19	Abstract
20	The optimal spatial layout of a radar wind profiler (RWP) network for, rainfall forecasting, especially 删除: for
21	over complex terrain, remains uncertain. This study explores the benefits of assimilating vertical wind 删除: in
22	measurements from various RWP network layouts into convective-scale numerical weather prediction
23	(NWP) through observing system simulation experiments (OSSEs). Synthetic RWP data were
24	assimilated into the Weather Research and Forecasting (WRF) model using the National Severe Storms
25	Laboratory three-dimensional variational data assimilation (DA) system for three southwest (SW)-type
26	heavy rainfall events in the Beijing-Tianjin-Hebei region. Four types of DA experiments were
27	conducted and compared: a control experiment (CTL) that assimilates data solely from the operational
28	RWP network, and three additional experiments incorporating foothill (FH), ridge (RD), and combined
29	foothill-ridge (FH_RD) RWP network layouts. A detailed examination of the 21 July 2023 case reveals
30	that the FH_RD experiment generally exhibits more skillful storm forecasts in terms of areal coverage,
31	storm mode, and orientation, benefiting from refined mesoscale wind analysis. Particularly, in the RD 删除: i
32	experiment, RWP data assimilation notably reduces wind errors and improves the representation of
33	mesoscale atmospheric features, near the Taihang Mountains upstream of Beijing, crucial for 删除: enhances mesoscale dynamics
34	convective initiation (CI). Aggregated score metrics across all cases also indicate that both FH and RD
35	experiments offer substantial added value over the operational network alone. Further sensitivity
36	experiments on vertical resolution and maximum detection height indicate that the RWP system
37	configuration with the highest detection height achieves the best performance, while lower detection
38	height degrades forecast quality. These findings highlight the importance of strategic RWP network
39	placement along the Taihang Mountains' ridge and foothill for short-term quantitative precipitation
40	forecast in the Beijing-Tianjin-Hebei region.

41 **1 Introduction**

42 Radar wind profilers (RWPs) are state-of-the-art meteorological observation instruments that 43 provide wind profilings at 6-min intervals with a vertical resolution ranging from 60 to 240 meters. 44 enabling the detection of fine-scale atmospheric dynamic structures throughout the troposphere. 45 Researches have demonstrated the capability of RWP to observe the evolution of mesoscale cyclonic 46 circulations, shear lines, and low-level jets (LLJs), which are closely associated with the development 47 of heavy rainfall and convection (Dunn, 1986; Guo et al., 2023; Liu et al., 2003; Wang et al., 2023; 48 Zhong et al., 1996). The wind observations from RWPs are expected to improve initial conditions and 49 severe weather forecasts for convective-scale numerical weather prediction (NWP) through data 50 assimilation (DA). Significant progress has been made in RWP data assimilation, resulting in wind 51 analysis error reduction and short-term forecast skill enhancement (Benjamin et al., 2004; Bouttier, 52 2001; Ishihara et al., 2006; Liu et al., 2022; St-James & Laroche, 2005; Wang et al., 2022; Zhang et al., 53 2016). Furthermore, efforts in developing quality control and observation operator schemes are also 54 critical to ensuring the reliability of the observations and enhancing assimilation effectiveness (Wang et 55 al., 2020; C. Wang et al., 2023; Zhang et al., 2016; Zhang et al., 2017). 56 In China, the deployment of a nationwide <u>RWP</u> network initiated in 2008, with over 260 sites 57 established by the end of 2024. These sites primarily utilize the 1290 MHz Doppler radar to monitor 58 the lower and middle atmosphere (Liu et al., 2020). Currently, the nationwide <u>RWP</u> network is 59 unevenly distributed: the spatial concentration of RWP sites over densely populated metropolitan 60 regions, such as the Beijing-Tianjin-Hebei region, Yangtze River Delta, and Pearl River Delta, are 61 above the national average, while the other regions, especially in west-central China, are lagged behind. 62 Notably, in regions where observation data is relatively abundant, there is still an issue of uneven 63 spatial distribution of stations, mainly due to the terrain complexity. Taking the RWP network in the 64 Beijing-Tianjin-Hebei (BTH) region as an example, seven RWPs are deployed in Beijing within an 65 area of approximately $100 \text{ km} \times 100 \text{ km}$, while there are only 11 profilers in the whole Hebei province 66 (Wang et al., 2022; refer to blue stars in Fig. 3).

67 Accurate short-term forecasts of heavy rainfall are crucial for mitigating the risks posed by 68 severe weather events in the BTH region, one of China's most densely populated and economically 69 vital areas. The BTH region includes the cities of Beijing and Tianjin, and the Hebei Province, and is 删除: high vertical and temporal resolution

70	bounded by the Taihang Mountains to the west and Bohai Bay to the east (Fig. 3). Its complex terrain
71	features with high elevations in the northwest and north, gradually transitioning into plains in the south
72	and east. The dominant, weather circulations affecting heavy rainfall in the BTH region include the cold 删除: ting
73	vortex, the cold trough, and the trough-anticyclone patterns (Sheng et al., 2020; Zhao et al., 2018; Zhou
74	et al., 2018). The complex underlying surface and the interaction with synoptic- and mesoscale 删除: large
75	weather processes make the initiation and maintenance mechanisms of convective systems in the BTH
76	region highly unique. Convective initiation (CI) is especially difficult to predict due to local
77	environmental uncertainties and the rapid evolution of meteorological variables. The existing RWP
78	network <u>is mainly located</u> in urban and lowland areas (Fig. 3, blue stars), while the mountainous 删除: concentrated
79	regions like <u>the</u> Taihang Mountains, where significant terrain-induced convection <u>occurs</u> , are in 删除: occurrs
80	shortage of sufficient wind profile observations (Liu et al., 2020). These observational gaps can lead to
81	suboptimal initial conditions in NWP models, thereby reducing the accuracy of short-term precipitation
82	forecasts. Therefore, optimizing the distribution of the RWP network, particularly in the Taihang
83	Mountains, could strengthen the ability to monitor these critical regions and improve quantitative
84	precipitation forecasts.
85	Observation System Simulation Experiments (OSSEs) are widely used to assess the impact of
86	assimilating specific observational data into NWP models (Huang et al., 2022; Zhao et al., 2021a).
87	Previous studies by Zhang & Pu (2010) and Hu et al. (2017) have demonstrated the effectiveness of
88	OSSEs in evaluating the benefits of assimilating <u>RWP</u> data for improving forecasts. Recent research 删除: wind profiler
89	(Bucci et al., 2021; Huo et al., 2023) has also highlighted the advantages of joint assimilation of
90	multiple observational platforms to enhance analysis of convective dynamics, underlining the
91	importance of an optimized RWP network. These OSSEs have provided valuable insights into the
92	strategic RWP site placement to maximize their impact on model performance. To our knowledge,
93	there are few peer-reviewed published research investigating the potential benefit of <u>a RWP network in</u> 删除: s
94	complex terrain on mesoscale and convective scale weather forecasts_(Bucci et al., 2021; Hu et al., 删除: associated with
95	2017; Huo et al., 2023; Zhang and Pu, 2010).
96	To investigate the impact of <u>a</u> RWP network <u>in</u> complex terrain on heavy rainfall forecasts, we 删除: associated with
97	focus on southwest (SW)-type rainfall events associated with southwesterly flow, which constitutes
98	approximately 40% of the total circulation patterns in the BTH region during early summer (Li et al.,
99	2024; Zhou et al., 2018). When warm, moist air from the south meets the cold air from the Taihang
	4

Mountains, the terrain causes the air to rise, enhancing convective activity. Meanwhile, the topography of the Taihang Mountains affects the distribution and intensity of the wind field, particularly during severe convective weather events_(Li et al., 2024; Sheng et al., 2020). For example, <u>a</u> prior study showed that the quasi-linear convective systems with extreme heavy rainfall primarily occurred at the foothills of the Taihang Mountains or in the plains close to the foothills (Sheng et al., 2020). To address observational gaps, simulated RWP stations are strategically placed along the ridge and foothills, reinforcing the existing operational network.

107 In this study, the following questions will be addressed. How does the assimilation of RWPs 108 from ridge and foothill sites combined with that from operational stations impact heavy rainfall forecast 109 in the BTH region? Do ridge and foothill networks offer added forecast skill over the operational RWP 110 network on short-term convective-scale NWP? Are the benefits of assimilating RWP observations 111 sensitive to the vertical resolution and maximum detection height of profilers? Ultimately, this research 112 aims to provide guidance on optimizing the RWP network to improve forecasting accuracy for heavy 113 rainfall events in the BTH region, thereby enhancing disaster preparedness and response strategies in 114 the region.

