**Abstract.** Downscaling global climate models (GCMs) provides crucial, high-resolution data needed for informed decision-making at regional scales. However, there is no uniform approach to select the most suitable GCMs. Over Southeast Asia (SEA), observations are sparse and have large uncertainties, complicating GCM selection especially for rainfall. To guide this selection, we apply a standardised benchmarking framework to select CMIP6 GCMs for dynamical downscaling over SEA, addressing current observational limitations. This framework identifies fit-for-purpose models through a two-step process: (a) selecting models that meet minimum performance requirements in simulating the fundamental characteristics of rainfall (e.g., bias, spatial pattern, annual cycle, and trend) and (b) selecting models from (a) to further assess whether key precipitation drivers (monsoon) and teleconnections from modes of variability are captured [El Niño-Southern-Oscillation (ENSO) and Indian Ocean Dipole (IOD)]. GCMs generally exhibit wet biases, particularly over the complex terrain of the Maritime Continent. Evaluations from the first step identify 19 out of 32 GCMs that meet our minimum performance expectations in simulating rainfall. These models also consistently capture atmospheric circulations and teleconnections with modes of variability over the region but overestimate their strength. Ultimately, we identify eight GCMs meeting our performance expectations. There are obvious, high-performing GCMs from allied modelling groups, highlighting the dependency of the subset of models identified from the framework. Therefore, further tests on model independence, data availability, and future climate change spread are conducted, resulting in a final sub-set of two independent models that align with our a priori expectations for downscaling over CORDEX-SEA.

**Keywords:** CORDEX, regional climate models, CMIP6, standardised benchmarking framework, GCM selection.

## 30 **1 Introduction**

31 The Sixth Assessment Report (AR6) of the Intergovernmental Panel on Climate Change (IPCC) underscores, with  
32 high confidence, the escalating water-related risks, losses and damages associated with each increment of global  
33 warming (Ipcc, 2023). The report specifically notes a projected increase in the frequency and intensity of heavy  
34 rainfall, leading to an increased risk of rain-generated localised flooding, particularly over coastal and low-lying  
35 cities and regions [Section 3 (Ipcc, 2023)]. Therefore, climate projections at regional scales are required to inform  
36 climate change adaptation strategies and enhance resilience efforts.

37 Different types of models have been developed and have become fundamental tools for assessing future regional  
38 climate changes, including state-of-the-art Global Climate Models (GCMs) and Regional Climate Models  
39 (RCMs). GCMs are generally used to explore climate interactions and underpin climate projections through the  
40 Coupled Model Intercomparison Project [CMIP ; (Meehl et al., 2000)], an initiative of the World Climate Research  
41 Programme (WCRP). However, with a typical horizontal resolution of 50-250 km, GCMs have limited ability to  
42 simulate sub-grid weather (e.g., local variance, persistence, topography, etc.) and therefore cannot accurately  
43 define local-scale processes and feedbacks (e.g., deep convection, land-atmosphere interactions, etc.). This limits  
44 GCMs' ability to simulate aspects of the present-day water cycle and to determine robust future changes for local  
45 and regional applications (Maraun and Widmann, 2018; Douville et al., 2021). RCMs dynamically downscale  
46 GCM outputs to create higher spatial resolutions of ~2 -50 km, providing richer regional spatial information (e.g.,  
47 small-scale processes and extreme events) for climate assessments and for impact and adaptation studies  
48 (Diaconescu and Laprise, 2013; Giorgi and Gao, 2018). However, such experiments are computationally  
49 expensive, so it is not practical to choose all GCMs for dynamical downscaling. Thus, a sub-set of GCMs has to  
50 be selected.

51 The WCRP's Coordinated Regional Climate Downscaling Experiment (Cordex) initiative delivers dynamically  
52 downscaled simulations of various GCMs (Giorgi and Gao, 2018) over 14 regions worldwide. This includes Phase  
53 I using CMIP5 (Giorgi et al., 2008) and Phase II Coordinated Output for Regional Evaluations (CORDEX-CORE)  
54 (Giorgi et al., 2021) as well as on-going experiments (CMIP6). However, there is no agreed approach to selecting  
55 which GCMs would be most suitable for dynamical downscaling, either in the recent WCRP's guideline for  
56 CMIP6 CORDEX experiments (Cordex, 2021) or across different CORDEX domains (Di Virgilio et al., 2022;  
57 Grose et al., 2023; Sobolowski et al., 2023). In the earliest initiatives, GCMs were eliminated based on their skill  
58 in reproducing the current climate for the region of interest given the fact that the bias in the GCMs can propagate  
59 into the RCM through the underlying and lateral boundary conditions (i.e., driven by initial and time-dependent  
60 meteorological variables from GCMs) (Mote et al., 2011; Overland et al., 2011; Mcsweeney et al., 2012;  
61 Mcsweeney et al., 2015). In addition, the selection of GCMs considers the need to generate a reasonable  
62 uncertainty range for future climate projections (Mote et al., 2011; Overland et al., 2011). Given the shared  
63 physical components of the design of CMIP6 GCMs, there are inherent biases in statistical properties like the  
64 multi-model mean or standard deviation of the full ensemble (Boé, 2018; Brands, 2022; Sobolowski et al., 2023).  
65 To address this problem, model dependency is also considered. These considerations and methodologies have  
66 been integrated into the most recent CMIP6 CORDEX experimental design for specific regions, such as Europe  
67 (Sobolowski et al., 2023) or Australia (Di Virgilio et al., 2022) and are recommended for widespread application  
68 across other CORDEX-domains.

