clim and its revised calculation of aerosol and cloud pH (Metzger et al., 2024) on its ability to improve air quality Corecasts by segregating and investigating the individual inorganic components. To scrutinise its effect on the atmospheric composition, we compared the current operational IFS version, that contains a rather basic description of aerosol and cloud pH Cy48r1), with the next operational IFS version, which uses EQSAM4Clim in combination with a unified wet scavenging approach and other developments (Cy49r1). Further improvements are also made with respect to both in-cloud and below cloud scavenging of soluble trace gases and aerosols through an implementation of updated parameterizations as detailed in Rémy et al. (2024).

We have shown that the most significant impacts of our IFS-COMPO updates <u>concern</u> the production efficacy of SIA and subsequent phase partitioning of reduced/oxidised nitrogen species. Comparing simulations with and without EQSAM4Clim, shows that changes in SIA are principally caused by altering the gas/aerosol partitioning. The verification and analysis <u>has been presented</u> for three dominant <u>global</u> source regions (Europe, the U.S. and South-East Asia), where we focus on evaluations of SIA surface concentration and wet deposition totals, by comparing against <u>weekly/ammual</u> observational composites for 2018.

For SO₂(g)/SO₄², the conversion rate only exhibits moderate changes, For SO₂(g), an increase in the global tropospheric burden of 7% indicates less phase transfer due to limitations in the uptake imposed by the increase in the solution pH_e An increase in the gas phase production term of H₂SO₄(g), which is subsequently scavenged, offsets a modest reduction in the aqueous phase production term. For surface [SO₂(g)], this results in a lower mean annual bias for Europe with moderate correlation and a corresponding higher negative bias for the U.S. and with little correlation. No appreciable impact occurs for China, which shows a high positive bias of 11.5 μg/m³ with respect to CNEC and a correlation coefficient near zero. For [SO₄²-] there is an increase in both the tropospheric

which evaluates the impact of EQSAM4Clim and its revised

burden and lifetime by one third due to the updates made to IFS-COMPO, with an associated reduction in the annual mean biases for Europe and the U.S. and increases in the corresponding correlation coefficients. However, for China there is a degradation in the performance which is associated with a positive annual mean bias and a decrease in the correlation coefficient.

For NH₃(g)/NH₄⁺ the changes are more substantial, resulting in beneficial improvements in the global modelling of reduced nitrogen. For NH₃(g) the tropospheric burden almost doubles due to a halving of the conversion rate into NH₄⁺, where more NH₃(g) is directly deposited to the surface. For surface [NH₃(g)], there is a contrasting change in the simulated weekly mean bias between Europe and the U.S. . For Europe, there is no significant improvement on the persistent high weekly mean biases, which increase by 10-25% during the spring and summer time despite all updates. For the U.S., the lower weekly [NH₃(g)] has an associated low bias in the simulations, meaning the increase in the tropospheric burden improves the surface comparison markedly. For [NH₄⁺] in Europe, the application of EQSAM4Clim results in limited changes in the simulated weekly bias during the wintertime while significant reductions are found during summertime, with an associated increase in the annual mean correlation. For the U.S. and China, similar reductions in the annual mean bias of nearly 50% occur although the correlation is depreciated.

For HNO₃(g)/NO₃⁻ the changes are similar to those simulated for the NH₃(g)/NH₄⁺ partitioning due to the speciation of the SIA being mainly linked via NH₄NO₃. The gas-phase production of HNO₃(g) increases without an associated increase in the global tropospheric burden due to increases in the loss to surface via dry deposition. The application of EQSAM4Clim increases the fine aerosol component whilst reducing the coarse aerosol component, which reduces the fraction of HNO₃(g) held in the particulate phase by 50%. For HNO₃(g) in Europe and the U.S., there is a persistent negative bias which is changed to a significant positive bias. For [NO₃⁻], significant improvements in the annual mean biases occur across the globe as illustrated by the three chosen regions, which comes with improvements in the simulated correlation coefficients.

EQSAM4Clim significantly influences wet deposition processes through its impact on aerosol loading and gasaerosol partitioning. By altering the aerosol and cloud pH, the scheme modulates the chemical oxidation rates of precursor gases such as NH3, SO2 and HNO3. This, in turn, affects the formation and partitioning of SIA, their hygroscopic growth, and their subsequent removal of both dry and wet deposition pathways - including in-cloud and below-cloud scavenging. These changes also influence the aerosol radiative effects, both directly and indirectly, underscoring the interconnected role of thermodynamic aerosol modeling in atmospheric composition and deposition simulations.

For the wet deposition component, changes in the SIA concentrations are qualitatively similar to the annual wet deposition totals, although regional changes are variable and species specific. For Europe, there are reductions in the simulated annual mean bias for all three chemical types, with oxidised N improving markedly. For the U.S., the annual mean bias increases for wet S deposition, with decreases in biases for both reduced wet N and oxidised wet N. For South-East Asia, there is a marked improvement in wet S deposition, a moderate improvement in oxidised wet N and a degradation in reduced wet N. Overall, the recent improvements brought by EQSAM4Clim (Metzger et al., 2024) as applied here and in Rémy et al. (2024), shows that Cy49r1 is fit-for-purpose with respect to capturing regional particle concentration and the loss terms via wet deposition.