To address these questions, a series of OSSEs are conducted, assuming a perfect model, using three representative southwest (SW)-type heavy rainfall cases. The remainder of this paper is organized as follows: Section 2 provides an overview of <u>the NWP</u> model and data assimilation system. Truth and background simulation configuration, synthetic observations, experiment design, and evaluation methods are presented in Sect. 3. Section 4 presents the analysis and forecast results for the 21 July 2023 case, as well as the aggregated performance across all three cases. Section 5 summarizes the key findings and conclusions.

122 2 Model and Data Assimilation System

126

123 The forecast model used in this study is the version 3.7.1 of the Weather Research and

- 124 Forecasting Model (WRF) with the Advanced Research WRF (ARW) dynamic solver (WRF-ARW;
- 125 Skamarock et al., 2008). All DA and forecast experiments are performed on a 1.5-km grid of 408×480

157	is quite suitable for the severe weather forecasts by providing highly efficient and rapid updating
158	analysis and forecast, such as 15-min cycle intervals. Our focus is to assess the potential impacts of
159	RWP network enhancements on convective-scale analysis and short-term severe weather prediction
160	with this efficient DA method, so we did not use the ensemble derived background error covariance,
161	which is also incorporated in the variational framework (Gao et al., 2016; Gao & Stensrud, 2014; Wang
162	et al., 2019). The background error covariance matrix used in this study is constructed as the product of
163	a diagonal matrix representing the standard deviations of background errors and a spatial recursive
164	filter (Gao et al., 2004, 2013). The standard deviations for the pressure, potential temperature, relative
165	humidity, zonal and meridional wind components are derived from the statistics of the Rapid Update
166	Cycle (RUC, Benjamin et al., 2004) 3-hour forecasts over several years (Fierro et al., 2019b; Pan et al.,
167	2021). The background error correlations are modeled by the recursive filter described by Purser et al.
168	(2003a, b). The recursive filter can be applied in multiple passes (or outer loops), using different
169	correlation length scales tailored to the scale of the weather systems represented by the assimilated
170	observations.

171 **3. Experimental design**

172 **3.1 Truth run and background run for OSSE**

173 In the OSSE, synthetic RWP observations are generated by adding observation errors to the truth 174 run. To obtain this truth run, the WRF model is initialized with the fifth-generation European Centre 175 for Medium-range Weather Forecasts (ECMWF) atmospheric reanalysis of the global climate (ERA5; 176 Hersbach et al., 2020; Hoffmann et al., 2019), based on the model configuration and parameterization 177 schemes described in Sect. 2. Three SW-type heavy rainfall cases that occurred over the 178 Beijing-Tianjin-Hebei region on 28 June, 12 July, and 21 July of 2023 are selected to construct OSSEs 179 and assess the impact of RWP data observed from different spatial layout schemes on convective 180 initiation and the development of storms. For each case, the model is initialized using the ERA5 data 181 and integrated forward for 15 hours, with the boundary conditions also provided by the hourly ERA5 182 data. An overview of composite reflectivity in the truth simulation from the case on 21 July 2023 is 183 shown in Fig. 1 as an example. This case was characterized by the presence of an upper-level trough 184 gradually moving eastward into the Beijing-Tianjin-Hebei region, accompanied by a corresponding

删除: truth run is cold started from the start of DA cycling

truth simulation from 1300 UTC 20 July to 0300 UTC 21 July, 2023.

197

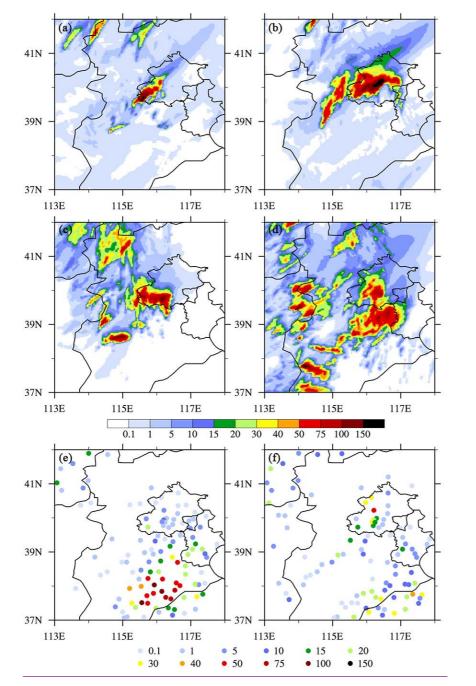

- 200 This study utilizes an OSSE framework with an identical twin setup, where the same numerical
- 201 model is used for both the truth simulation and the forecast system. As noted by Hoffman and Atlas
- 202 (2016), OSSEs with identical twin setups can lead to overly optimistic assessments of data impacts.
- 203 Therefore, the results should be interpreted within the constraint. To mitigate unrealistic assumptions
- about observational capabilities and overly optimistic OSSE results, the first-guess background run
- 205 (NoDA) uses the National Centers for Environmental Prediction (NCEP) Global Forecast System (GFS)

删除: of

206	forecasts for initial and boundary conditions, which differ from those of the truth run. The 6-h
207	accumulated precipitation (APCP) forecasts from the truth and background runs are verified against the
208	rain gauge measurements at national weather stations in the Beijing-Tianjin-Hebei region (Fig. 2).
209	Compared with the rainfall observations (color-filled dots in Fig. 2 e and f), the truth simulation
210	generally captured the southwest-to-northeast orientation and northeastward movement of the observed
211	precipitation in Beijing, although it underpredicted the precipitation in southeastern Hebei (Fig. 2a and
212	b). Conversely, NoDA produced a more west-east oriented rainfall pattern south of Beijing, rather than
213	a southwest-to-northeast band structure. NoDA missed the precipitation in southeastern Hebei (Fig. 2c),
214	whereas it overpredicted the rainfall in western Hebei and areas along Beijing's southern border (Fig.
215	2d). Notably, the NoDA experiment failed to predict the convection in southwestern Beijing during the
216	CI stage (discussed later in Sect. 4.1.2).

218 Figure 2. The 6-h accumulated precipitation (APCP) forecasts (mm, shaded) from 2100 UTC 20 July

Truth, (c)-(d) NoDA experiments, and (e)-(f) the rain gauge measurements at national weather stations.

删除: . The dots represent

221 **3.2** Synthetic RWP observations

222 The real-time Chinese RWP network provides horizontal wind direction, horizontal wind speed,

- and vertical wind speed at 60-240 m intervals, from the ground surface up to 3-10 km, depending on
- the operating frequency (Liu et al., 2020). The network comprises three RWP types: high-troposphere,

 $H(1) = H_{elev} + 500$ $H(k) = H(1) + k \times H_{inc}, \text{ if } H(k) \le H_{max}$ (2)

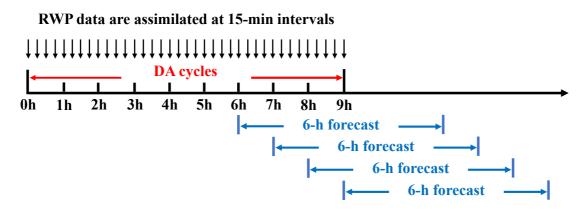

删除:1

where H_{elev} is the elevation of the observation site, *k* is the index number of the vertical level, H_{inc} and H_{max} are specified vertical resolution and maximum detection height, respectively. The units of all height variables are meters. Similar to Zhang et al. (2016), 500 m is selected as the first level of wind profile used for assimilation. The final observations are obtained by adding perturbations to the wind profiles extracted from the truth run. The perturbations are assumed to be normally distributed Gaussian random errors with a mean of zero and a standard deviation of 2 m/s (Hu et al., 2017; Huang et al., 2020; Zhao et al., 2021a).

As our focus is to assess the impacts of assimilating wind observations from various RWP
network layouts on convective-scale analysis and short-term severe weather prediction, only synthetic
RWP data are assimilated in this study, excluding conventional observations such as radiosondes,
surface weather stations, and satellite observations. This exclusion simplifies the analysis by isolating
the impact of RWPs but may inflate their relative importance (Hoffman and Atlas, 2016).