69 Model evaluation is an essential part of CMIP6 model selection since simulating past performance well is a  
70 necessary (but insufficient) condition to have more confidence in future performance. Different metrics are  
71 employed to quantify model skill in simulating various climate variables at either global (Kim et al., 2020; Ridder  
72 et al., 2021; Wang et al., 2021b; Donat et al., 2023) or regional scales [e.g., Australia (Deng et al., 2021; Di  
73 Virgilio et al., 2022) Europe (Ossó et al., 2023; Palmer et al., 2023); South America (Díaz et al., 2021); Asia  
74 (Dong and Dong, 2021); Southeast Asia (Desmet and Ngo-Duc, 2022; Pimonsree et al., 2023)]. However, the lack  
75 of consistency in the list of metrics used makes it difficult to perform one-to-one comparisons between studies or  
76 to track model performance across various regions.

77 Recently, Isphording et al. (2024) introduced a standardised benchmarking framework (BMF) underpinned by the  
78 work of the U.S DOE (2020), which included a set of baseline performance metrics for assessing model  
79 performance in simulating different characteristics of rainfall. The BMF is different from traditional model  
80 evaluation in that it defines performance expectations a priori (Abramowitz, 2005; Abramowitz, 2012; Best, 2015;  
81 Nearing et al., 2018). Under the BMF, a model will not be considered fit-for-purpose if it fails any performance  
82 metric. The BMF consists of two tiers of metrics: the first tier includes minimum standard performance metrics  
83 related to fundamental characteristics of rainfall, and the second tier allows users to define metrics that help to  
84 answer specific scientific research questions. The BMF was initially designed for rainfall but can be widely  
85 applied to other climate variables (e.g., surface temperature), depending on the user's purpose (Isphording et al.,  
86 2024).

87 IPCC highlights Southeast Asia (SEA) as a region facing considerable climate change risks from extreme events  
88 (e.g., floods, extreme heat, and changing precipitation and extremes) (Ipcc, 2022). However, available regional  
89 climate simulations for SEA, particularly from CMIP5 CORDEX-SEA experiments are limited to 13 simulations  
90 (Tangang et al., 2020) compared to EURO-CORDEX with 68 simulations (Jacob et al., 2020) or CORDEX-  
91 Australasia with 20 simulations (Evans et al., 2021). Consequently, future projections come with a higher degree  
92 of uncertainty, especially for rainfall (Tangang et al., 2020; Nguyen et al., 2023). This motivated the CORDEX-  
93 SEA community to update their regional climate model simulations with the latest CMIP6 models. Note that over  
94 SEA, observations are sparse with large uncertainties, particularly for rainfall (Nguyen et al., 2020), making GCM  
95 evaluations more complicated (Nguyen et al., 2022; Nguyen et al., 2023). To date, the performance of various  
96 CMIP6 GCMs has been evaluated and ranked over the whole region of SEA (Desmet and Ngo-Duc, 2022;  
97 Pimonsree et al., 2023) and its sub-regions [e.g., Philippines (Ignacio-Reardon and Luo, 2023); Thailand  
98 (Kamworapan et al., 2021); Vietnam (Nguyen-Duy et al., 2023)]. Although there are groups of GCMs that  
99 consistently perform well (e.g., EC-Earth3, EC-Earth3-Veg, GFDL-ESM4, MPI-ESM1-2-HR, E3SM1-0,  
100 CESM2) and poorly (e.g., FGOALS-g3, CanESM, NESM3, IPSL-CM6A-LR) across available literature, their  
101 ranking varies differently given inconsistencies in evaluation metrics and observational reference datasets. This  
102 creates challenges in conducting direct intercomparisons across the above-mentioned studies. In addition, it is  
103 crucial to consider other important aspects discussed above (e.g., observational uncertainty, model dependency,  
104 and future climate change spread) in identifying the list of reliable models over SEA.

105 In this research, we aim to apply the lessons learnt from CMIP6 selection over different CORDEX-domains for  
106 SEA by assessing different aspects of models: model performance, model independence, data availability and  
107 future climate change spread. We apply the BMF to provide a consistent set of metrics for holistically evaluating

108 model performance and to deal with large observational uncertainties over the region. Focusing on precipitation,  
 109 where future projections are much more uncertain, the objectives of this research are twofold:

- 110 1. To evaluate the performance of CMIP6 GCMs in simulating the fundamental characteristics of  
 111 precipitation, its drivers and teleconnection with modes of variability over SEA using a standardised  
 112 benchmark framework and to identify a subset of models that meet our performance expectations.
- 113 2. To retain models that are relatively independent and are representative of the full range of possible  
 114 projected change for finalizing a subset of CMIP6 GCMs for dynamical downscaling over SEA using  
 115 model independence tests and assessment of climate change response patterns.

116 The structure of the paper is as follows: Section 2 introduces the data and the benchmarking framework employed  
 117 in this study. The results are presented in three subsections: Section 3.1 focuses on model assessment using the  
 118 benchmarking framework; Section 3.2 examines the spread of future climate change among models; and Section  
 119 3.3 assesses model dependence through cluster analysis. Finally, we conclude with a discussion of our results in  
 120 Section 4 and a summary of the main conclusions in Section 5.

## 121 2 Methods

### 122 2.1 Data

#### 123 2.1.1 CMIP6 GCM data

124 We use the historical daily data of precipitation, near surface temperature, 850 hPa wind speed and both monthly  
 125 and daily sea-surface temperature data from the 32 CMIP6 models listed in Table 1. We consider only models  
 126 which have a horizontal grid spacing finer than  $2^\circ \times 2^\circ$  which are likely to be more suitable for dynamical  
 127 downscaling. One simulation (typically the first member r1i1p1f1) is utilized in the benchmarking process to  
 128 enable a fair comparison. At the time of this analysis, the first member of some models (e.g., CNRM-family  
 129 models, UKESM1-0-LL and HadGEM3-GC31-MM) was not available so another member was utilized.

130 **Table 1.** Information on model components from the CMIP6 GCMs used in this study.

131 \*Model offers atmospheric variables available in three dimensions at each 6 hours for dynamical downscaling at  
132 the time of analyses.

133

134 **2.1.2 Observations and reanalyses**

135 Given the large observational uncertainty in precipitation over the region (Nguyen et al. 2022), we use multiple  
 136 daily observed datasets from different in situ and satellite sources to quantify model skill (Table 2). These datasets  
 137 have been chosen given their high consistency in representing daily precipitation (Nguyen et al., 2022) and  
 138 extremes (Alexander et al., 2020; Nguyen et al., 2020) over SEA.

139 ERA5 reanalysis (~31 km grid resolution) (Hersbach et al., 2020) was used to benchmark model performance in  
 140 representing the climatology of atmospheric circulation (e.g., metrics related to horizontal wind at 850 hPa level  
 141 are described in section 2.2).

142 We acknowledge that different observational sea surface temperatures (SST) have different abilities to capture  
 143 signals of the modes of variability. Therefore, we utilize multiple SST products (Table 2) to take account of the  
 144 observational uncertainties in simulating the teleconnection between rainfall and main modes of variability,  
 145 including El Niño-Southern Oscillation (ENSO) and Indian Ocean Dipole (IOD) as described in section 2.2.

146 **Table 2.** The main characteristic of observational datasets used in this study.

Type of dataset	Product short name	Dataset name	Temporal coverage	Spatial resolution	Data source	Reference
Precipitation dataset	APHRODITE	APHRODITE V1101 and V1101XR	1950-2015	0.5° × 0.5°	In situ	Yatagai et al. (2012)
	CHIRPv2	CHIRPSv2	1981-2016	0.25° × 0.25°	In situ + Satellite	Funk et al. (2015)
	REGEN_ALL	REGEN Allstns V1 2019	1950-2019	1° × 1°	In situ	Contractor et al. (2020)
	GPCC_v2018	GPCC FDD v2018	1982-2019	1° × 1°	In situ	Schamm et al. (2014)
Sea Surface Temperature dataset	HadISST	HadISST1 v1	1870-2021	1° × 1°	In situ + Satellite	Rayner et al. (2003)
	OISST	OISST v2.0	1981-2020	0.25° × 0.25°	In situ + Satellite	Huang et al. (2021)
	ERSST	ERSST v5	1854-2024	2° × 2°	In situ	Huang et al. (2017)

147 **2.2 Benchmarking CMIP6 GCMs over Southeast Asia**

148 Given the large uncertainties and model inconsistency in rainfall projections, our main aim is to identify a subset  
 149 of CMIP6 GCMs that meet our a priori expectations. That is, as a minimum requirement a model should simulate  
 150 past rainfall statistics over SEA reasonably well using consistent criteria. Figure 1 illustrates the GCM selection  
 151 process applied in this research based on a standardised benchmarking framework (Isphording et al., 2024). A  
 152 subset of CMIP6 GCMs that meet our model performance expectations are identified through a two-step process:  
 153 (a) selecting models that meet minimum performance requirements in simulating the fundamental characteristics  
 154 of rainfall (Fig. 1) and (b) selecting models from (a) to further assess performance in simulating precipitation  
 155 drivers (e.g., monsoon) and teleconnections with modes of variability (Fig. 1).