- 267 cycles. For comparison, a first-guess background run (NoDA) is conducted by advancing the model
- 268 forward without assimilating any observations.

271 every hour from the sixth hour to the end of <u>the DA cycles (namely, four separate forecasts)</u>.

To investigate the impact of simulated foothill and ridge RWP networks on convective-scale NWP, four types of DA experiments are performed (Table 1). These experiments differ in their assimilation of synthetic profiler data from various RWP network spatial layouts. The baseline experiment, CTL, assimilates synthetic observations from the operational RWP network with a vertical resolution of 60 m (from 500 m to 8 km height), serving as a benchmark for comparison. This vertical resolution represents a best-case scenario for RWP capabilities.

278 **Table 1**. List of the DA sensitivity experiments based on various spatial layout schemes of radar wind

279 profiler (RWP) network over the Beijing-Tianjin-Hebei region.

Experiment	Operational	Foothill	Ridge	Maximum height (km)	Vertical resolution (m)
CTL	\checkmark			8	60
FH	\checkmark	\checkmark		8	60
RD	\checkmark		\checkmark	8	60
FH_RD	\checkmark	\checkmark	\checkmark	8	60
FH_RD_V120	\checkmark	\checkmark	\checkmark	8	120
FH_RD_H3	\checkmark	\checkmark	\checkmark	3	60
FH_RD_H12	\checkmark	\checkmark	\checkmark	12	60

280 CTL: control DA experiment;

RD: ridge

FH: foothill;

281 The second and third types of experiments assimilate the simulated foothill and ridge RWPs, 282 respectively, in conjunction with data from operational sites (referred to as FH and RD). The fourth 283 type of experiment FH RD is performed by assimilating the operational, foothill, and ridge profilers 284 with the same vertical resolution and maximum detection height as before. Additionally, three 285 sensitivity experiments FH_RD_V120, FH_RD_H3, FH_RD_H12 are designed to assess the influence 286 of assimilating RWP data with different vertical resolution (120 m) and maximum detection heights (3 287 km, 12 km) on the analyses and forecasts, to address the potential usage of real-time data from RWPs 288 operating at different frequencies.

289 In all DA experiments, the background errors for zonal and meridional wind components are 290 specified as 3–6 m/s, gradually increasing with altitude from the surface to 20 km above ground level 291 (AGL). The observation error is set to 3 m/s, based on sensitivity tests within the 2-6 m/s range and 292 consistent with previous studies (Hu et al., 2017; Huo et al., 2023; Wang et al., 2022; Zhang et al., 293 2016). In the minimization process two outer loops are adopted, each with a prescribed horizontal and 294 vertical correlation scale for the recursive filter used in the program (Gao et al., 2004; Purser et al., 295 2003). Following previous studies (Wang et al., 2022; Zhao et al., 2022), The horizontal correlation 296 scale lengths are set to be 50 km in the first loop and 20 km in the second loop, while the corresponding 297 vertical correlation lengths are 5 and 2 grid points, respectively.

298 **3.4 Evaluation metrics**

299 This study examines the impact of RWP DA on wind analyses and forecasts during a southwest 300 (SW)-type heavy rainfall event on 21 July 2023. To obtain an overall insight into the impact of RWP 301 DA on wind analyses and forecasts, time series and probability density distributions, as well as vertical 302 profiles of root-mean-square errors (RMSEs) for wind components during the DA cycles and 6-h free 303 forecasts are calculated for each type of assimilation experiment. Additionally, subjective diagnostic 304 analyses of wind vectors improved by assimilation of RWPs are also discussed in more detail. To 305 investigate the impact on short-term forecasts, both qualitative and quantitative assessments of radar 306 reflectivity and accumulated precipitation forecasts are conducted against the truth run. To evaluate the 307 performance quantitatively, the neighborhood-based equitable threat score (ETS, Clark et al., 2010) is 308 calculated using a neighborhood radius of 12-km for different thresholds of composite reflectivity 309 (CREF) and hourly precipitation (HPRCP). Using the same neighborhood radius and thresholds,

│ 删除: , │ 删除: t │ 删除: .

删除: And

删除: s

310	contingency-table based metrics including the probability of detection (POD), false alarm ratio (FAR),
311	success ratio (SR), frequency bias (BIAS), and critical success index (CSI) are also calculated to
312	quantify the CREF and HPRCP forecasts. To account for case-to-case variability, two additional
313	SW-type heavy rainfall events (28 June and 12 July 2023) are examined. Finally, score metrics are
314	aggregated from each initialization hour (sixth hour to end of the DA cycles) across three cases,
315	ensuring a fair and consistent measure of forecast skill.
316	4 Results and discussion
317	4.1 21 July 2023 case
318	4.1.1 The impact on wind fields
319	The first question we attempt to answer is how the spatial distribution of RWP sites should be
320	planned to optimize the accuracy of short-range convection- <u>allowing_NWP system_(Potvin and Flora,</u> 删除: resolving
321	2015). The influence of assimilating RWP data from different networks, as described in Sect. 3.3, on
322	wind analysis and forecast can be straightforwardly assessed by examining the RMSEs of wind
323	components during the 9-h assimilation cycles and 6-h free forecasts. For clarity, the time series and
324	probability density distribution (PDF) of the wind RMSEs from the CTL, FH, RD, and FH_RD
325	experiments are compared in Fig. 5. The statistics are computed against the truth run at all model levels
326	within the simulation domain shown in Fig. 3. Overall, the RMSEs of wind analyses from all DA
327	experiments during the analysis cycling decrease over the first six hours and then gradually increase
328	afterward, exhibiting an evident staircase pattern (Fig. 5a and c), indicating that the wind field is
329	modified by the NSSL3DVAR system towards the truth in each analysis cycle. A comparison among
330	all DA experiments reveals that the FH_RD experiment yields the smallest wind errors, followed by
331	RD, then FH, with CTL exhibiting the largest errors. This likely occurs because (a) FH_RD assimilates
332	the largest amount of wind observations, while CTL assimilates the fewest, and (b) the uncert <u>ainties of</u> 删除: ia

333	wind field in the background field are larger in mountainous regions than flatlands (this issue will be
334	discussed in detail later in this section). The superiority of FH_RD, RD, and FH over the CTL
335	experiment persists during the subsequent 6-h free forecasts, highlighting the impact of wind profile
336	observations gathered from ridge and foothill networks. It is also noted that the difference in the
337	meridional wind among FH, RD, and FH_RD is more pronounced than that of the zonal wind, which
338	can be related to the varying degree of improvement in the southerly jet intensity. Generally, the PDF
339	figures show that the distributions of wind analyses are skewed towards smaller error values compared
340	to those of forecasts, with the wind forecasts exhibiting a heavy tail towards larger error values (Fig. 5b
341	and d). For example, the analysis errors for the v variable tend to cluster around 1.6–2.6 m/s, while the
342	PDFs of forecast errors show peaks near 2.0-3.4 m/s. The patterns in distributions from different
343	assimilation experiments align with the results observed in the time series analysis.