156 **2.2.1 Minimum standard metrics**

157 The BMF introduces a set of minimum-standard metrics (MSMs): 1. mean absolute percentage error (MAPE), 2.  
158 spatial correlation (Scor), 3. seasonal cycle (Scyc) and 4. significant changes (SigT) (Isphording et al., 2024) to  
159 assess the skill of climate models in simulating very fundamental characteristics of precipitation (e.g., magnitude  
160 of biases, spatial distributions, annual cycles and temporal variability). Before exploring complex processes, a  
161 model should meet performance expectations for these MSMs. Therefore, we initially calculate the MSMs for  
162 precipitation. In addition, we acknowledge that models should produce adequate present-day simulations of other  
163 fundamental climate variables like near-surface temperature. Hence, we also apply the MSMs for near-surface  
164 temperature in the supplementary information. Given the strong seasonality of precipitation in the region (Juneng  
165 et al., 2016), the analyses related to precipitation are conducted at a seasonal scale (e.g., the dry season November-  
166 April – NDJFMA and the wet season May-October – MJJASO). Meanwhile, temperature analyses are conducted  
167 at the annual scale.

168  
169 **Figure 1.** A schematic of the CMIP6 GCM selection process, including (1) model evaluation using a standardized  
170 benchmarking framework (BMF) and (2) assessment of model independence and future climate change spread. The BMF  
171 includes two steps: minimum standard metrics (MSMs) which assess very basic characteristics of rainfall and second-tier  
172 metrics (e.g., versatility metrics) which quantify model skill of the models that pass the MSMs in simulating precipitation  
173 drivers (monsoon) and teleconnections with modes of variability [the El Niño-Southern Oscillation (ENSO) and Indian Ocean  
174 Dipole (IOD)].

175 Note that in this research, we focus only precipitation over land given the lack of in situ reference over ocean.  
 176 Some satellite-derived products provide oceanic precipitation data but most of their temporal coverage is not  
 177 sufficiently long to use as a reference. In addition, the observational uncertainties among satellite clusters in  
 178 estimating oceanic precipitations over SEA is quite substantial, with discrepancies reaching up to 4 mm/day  
 179 (Figure s1).

## 180 **2.2.2 Versatility metrics**

181 The MSMs provide statistical measurements that are not always correlated with future projections (Knutti et al.,  
 182 2010), given that some models may simulate historical precipitation well for the wrong reasons. A further  
 183 recommendation is therefore to also assess model performance based on key physical processes (Doe, 2020;  
 184 Nguyen et al., 2023). This approach offers additional insights into the relative roles of model biases in simulating  
 185 large-scale environments versus the limitations of model parameterizations in generating precipitation biases.  
 186 Therefore, we define second tier versatility metrics to assess those GCMs selected from section 2.2.1 in simulating  
 187 the complex precipitation-related processes, including drivers and teleconnections with modes of variability.

### 188 **Monsoon circulation**

189 SEA is situated within the Asian monsoon regime, where atmospheric circulation is modulated by two primary  
 190 monsoon systems: the Indian monsoon characterized by westerlies from the Bay of Bengal into northern parts of  
 191 SEA including the mainland and northern Philippines (along 10°N) during the boreal summer (JJAS) and reversed  
 192 in direction during the boreal winter (DJF); and the Australian monsoon [e.g., easterlies from Australia to the  
 193 Maritime Continent (MC) and Papua] (Chang et al., 2005). These monsoon systems drive regional rainfall  
 194 seasonality. Therefore, we focus on assessing model skill in simulating the intensity and direction of monsoon  
 195 wind (e.g., 850-hPa wind) for JJAS and DJF. While wind speed is evaluated using the MAPE and Scor metrics  
 196 similar to the MSMs for precipitation and temperature, wind direction is quantified using an equation from Desmet  
 197 and Ngo-Duc (2022):

$$198 \text{ MD} = \frac{\sum_i u_i \times |\theta_i - \theta_{i,ref}|_{[0,180]}}{\sum_i u_i}$$

199 where  $u_i$  refers to the simulated wind speed at the grid  $i$ ,  $\theta_i$  and  $\theta_{i,ref}$  are the wind direction at grid  $i$  in the  
 200 simulated and reference data respectively.  $|\theta_i - \theta_{i,ref}|_{[0,180]}$  is the absolute value of difference at the  $i$ th grid  
 201 between directions of simulated and reference wind speed (e.g., ERA5). The MD metric allows us to quantify the  
 202 agreement in wind direction between two datasets in which the impact of high wind speed is taken into account.

### 203 **ENSO, IOD and Teleconnections**

204 Various parts of SEA are also affected by two prominent modes of variability: the El Niño - Southern Oscillation  
 205 (ENSO) (Haylock and Mcbride, 2001; Chang et al., 2005; Juneng and Tangang, 2005; Qian et al., 2013) and  
 206 Indian Ocean Dipole (IOD) (Xu et al., 2021) via atmospheric teleconnections. In this research, the teleconnection  
 207 is defined by the temporal correlation between precipitation anomalies at each grid point and the ENSO/IDO  
 208 indices.

209 To track ENSO variability, the Niño3.4 index (5°S-5°N and 160°E-120°W) (Trenberth and Hoar, 1997; Shukla et  
210 al., 2011) derived for the 1951-2014 period as area-mean monthly SST anomalies with respect to a 1961-1990  
211 climatology is used. For IOD, we use the Dipole Mode Index [DMI; (Saji et al., 1999; Meyers et al., 2007)] DMI  
212 measures differences of monthly SST anomalies between the west equatorial Indian Ocean (50-70° E, 10°S-10°N)  
213 and those in the east (90-110°S, 10°S -0°N).

214 We use a 5-monthly average Niño3.4 and IOD index to remove seasonal cycles. The resulting monthly time series  
215 are detrended using a fourth-order polynomial fit to remove the possible influence of a long-term trend and to  
216 better preserve high amplitude (<10 years) variability (Braganza et al., 2003).

217 Since ENSO typically matures toward the end of the calendar year (Rasmusson and Carpenter, 1982), we consider  
218 ENSO developing years as year (0) and use the DJF means to identify ENSO events. Over SEA, ENSO interacts  
219 with the monsoon cycle and due to the varying monsoon onset between the northern and southern parts of the  
220 region, its seasonal evolution differs across regions (Figure s2). In particular, there is a lagged negative correlation  
221 between rainfall and ENSO over the Maritime Continent (MC) and the Philippines, which develops from May-  
222 June, strengthens during July-August, and reaches its highest correlation during September-October of the  
223 developing year (year 0). On the other hand, this negative correlation becomes prominent over the northern parts  
224 during the subsequent boreal spring (from March-May of the year +1) (Wang et al., 2020; Chen et al., 2023). The  
225 negative correlation indicates dry anomalies during El Niño and/or wet anomalies during La Nina. Therefore, in  
226 the context of this research, we examine the lead/lag Pearson correlation of the DJF Niño3.4 index in the  
227 developing year (year 0) with two different seasonal rainfalls: May-Oct (MJJASO) of the developing year (year  
228 0) and March-May (MAM) of the following year (year +1).

229 Furthermore, considering the stronger influence of the IOD and its associated teleconnection during SON  
230 compared to other seasons (Mckenna et al., 2020), we calculated the in-phase Pearson correlation coefficient  
231 between the detrended precipitation anomaly and DMI for the SON season. The statistical significance of the  
232 correlation coefficient is tested using the Student t-test ( $\alpha = 0.05$ ). Note that IOD could exist as part of ENSO  
233 (Allan et al., 2001; Baquero-Bernal et al., 2002) and their coexistence could have strong impacts on rainfall  
234 variability over many parts of SEA (D'arrigo and Wilson, 2008; Amirudin et al., 2020), which is not investigated  
235 in this study.

236 Previous literature has often focused on assessing the robustness of rainfall teleconnections (e.g., spatial patterns  
237 and amplitudes) across CMIP model ensembles. These assessments typically involve examining agreement in the  
238 sign of teleconnections such as through rainfall anomaly composites (Langenbrunner and Neelin, 2013) and  
239 regional average teleconnection strength over land (Perry et al., 2020) or a combination of both (Power and  
240 Delage, 2018) rather than evaluating the skill of an individual model. However, since rainfall teleconnections  
241 across SEA exhibit spatial and seasonal variability, the above metrics may be substantially influenced by internal  
242 variability. For high level qualification, we employ spatial correlation and simplified metrics to assess whether  
243 there are significant correlations teleconnections as recommended by Liu et al. (2024). We assess the similarity  
244 in the number of grid points detecting significant signals between observed and modelled teleconnections using a  
245 set of three metrics: Hit rate (HR), Miss Rate (MR) and False Alarm rate (FAR) as follows:

$$246 \text{HR} = \frac{\text{Area with correct sign of significant correlation}}{\text{Area with significant correlation in OBS}}$$

247  $MR = \frac{\text{Area with significant correlation in OBS but with no significant correlation in model}}{\text{Area with significant correlation in OBS}}$

248  $FAR = \frac{\text{Area with no significant correlation in OBS but with significant correlation in model}}{\text{Area with no significant correlation in OBS}}$

249 These metrics allow us to make sure that the model adequately simulates significant signals across the entire  
250 region. While HR ranges from 0-1, MR and FAR vary. A desirable model outcome includes a high HR value  
251 coupled with a low MR and FAR value, indicating the model's ability to adequately capture the significance of  
252 the correct signal in the right region (on grid scales) of teleconnections between ENSO and IOD and rainfall  
253 pattern.