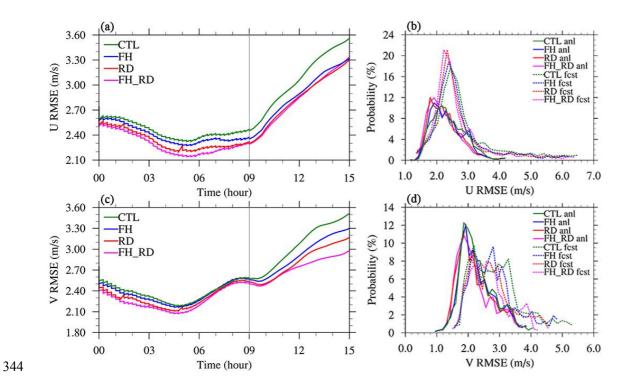

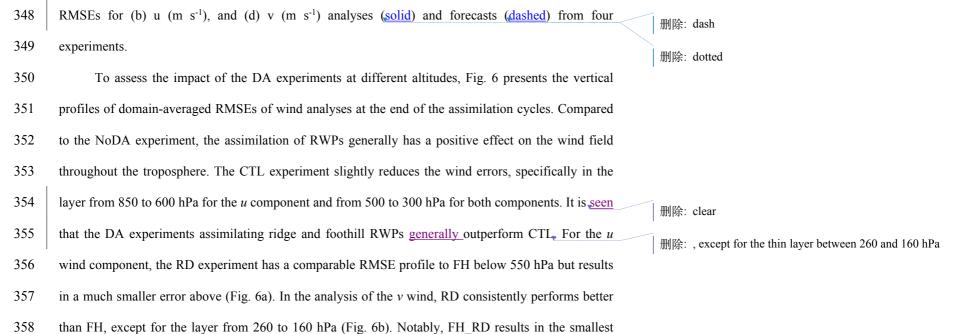

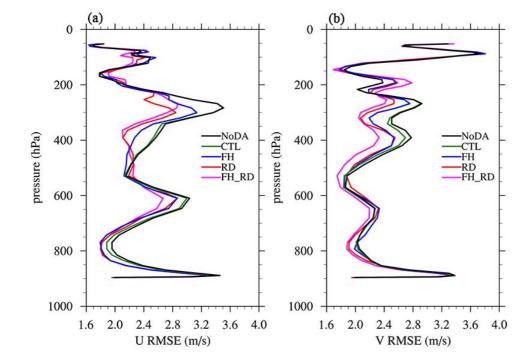

Figure 5. Time series of root-mean-square errors (RMSEs) for (a) u (m s⁻¹), and (c) v (m s⁻¹) analyses
and forecasts from the CTL (green), FH (blue), RD (red), and FH_RD (magenta) experiments. The thin

(red), and FH_RD (magenta) experiments.

To examine how the RWP DA adjusts the mesoscale airflow, we present the 700-hPa wind vectors and wind speeds from all experiments as an illustration of the model's dynamic conditions (Fig. 7). For clarity, Fig. 7b-f compare the differences in wind vectors and wind speeds between the DA 367 experiments and the corresponding field from the truth run. These differences, considered as wind 368 errors, help evaluate how assimilating RWPs from different observation networks adjusts the wind field. 369 The red (blue) color represents positive (negative) wind speed bias compared to the truth. In the NoDA 370 experiment, there is a notable southeasterly wind bias in Beijing and the mountainous regions to its 371 west, characterized by excessively high wind speeds. Conversely, the true simulation reveals a strong 372 southwesterly flow (Fig. 7b). Meanwhile, the southwest wind is remarkably weaker in southwestern 373 Hebei (at the foothills of the Taihang Mountains), and the westerly wind in the upstream Taihang 374 Mountains region is also underestimated. The CTL experiment significantly reduces the easterly wind 375 bias in Beijing and its surrounding areas while enhancing the southwesterly winds in Hebei (Fig. 7c). 376 However, unignorable wind errors persist upstream of Beijing, particularly along the mountainous 377 regions, due to the absence of operational wind profiler sites. The FH experiment produces wind 378 adjustments similar to those in CTL but further reduces wind errors in the plains of Hebei by 379 assimilating observations from foothill sites (Fig. 7d). Conversely, with the assimilation of RWP data 380 from the ridge network, both RD and FH RD significantly reduce positive wind speed errors upstream 381 of Beijing along the mountains, which is crucial for convection initiation (CI) near the boundary 382 between Hebei and southwestern Beijing (Fig. 7e and f). While the southwest winds in southwestern 383 Hebei remain slightly weaker in RD, FH RD addresses this by assimilating ridge RWPs alongside 384 foothill data. However, all DA experiments still show negative wind speed errors and 385 northwesterly/northeasterly wind direction errors near the border of Shanxi, Hebei, and Inner Mongolia, 386 with errors even larger than those in NoDA. This is mainly due to the lack of RWP observations in this 387 tri-provincial border area. As a result, the influence of ridge RWP data may propagate northward into 388 this region by the RD and FH RD experiments, significantly reducing positive errors upstream of 389 Beijing along the mountains but increasing negative errors in this area.

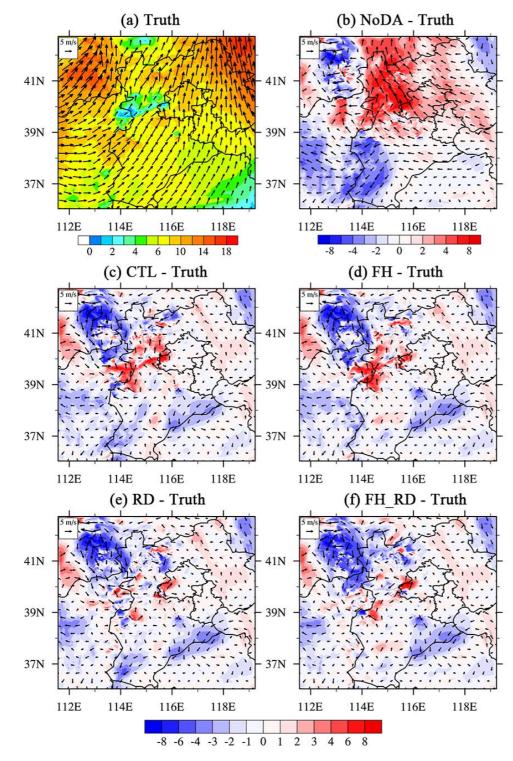

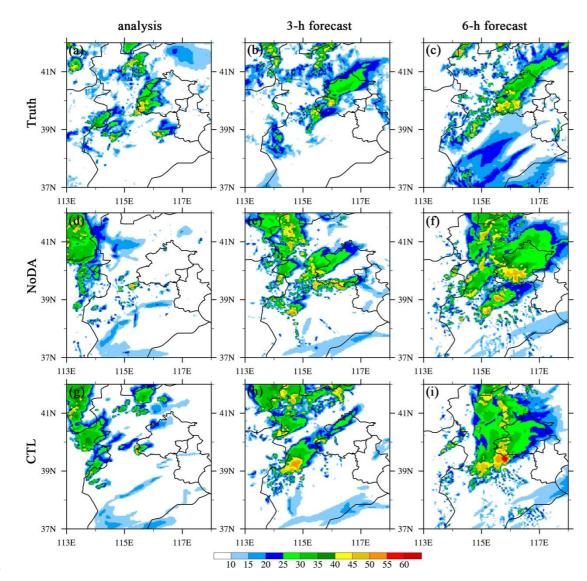

Figure 7. (a) 700-hPa wind (vectors) with wind speed (m s⁻¹, color shaded) from the truth run, and
differences between the 700-hPa winds from (b) NoDA, (c) CTL, (d) RD, (e) FH, and (f) FH_RD
experiments and the truth run at 2100 UTC 20 July 2023 (end of analysis cycling). The red (blue) color
represents positive (negative) wind speed bias compared to the truth.

395 4.1.2 The impact on reflectivity and precipitation forecasts

396 The analysis, along with the 3- and 6-h forecasts of composite reflectivity from all experiments, 397 is compared to the truth run in Fig. 8 and 9. In the southwest of Beijing, a convective system initiates 398 and develops. As it merges with scattered storms originating in western Hebei near the foothills of the 399 Taihang Mountains, the system intensifies rapidly. Eventually the convection becomes a 400 southwest-northeast oriented mesoscale system across the western and central parts of Beijing (Fig. 401 8a-c). At the initial stage, the NoDA experiment underestimates convection in Beijing and Hebei (Fig. 402 8d), but in the 6-h forecast, NoDA overpredicts the storm coverage and intensity in Beijing and 403 produces excessive spurious convection in western and northern Hebei (Fig. 8d-f). At analysis time, all 404 DA experiments show improvement in the location and shape of the convective system in southwestern 405 Beijing, and FH RD produces the strongest reflectivity analysis (Fig. 8g, 9a, 9d, and 9g). This implies 406 that the assimilation of RWP data can improve CI timing and location by capturing the mesoscale flow 407 features in the pre-storm environment (Fig. 7). The RWP DA also helps alleviate storm displacement 408 and intensity errors and suppress spurious cells in subsequent forecasts, owing to a better representation 409 of the storm environment. Although CTL correctly analyzes the CI near the observed location, its 410 analysis and 3-h lead-time reflectivity forecast show that the storm intensity in Beijing is still weaker 411 than the truth simulation, especially over western and central Beijing (Fig. 8g-i). The FH experiment 412 produces stronger storms with a larger coverage area in Beijing compared to the CTL experiment, 413 although the storm intensity remains slightly underestimated; however, spurious echoes to the west of 414 Beijing remain evident in the 6-h forecast (Fig. 9a-c). With the assimilation of ridge RWP data, the RD 415 and FH RD experiments further strengthen the CI process and improve the storm pattern and 416 development. A comparison among all experiments reveals that FH RD demonstrates overwhelming 417 superiority over the other three DA experiments in terms of areal coverage, storm mode, and storm 418 orientation (Fig. 9g-i).

426 Concerning precipitation, the 1-, 3-, and 6-h accumulated precipitation (APCP) forecasts exhibit 427 similar behavior to the reflectivity results in terms of rainfall location, onset time, and amount (Fig. 10 428 and 11). As discussed above, all assimilation experiments predict the initial precipitation area and 429 intensity in the southwest of Beijing more accurately than NoDA, leading to improvements in 430 subsequent APCP forecasts in this area. For example, assimilating ridge and foothill RWPs corrects the 431 weaker biases associated with this storm in the 1- and 3-h forecasts (Fig. 11a-b, d-e, g-h). Meanwhile, 432 the more west-east oriented heavy rainfall occurring over the south of Beijing in the 6-h forecast of 433 NoDA is revised by the assimilation experiments, shifting to a southwest-northeast orientation that is 434 closer to the truth simulation. Although the areal coverage of rainfall in the 1-h forecast is better 435 captured by CTL compared to NoDA, CTL still tends to underpredict the precipitation amount in 22

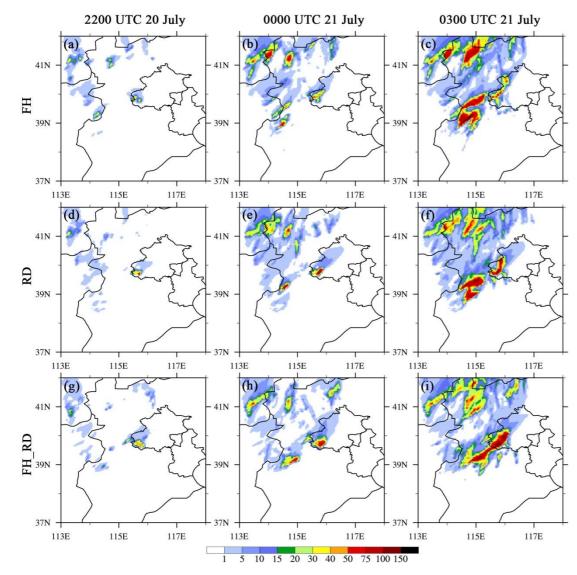

删除: initial

436	southwestern Beijing, while overestimation is commonly observed in parts of the mountainous areas to	
437	the southwest of Beijing (Fig. 10g-i). One potential factor contributing to the overpredicted rainfall in	
438	the mountainous areas to the southwest of Beijing is the CTL experiment's reduction of positive wind	
439	errors in Beijing, while higher wind speeds (compared to the truth) persist along the upstream	
440	mountains. It is due to the absence of operational wind profiler sites. The stronger southwesterly winds	删除: This
441	of the CTL experiment enhance moisture transport and convergence in the upstream mountains, leading	删除: creates a favorable environment for heavy rainfall in the
442	to overestimated rainfall in those areas and underpredicted precipitation over Beijing. Both RD and	upstream mountain and foothill regions
443	FH_RD experiments yield a smaller areal coverage of precipitation at the same region, and they also	
444	better capture the southwest-northeast orientation of the rainband in southwestern Beijing (Fig. 11d-i),	
445	as the large wind errors in the upstream mountains are remarkably reduce by assimilating RWP data	
446	from the ridge network (Fig. 7e and f). As expected, the APCP forecasts from FH_RD align well with	
447	the true rainfall <u>forecasts</u> in terms of placement, orientation, and amount (Fig. 11g-i vs. 10a-c).	删除: estimates

453 Figure 11. Same as in Fig. 10, but for the APCP forecasts (mm, shaded) from (a)–(c) FH, (d)–(f) RD,
454 and (g)–(i) FH_RD experiments.

455 To quantify the performance of the reflectivity and precipitation forecasts by assimilating RWP 456 data from different observation networks, categorical performance diagrams and neighborhood-based 457 ETS are calculated and aggregated over four 6-h free forecasts. These forecasts are launched hourly 458 from the sixth hour to the end of the analysis cycle. All score metrics are computed for a neighborhood 459 radius of 12 km. The ETS for composite reflectivity is calculated every 15 minutes, while for APCP, it 460 is calculated hourly. In the performance diagrams, values of POD, SR (1 - FAR), and CSI closer to 461 unity indicate higher forecast skill, with the perfect forecast located at the upper-right corner of the 462 diagram. A BIAS value greater (less) than unity indicates overprediction (underprediction). Because of 463 decreased PODs along with increased FARs, most experiments show a slight decline in forecast scores when the composite reflectivity threshold increases from 20 to 40 dBZ (Fig. 12). Overall, all DA 464

465	experiments consistently outperform NoDA at all thresholds, exhibiting higher POD, SR, CSI, and ETS	
466	values, except for the CTL (FH and FH_RD) experiment during the 0-4 h (4-5 h) forecast period at the	
467	threshold of 40 dBZ. Among them, the FH_RD, RD, and FH experiments show overwhelming	
468	superiority over CTL for the 0-4 h reflectivity forecasts in terms of ETS, POD, SR and CSI values at all	
469	thresholds. For the 20- and 30-dBZ thresholds, it is evident that FH_RD produces the highest ETS,	删除: Upon further comparison
470	POD, SR, and CSL scores during the 0-3 h forecast period, the improvement in BIAS values was	
471	minimal (Fig. 12a-d). However, for 40 dBZ, the RD experiment achives slightly higher ETS, POD, SR,	│ 删除: and ETS
472	and CSI scores than FH_RD does at most forecast lead times (Fig. 12e and f). It is also worth noting	删除: as well as the smallest BIAS for the 20- and 30-dBZ
473	that, for 20- and 30-dBZ thresholds, FH produces higher ETS, POD, and CSI scores than RD does	thresholds
474	before the 2-h forecast lead time, while RD exhibits better forecast skill thereafter (Fig. 12a-d). This	删除: performs

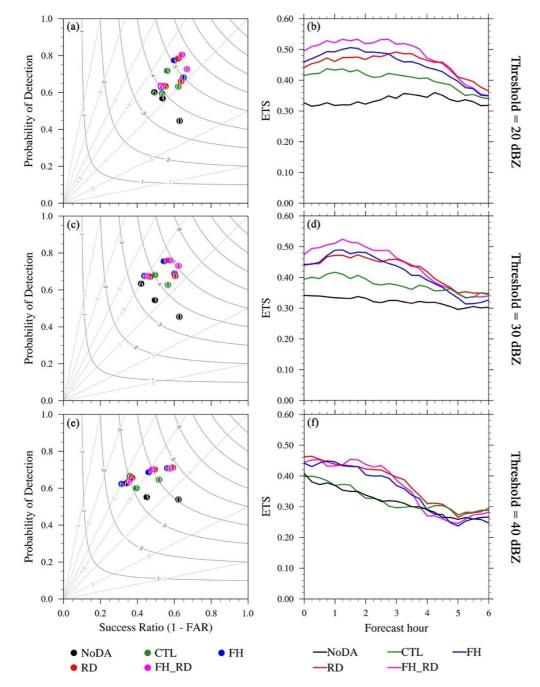

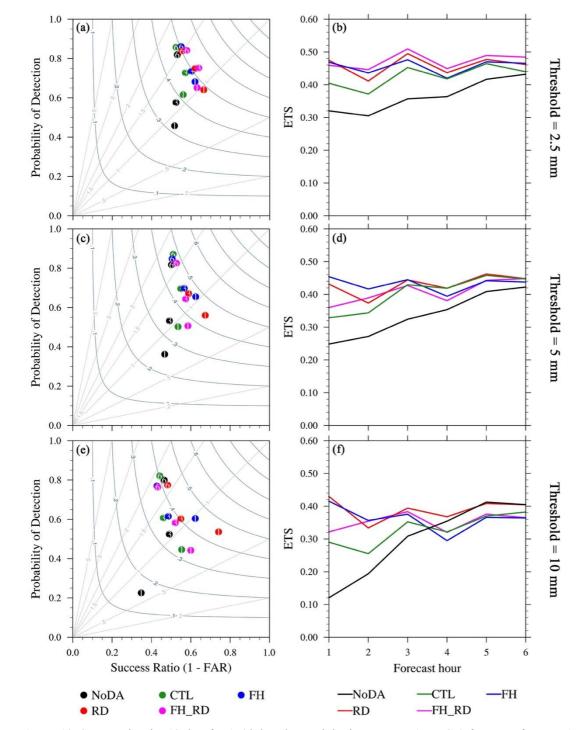

Figure 12. Aggregate score metrics of 0-6 h composite reflectivity (CREF) forecasts aggregated from each initialization hour from the sixth hour to the end of the_DA cycles for case 1 for the NoDA (black), CTL (green), FH (blue), RD (red), and FH_RD (magenta) experiments. (left) The performance diagrams, and (right) the equitable threat score (ETS) for (a)–(b) 20 dBZ, (c)–(d) 30 dBZ, and (e)–(f) 40 dBZ thresholds, respectively. Results are shown for a neighborhood radius of 12-km. The numbers within the colored dots in the performance diagrams denote the forecast hour (i.e. 0-, 3- and 6-h forecasts).