### 254 **2.3. GCM independence assessment and future climate change spread**

255 Model independence could be assessed based on model components (e.g., shared atmospheric, land, and/or ocean  
256 models) and/or model output patterns. In this study, we employ both methods for testing GCM independence.  
257 Table 1 provides information on the principal components of the models used in this study. Note that model  
258 independence based on this criterion could depend on the model version (e.g., the same model with different levels  
259 of complexity). In addition, we acknowledge that the spatial pattern of error maps and future changes maps seem  
260 to correlate well with model dependency (Knutti et al., 2010; Knutti and Sedláček, 2013; Brunner et al., 2020;  
261 Brands, 2022). Therefore, we determine the independence of GCMs simply by calculating the correlation  
262 coefficient of historical biases and future projections between models and then apply a hierarchical clustering  
263 approach (Rousseeuw, 1987) to this correlation matrix to group models. This cluster analysis has been employed  
264 in previous literature for multiple purposes, e.g., to assess model dependency (Brunner et al., 2020; Masson and  
265 Knutti, 2011), spatial patterns of climatology and trends in climate extremes (Gibson et al., 2017) or spatial pattern  
266 of precipitation change signals (Gibson et al., 2024).

267 Note that historical biases are calculated by comparing the climatology of total rainfall over the land area of SEA  
268 for the 1951-2014 period with corresponding data from an observed reference. Meanwhile, for future signals, we  
269 focus on the relative change (in percentage) between the far future (2070-2099) and the baseline (1961-1990) as  
270 suggested by the World Meteorological Organization (WMO). All analyses are conducted for two seasonal  
271 periods: wet MJJASO and dry NDJFMA seasons.

272 We use the coarsest resolution (i.e., NESM ~216 km or 1.9°×1.9° resolution) among 32 GCMs as the target  
273 resolution for comparison. All data are interpolated into a spatial resolution of 1.9°×1.9° using a first-order  
274 conservative regridding method (Jones, 1999) to better capture the spatial discontinuity of precipitation  
275 ((Contractor et al., 2018).

276 Benchmarking CMIP6 GCMs against observations is conducted over land for precipitation and the  
277 teleconnections between precipitation and modes of variability while 850-hPa winds from ERA5 allow the  
278 comparison to also be extended over the ocean.

279 Hereafter, we select APHRODITE as the primary baseline for all the main figures, as it utilises the greatest number  
280 of rain gauges of any dataset. We include the results related to all other observational datasets in the  
281 Supplementary section (Fig. s3-8) and provide a detailed explanation of related results in the main text for  
282 intercomparison purposes.

## 283 3 Results

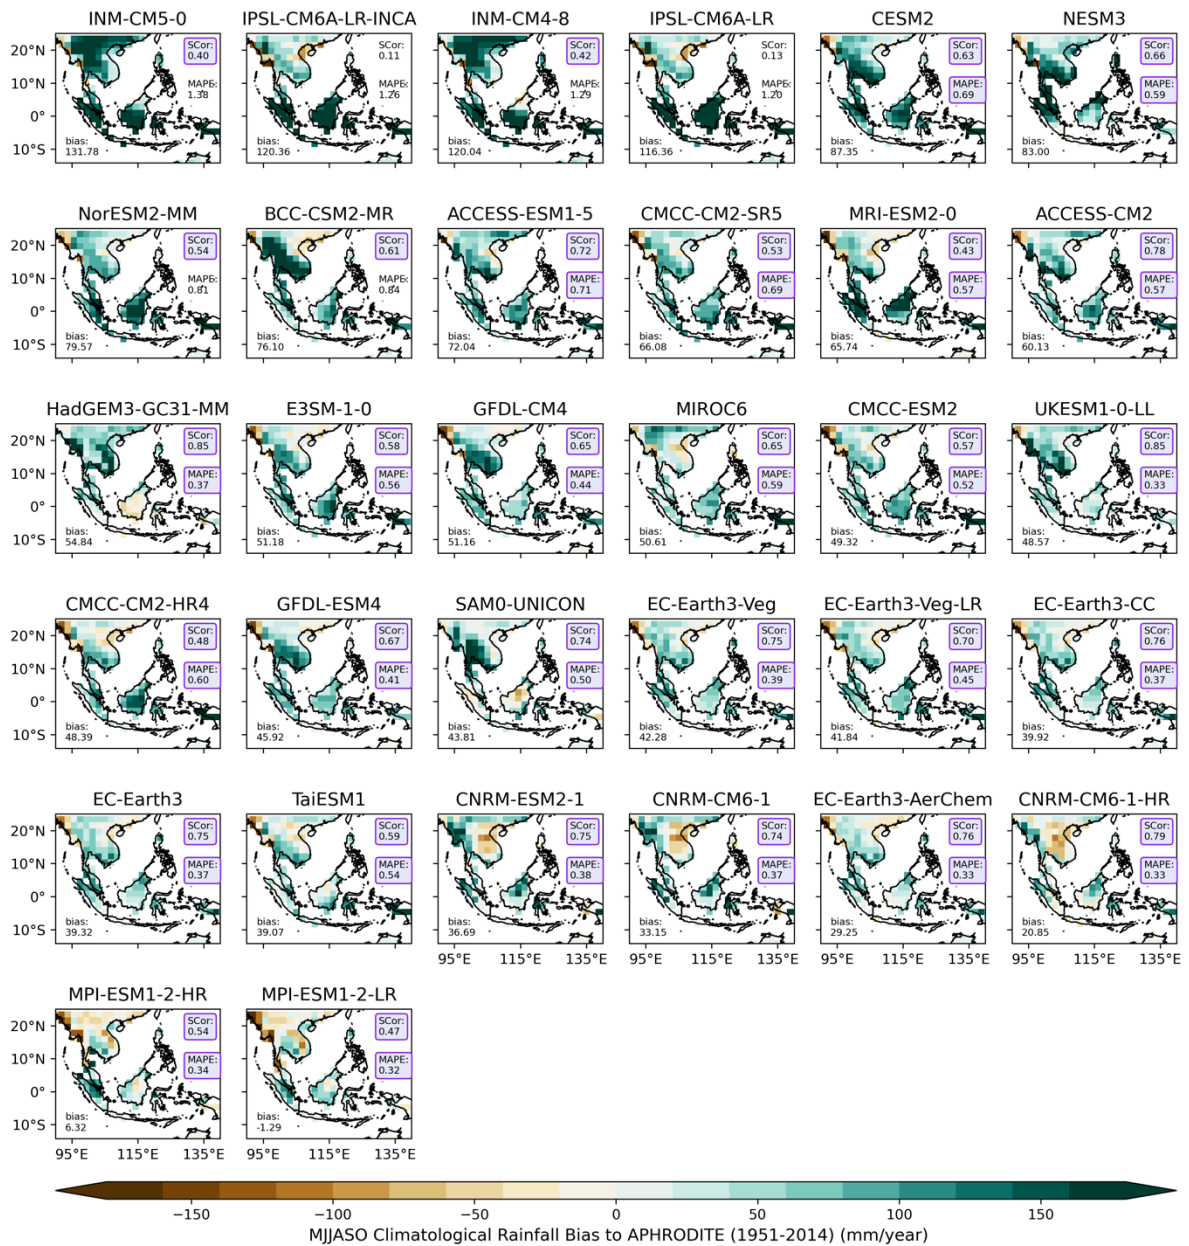

### 284 3.1 Minimum Standard Metrics (MSMs)

#### 285 3.1.1 Mean absolute percentage error (MAPE) and Spatial correlation (Scor)

286 We initially assess the performance of CMIP6 GCMs in reproducing the spatial distribution of precipitation, using  
287 the first two MSMs: MAPE and Scor. Previous studies have emphasized strong seasonal and regional contrasts in  
288 rainfall distribution over Southeast Asia (Nguyen et al., 2023). Therefore, we focus on comparing the seasonal  
289 climatology (1951-2014) of total rainfall during wet days (e.g., precipitation  $\geq 1$ mm) between models and  
290 APHRODITE for both wet MJJASO and dry NDJFMA seasons (Fig. 2 and Fig. 3 respectively). For MSMs, our  
291 strategy is to retain as many models as possible. We establish benchmarking thresholds based on the requirements  
292 of downscaling CMIP6 from CORDEX communities and our understanding of reasonable model performance  
293 based on current scientific understanding. In particular, GCMs should adequately produce the spatial distribution  
294 of rainfall and without a strong wet or dry bias. In addition, we also identify observational uncertainties through  
295 inter-comparison of multiple precipitation datasets. Considering variations in model performance across seasons,  
296 we also set different thresholds for benchmarking models for different seasons. In particular, due to a better  
297 model's ability to capture spatial variability of precipitation during the dry season compared to the wet season  
298 (Desmet and Ngo-Duc, 2022), we adopt a more lenient approach by relaxing our expectation for a spatial  
299 distribution metric, setting the Scor threshold  $\geq 0.4$  for the wet season and  $\geq 0.75$  for the dry season. However,  
300 for the MAPE score, we apply a stricter criterion, as we require models to closely simulate observed rainfall  
301 intensity over SEA. For both wet and dry seasons, we set the benchmarking threshold for MAPE at  $\leq 0.75$ . With  
302 this threshold, our objective is to identify models capable of capturing the spatial variability of rainfall across at  
303 least 40% (Scor  $\geq 0.4$ ) or 75% (Scor  $\geq 0.75$ ) of the domain during wet and dry seasons respectively, with a  
304 wet/dry bias of no more than 75% compared to observations (MAPE  $\leq 0.75$ ) for both seasons.