487	A similar trend and behavior are observed in the performance diagrams and ETS figures for the
488	HPRCP forecast, highlighting the superior performance of the RD and FH_RD experiments (Fig. 13).
489	In general, lower score metrics are obtained when a higher threshold for precipitation forecasts is
490	evaluated, likely resulting from a lower frequency of occurrence for heavy precipitation. As seen in the
491	CREF forecast, the FH_RD, RD, and FH experiments show more skillful precipitation forecasts than
492	CTL does. In terms of the 2.5-mm precipitation forecast, FH_RD generally achieves the highest POD,
493	SR, CSI, and ETS, along with the smallest BIAS, with RD exhibiting slightly inferior performance (Fig.
494	13a and b). For the 5-mm threshold, FH generates the highest POD and ETS in the first 3 hours,
495	whereas RD delivers the lowest FAR and largest ETS in the subsequent 3-h forecasts (Fig. 13c and d).
496	The RD experiment outperforms all the other experiments in the 1-, 3-, and 4-h forecasts at the
497	threshold of 10 mm (Fig. 13e and f). One possible reason for the inferior performance of FH_RD and
498	FH compared to RD at higher thresholds is that FH_RD exhibits a slight southward displacement error
499	for the 1-3 h heavier precipitation (>10 mm) forecasts in southwestern Beijing compared to the truth
500	simulation, while the precipitation in the FH experiment is located further north (Fig. 11a-b, 11g-h vs.
501	Fig. 10a-b). This may lead to larger penalties in the calculation of POD and ETS, resulting in lower
502	scores.

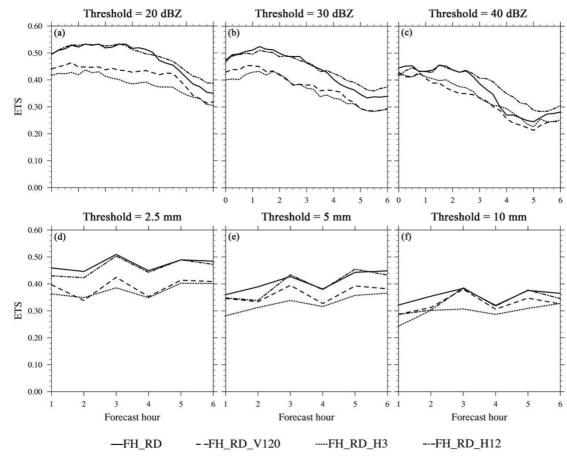

at thresholds of 2.5 mm (1st row), 5 mm (2nd row), and 10 mm (3rd row), respectively.

506 4.1.3 Sensitivity to vertical resolution and detection height

503

507 Given the encouraging preliminary results from the FH_RD experiment, ETS figures of CREF 508 and HPRCP forecasts from three additional sensitivity experiment—FH_RD_V120, FH_RD_H3, and 509 FH_RD_H12—are compared to examine the relative impact of different vertical resolutions and 510 maximum detection heights on the analyses and forecasts (Fig. 14). For reflectivity forecasts at 511 thresholds of 20-40 dBZ, the 0-3 h ETSs of FH_RD and FH_RD_H12 are comparable. However, the 512 FH RD H12 experiment achieves higher forecast scores after 3 hours, highlighting the benefit of a 513 higher detection height (Fig. 14a-c). Conversely, the FH RD H3 experiment (with the lowest detection 514 height of 3 km) shows the smallest ETS values at 20 and 30 dBZ, while FH_RD_V120 (with a lower 515 vertical resolution of 120 m) demonstrates the poorest forecast skill at 40 dBZ. Consistent with the 516 CREF forecast, both FH_RD and FH_RD_H12 show more skillful HPRCP forecasts than 517 FH RD V120 and FH RD H3. However, the ETSs of FH RD are higher than those of FH RD H12 518 at most forecast lead times, which differs from the reflectivity results. Additionally, FH RD H3 519 produces the lowest ETS values throughout the 0-6 h forecasts at thresholds of 2.5-10 mm. Generally, 520 the higher the maximum detection height of RWPs and the denser the vertical distribution of 521 observations, the more significant the positive impact of RWP DA in terms of ETS. Moreover, a 522 maximum detection height of 8 km seems to be a reasonable and effective choice, while the reduction 523 of vertical resolution from 60 m to 120 m has less impact compared to the effect of decreasing the 524 detection altitude to 3 km.

526 Figure 14. Equitable threat score (ETS) for 0-6 h CREF forecasts from the FH RD (solid),

530 **4.2 Aggregate forecast performance**

531 Considering the variations in weather scenarios and storm environments across cases, we also 532 examined two additional SW-type heavy rainfall events that occurred over the Beijing-Tianjin-Hebei 533 region on 28 June and 12 July 2023 to evaluate the impact of RWPs observed from different spatial 534 layouts on short-term forecasts. Despite the presence of a southwesterly jet stream in all three cases, 535 they produced distinct storm modes under different weather conditions. To delve deeper into the 536 verification metrics from the three cases, we present performance diagrams of CREF and HPRCP 537 forecasts from the FH RD experiment as the best assimilation experiment (Fig. 15). The results from 538 the NoDA experiment are also shown to provide a clear picture of how RWP observations improve the 539 short-term forecasts across different cases. For both the NoDA and FH RD experiments, the forecast 540 skills generally exhibit lower score metrics and more variability at higher thresholds. Overall, for 541 different cases, the FH RD experiment shows higher POD, CSI, and SAR values compared to the 542 NoDA experiment, with more significant improvements observed in the first 3 hours. Most of the BIAS 543 values for FH RD are smaller than those for the NoDA experiment. Except for 28 June 2023, the BIAS 544 values of FH RD fall within a reasonable range of 0.8-1.7 for reflectivity precipitation, indicating 545 overall good forecast performance. It is noted that some of the forecast scores do not decrease 546 monotonically with increasing forecast lead time. For example, in the case 12 July 2023, smaller BIAS 547 and FAR values are obtained for the 3- and 6-h reflectivity and precipitation forecasts, along with 548 higher CSI. This occurs due to several factors: (a) initial scattered convection develops into a 549 larger-scale west-east oriented system covering all of Beijing and central-northern Hebei at later times 550 in this case, which models usually capture better; (b) errors in the timing and location of CI become 551 less significant as convection evolves and forms clearer structures; and (c) for the free forecasts 552 initialized from the first few hours, convection may not have started until the final forecast hour. CREF 553 forecasts from FH RD for the case 28 June 2023 show the best performance in terms of high POD, SR, 554 and CSI. Meanwhile, persistent underprediction throughout the 1-6 h precipitation forecasts at all

删除: Except for 28 June 2023, the BIAS values fall within a reasonable range of 0.8–1.5 7 for reflectivity and 0.8–1.7 for precipitation, indicating overall good forecast performance.

571	0-6h reflectivity forecasts, with higher POD and CSI, and smaller FAR, The BIAS values of the
572	assimilation experiments are higher than that of the NoDA experiment (close to unity) at the analysis
573	time, and then decreases slightly in the 1-6 h forecasts. However, the BIAS of NoDA increase
574	consistently during 1-6 hours, making it farther from unity. Among CTL, FH, RD, and FH_RD,
575	FH_RD consistently outperforms others, showing the highest POD values across all forecast hours (Fig.
576	16a). A slight overprediction bias (1.1-1.2) is observed for all DA experiments at all forecast times
577	(Fig. 16b). CTL exhibits the largest BIAS in the first 3 hours, while FH's BIAS increases to 1.2 over
578	time. FH_RD shows the steepest decrease in FAR, indicating the most effective reduction in false
579	alarms (Fig. 16c). CTL remains relatively flat and maintains the highest FAR among the four DA
580	experiments throughout the 0-6h forecasts. The FARs for FH and RD forecasts fall between those of
581	FH_RD and CTL. Specifically, FH has a lower FAR in the first 3 hours, whereas in the next 3 hours,
582	RD performs better. Similar trend is also evident in CSI values over time (Fig. 16d). In conclusion,
583	FH_RD consistently performs best overall across all metrics, followed by RD and FH. CTL
584	underperforms, with less improvement in score metrics. Sensitivity tests show FH_RD_H12 performs
585	slightly better than FH_RD, while FH_RD_H3 shows the least improvement. FH_RD_V120 falls
586	between FH_RD_H12 and FH_RD_H3, consistent with the single-case study in Sect. 4.1.3.

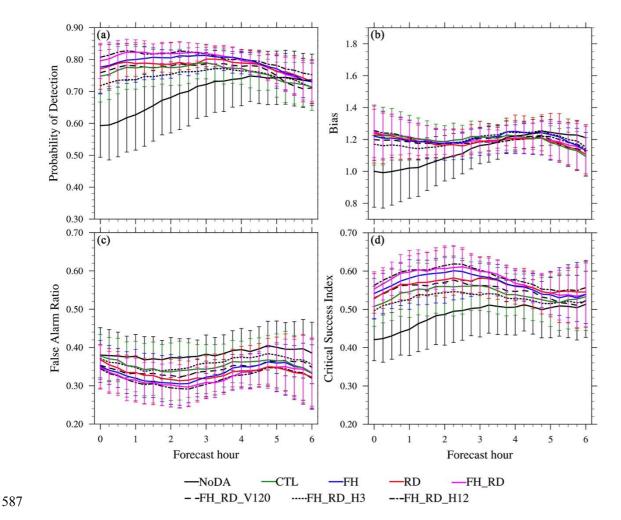

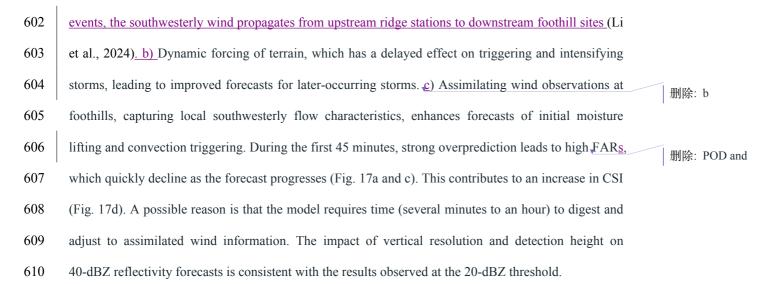

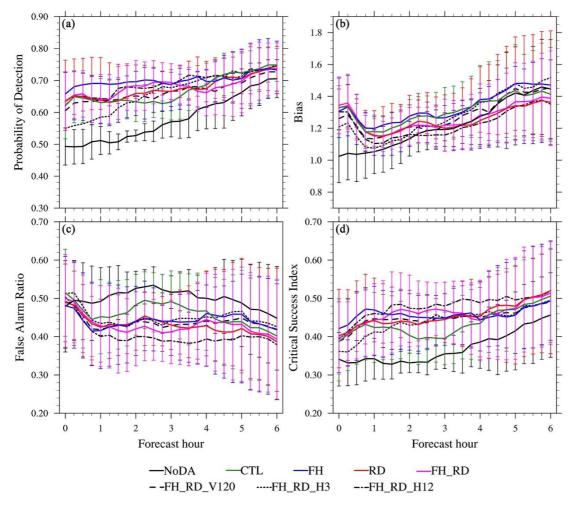

Figure 16. Time series of (a) Probability of detection (POD), (b) Bias, (c) false alarm ratio (FAR), and (d) critical success index (CSI) for CREF forecasts aggregated from each initialization hour from the sixth hour to the end of the_DA cycles across three cases (June 28, July 12, July 21 of 2023) at the threshold of 20 dBZ for the NoDA (black solid), CTL (green solid), FH (blue solid), RD (red solid), FH_RD (magenta solid), FH_RD_V120 (black dashed), FH_RD_H3 (black dotted), and FH_RD_H12 (black dashdot) experiments. Results are shown for a neighborhood radius of 12-km. Error bars for NoDA, CTL, FH, RD, and FH_RD experiments represent a 95% confidence interval.

Similar to the 20-dBZ reflectivity forecast, RWP DA experiments outperform NoDA at 40-dBZ,
although only the POD result in the first 3 hours is statistically significant at the 95% confidence level.
All DA experiments exhibit an overprediction bias (1.1–1.5) throughout the 0–6 h forecasts (Fig. 17b).
Notably, FH shows the highest bias. However, FH also exhibits the highest POD in the first 2 hours
and highest CSI and lowest FAR in the first hour. Subsequently, FH_RD and RD perform better, with
FH_RD slightly outperforming RD in 1–3 h forecasts and RD performing better in 4–6 hours. The
different impacts of ridge and foothill networks may be attributed to: a) For southwest-type rainfall

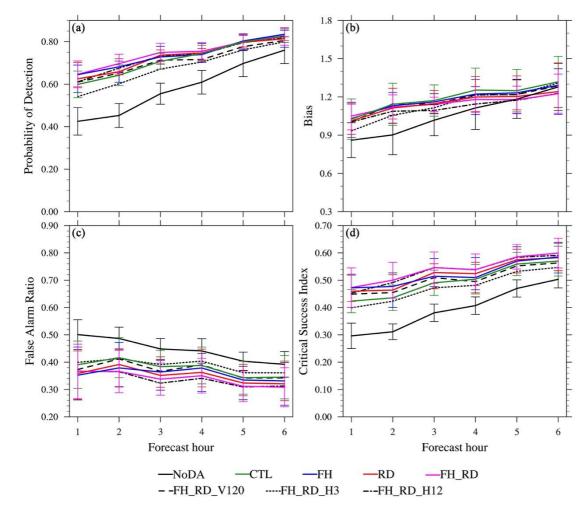

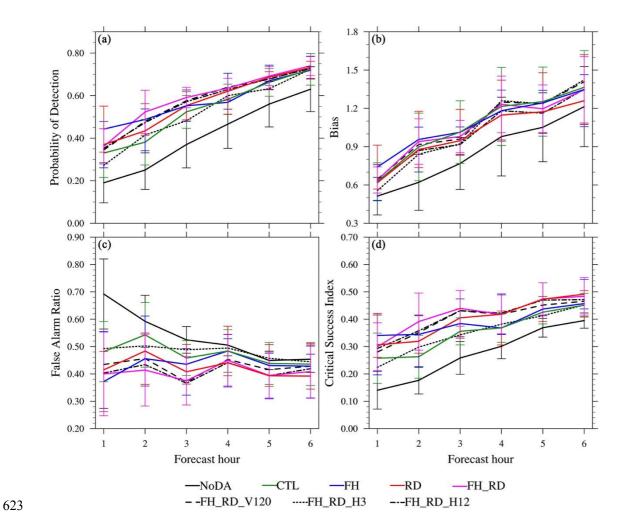

613 Consistent with the 20-dBZ reflectivity forecast, FH_RD and FH_RD_H12 consistently achieve 614 the best performance across all score metrics in HPRCP forecasts, followed by RD and FH (Fig. 18 and 615 19). Although the improvements are not statistically significant at the 95% confidence level, FH_RD 616 and FH_RD_H12 exhibit added forecast skill over the NoDA experiment. In contrast, CTL and

- 617 FH_RD_H3 show minimal improvement across all metrics. At 10-mm threshold, FH produces higher
- 618 forecast scores than the others in the first hour, while FH_RD and RD show superiority in 2-4 h and
- 619 4–6 h, respectively (Fig. 19).

625 5. Summary and conclusions

626 In this research, observing system simulation experiments are performed to study the benefits of 627 assimilating RWP observations for convective scale short-term heavy rainfall forecasts. Synthetic RWP 628 observations are assimilated into the WRF model using the NSSL3DVAR DA system for three 629 SW-type heavy rainfall events that occurred over the Beijing-Tianjin-Hebei region. To investigate the 630 impact of RWP data observed from multiple networks on convective scale short-term forecasts, the 631 background run (NoDA), which does not assimilate any observations, and four types of DA 632 experiments are carried out. A baseline experiment (CTL), which assimilates RWPs from the 633 operational network alone, is first performed and serves as a benchmark for comparison with 634 subsequent DA experiments. The FH and RD experiments assimilate simulated RWP observations 635 from the foothill and ridge networks of the Taihang Mountains in addition to the operational network.

删除: forecasting CI along small-scale boundary layer convergence zones

636 The FH RD experiment is conducted by assimilating combined RWP data from the operational, 637 foothill, and ridge sites. Comparison of analyses and forecasts from these four types of experiments 638 reveals improvements in model initial conditions and short-term severe weather forecasts by 639 assimilating simulated RWP observations, as well as the added value of RWPs from the foothill and 640 ridge networks over operational network data. Furthermore, three sensitivity DA experiments 641 (FH_RD_V120, FH_RD_H3, and FH_RD_H12) are carried out to test the impact of vertical resolution 642 and maximum detection heights. The purpose of these experiments is to investigate a potential optimal 643 configuration for the vertical data availability of real-time RWPs to be assimilated in future convective 644 scale NWP. For each DA experiment, the analysis is cycled for 9 hours at 15-min intervals, with a 6-h 645 free forecast initiated every hour starting from the sixth hour of the analysis cycles. First of all, both 646 subjective and objective verifications of the analysis and forecast were performed in detail for the 21 647 July 2023 case. Then statistical metrics, including neighborhood-based POD, FAR, BIAS, and CSI of 648 reflectivity and precipitation forecasts, were aggregated from each initialization hour across the three 649 cases. The main results are summarized as follows:

650 1) Comparison of wind analyses and forecasts among the CTL, FH, RD, and FH RD 651 experiments reveals that the FH RD experiment yields the smallest wind errors, both in terms of 652 the overall domain average and the vertical profile of RMSEs for wind components. Then, it is 653 followed by RD, then FH, with CTL exhibiting the largest wind errors. A qualitative evaluation of 654 the model's initial mesoscale dynamics indicates that the assimilation of RWP data successfully 655 corrects the wind direction and speed biases in Beijing and its surrounding areas, enhancing the 656 southwesterly jet. Moreover, both RD and FH_RD (with the assimilation of RWP data from the 657 ridge network) remarkably reduce large wind errors in the upstream of Beijing along the 658 mountains, which is crucial for CI in the vicinity of the boundary between Hebei and southwestern 659 Beijing.

660 2) For the 21 July 2023 event, qualitative verification focused on the convective system 661 initiated southwest of Beijing, which intensified after merging with storms from western Hebei, 662 forming a prominent southwest-northeast oriented system across Beijing. The NoDA experiment 663 initially underestimates convection in Beijing and Hebei but overpredicts storm coverage and 664 intensity in later forecasts, generating excessive spurious convection. All RWP DA experiments 665 enhance CI timing and location by capturing mesoscale flow features, subsequently reducing storm

666	displacement and intensity errors. Nevertheless, the CTL experiment underestimates storm
667	intensity, while FH still retains some spurious echoes in forecasts. Overall, the FH_RD experiment
668	demonstrates significant superiority in areal coverage, storm mode, and orientation compared to
669	the other DA experiments. The accumulated precipitation forecasts show similar trends to the
670	reflectivity results regarding rainfall location, onset time, and amount. The forecast statistics
671	indicate that FH_RD achieves the best performance in reflectivity and precipitation forecasts at
672	lower thresholds (i.e., 20- and 30-dBZ for CREF, and 2.5-mm for HPRCP), whereas the RD
673	experiment slightly surpasses FH_RD at the 50-dBZ and 10-mm thresholds. The lower
674	performance of FH_RD and FH at higher thresholds may be linked to slight displacement errors in
675	heavy precipitation forecasts, impacting their POD and ETS scores.

676 3) Quantitative verification results aggregated across the three SW-type heavy rainfall 677 cases in the Beijing-Tianjin-Hebei region confirm that FH RD exhibits the best performance in 678 reflectivity and precipitation forecasts, followed by RD and FH, while CTL shows minimal 679 improvement. An exception is that at higher thresholds, FH achieves the best scores in the first 1 or 680 2 hours despite stronger overprediction, while FH RD and RD are superior in subsequent hours. 681 This is potentially attributed to the delayed effect of dynamic forcing from the terrain, as well as 682 improvements in capturing the initial southwesterly flow and local convection by assimilating 683 wind observations at the foothills. In addition, the results from sensitivity experiments on vertical 684 resolution and maximum detection height indicate that FH RD H12 exhibits comparable or 685 slightly better performance compared to FH_RD, benefiting from its higher detection height. 686 Conversely, the FH_RD_H3 experiment, with the lowest detection height, has the poorest forecast 687 skills among all DA experiments, while FH RD V120 generally falls between FH RD H12 and 688 FH RD H3.

689 The results consistently demonstrate that the FH RD experiment, combining data from ridge, 690 foothill, and operational wind profiler networks, delivers the most accurate short-term forecasts. 691 Specifically, the assimilation of RWP data from ridge network significantly reduces wind errors in 692 complex terrain, such as the Taihang Mountains upstream of Beijing. These regions are critical for 693 convective initiation in Beijing and its surroundings. The findings highlight the essential role of 694 integrating both ridge and foothill data in improving overall reflectivity and precipitation forecasts over 695 the Beijing-Tianjin-Hebei region. Sensitivity experiments on vertical resolution and detection height 39

696 further emphasize the importance of high vertical resolution and maximizing detection height in697 optimizing the RWP network for enhanced forecast accuracy.

698 The insights gained from this OSSE study on the impacts of RWP observations on heavy rainfall 699 forecasting will inform the design of optimal RWP networks over the Beijing-Tianjin-Hebei region. 700 This preliminary study lays the groundwork for further research to fully understand the complexities of 701 precipitation forecasting related to data assimilation. The current investigation focused on three 702 SW-type heavy rainfall cases occurring in summer over the Beijing-Tianjin-Hebei region, utilizing 703 model-simulated states and observational networks. As the fraternal twin scheme is used in this study, 704 it does not account for model-related errors that occur in real-world applications. Consequently, the 705 results might overestimate the actual benefits of RWP assimilation in operational systems. Furthermore, 706 this study focuses exclusively on assimilating RWP data, without incorporating conventional 707 observations or satellite data. While this approach simplifies the analysis by isolating the impact of 708 <u>RWPs</u>, it may inflate their relative importance. Future research directions include: (1) Expanding the 709 study to other precipitation types and high-impact convective events under diverse weather scenarios. 710 (2) Evaluating the impact of RWP networks by assimilating RWPs together with more diverse 711 observation types and incorporating non-identical twin setups to enhance realism and provide broader 712 operational insights. (3) Investigating the benefits of assimilating real observational data on convective 713 scale NWP once proposed RWP networks become available. Moreover, future studies can address the 714 limitations of static background errors in 3DVAR by incorporating flow-dependent background error 715 covariances estimated from ensemble forecasts. As ensemble-based background error covariances can 716 dynamically adapt to the evolving state of the atmosphere, the DA system will better represent the 717 spatial and temporal variability of background errors, particularly in regions with complex topography 718 or mesoscale features like convective systems. By leveraging flow-dependent background errors, the 719 analysis can more accurately capture the initial atmospheric state, ultimately leading to more accurate 720 precipitation predictions.

732 Author contributions

- JZ and JG conceptualized the study. JZ executed the experiments, analyzed the results, and wrote the
- paper. JG supervised the project, provided critical feedback during the experiment implemention stage,
- and revised the paper. XZ assisted in the analysis and visualizations.
- 736
- 737 **Competing interests**
- 738 The contact author has declared that none of the authors has any competing interests.
- 739

740 Acknowledgements

- 741 This work was jointly supported by the National Natural Science Foundation of China (U2142209,
- 42325501 and 42375018), and the China Meteorological Administration Training Centre Key Research
- 743 Program (2023CMATCZDIAN08). Dr. Jidong Gao kindly provided internal review which led to
- 744 improvement of the manuscript. ChatGPT (GPT-4; OpenAI's large-scale language-generation model)
- 745 was used to improve the writing style of this article.