305 We first discuss key features of the wet season (MJJASO; Fig. 2). Models are ranked from wettest to driest based  
306 on their regionally-averaged climatologies (i.e., the average of accumulated precipitation over all land grid points  
307 inside the domain). Models that meet our benchmarking thresholds for MAPE and Scor (i.e., calculated against  
308 APHRODITE) are highlighted by purple-coloured boxes. In general, CMIP6 GCMs demonstrate a wet bias in  
309 terms of regional averages, ranging from 6.32 mm/year to 131.78 mm/year except for MPI-ESM1-2-LR (-1.29  
310 mm/year). However, there is spatial variability in the distribution of wet and dry biases. While most of these  
311 models consistently show wet biases over MC, dry biases are observed in different locations on the mainland  
312 across models [e.g., along the west coast (e.g., EC-Earth, IPSL and CMCC families) or east coast (e.g., CNRM  
313 family) as well as in some northern regions (e.g., MPI family)]. Among the wettest GCMs, including INM, IPSL,  
314 NorESM2-MM and CESM2 family, the largest biases are predominantly over MC. Interestingly, most CMIP6  
315 GCMs can capture the spatial variability of rainfall (Scor is around or greater than 0.5), except for the IPSL-family  
316 simulations (Scores of 0.11 and 0.13). Using the threshold definitions mentioned above, six models fail to meet  
317 these benchmarks, exhibiting obvious grouping by GCM group. For example, IPSL-CM6A-LR and IPSL-CM6A-  
318 LR-INCA fail due to their low Scor (0.13 and 0.11 respectively) and high MAPE (1.20 and 1.26 respectively).  
319 While INM-CM5-0 and INM-CM4-8 models meet our set expectation in relation to spatial variability, they fail  
320 to meet the MAPE threshold due to their overestimation of rainfall across the entire region (e.g., MAPE ranging

321 from 1.29 to 1.38 respectively). All mentioned failed models exhibit high MAPE values, ranging from 0.81 to  
 322 1.28.

323

324 **Figure 2.** The seasonal climatological (1951-2014) bias (in mm/year) for each model against the APHRODITE observational  
 325 product during the wet season (May-October; MJJASO), ranked wettest to driest based on regionally-averaged bias. The mean  
 326 absolute percentage error (MAPE) and spatial correlation (SCor) calculated against APHRODITE are shown in the upper right  
 327 corner. Values highlighted in purple-coloured boxes indicate values that meet our defined benchmarking thresholds. All  
 328 analyses are considered at the resolution of the coarsest CMIP6 GCM (i.e., NESM3, ~ 216km).

329  
330

**Figure 3.** Same as figure 2 but for the dry season (Nov-April; NDJFMA).

338  
339  
340

The corresponding results for the dry season reveal some interesting features (Fig. 3). First, there are substantial similarities in the spatial distribution of climatological rainfall biases across models during this season. CMIP6 GCMs consistently show small biases over Indochina and large wet biases over MC. A better spatial correlation with observations (i.e.,  $Scor > 0.8$ ) is obtained during the dry season, consistent with previous findings [e.g., CORDEX-CMIP5 RCMs (Nguyen et al., 2022) or CMIP6 GCMs (Desmet and Ngo-Duc, 2022)] in highlighting the dependence of model performance on the season. With improved performance in capturing the spatial variation of total precipitation intensity compared to the wet season, all models meet our expected performance in spatial variability. However, INM- and IPSL-family models still fail the MAPE criterion since they exhibit much higher precipitation intensity than APHRODITE, particularly over MC. Note that over SEA, APHRODITE is drier than other precipitation products particularly over MC (Nguyen et al., 2020).

341 It is important to note that whether a model passes or fails the benchmarking is strongly dependent on the choice  
 342 of threshold as emphasised in Ispording et al. (2024). For instance, more simulations would fail this test if we  
 343 set a higher threshold of Scor, notably for the MJJASO season case.

### 344 3.1.2. Seasonal cycle

345 In this section, we follow the simplified method developed by Ispording et al. (2024) in quantifying the phase  
 346 and structure of the seasonal cycle. In particular, we rank total monthly precipitation from wettest to driest. We  
 347 then define the benchmarking threshold such that the four wettest and driest observed months must fall within the  
 348 six wettest and driest months simulated by models (Fig. 4).

349

350 **Figure 4.** The climatological (1951-2014), average total monthly rainfall over the mainland Southeast Asia are ranked from  
 351 driest to wettest for each CMIP6 simulation. Brown shades (1-6) indicate the six driest months while teal colours (7-12)  
 352 indicate the six wettest months. The models failed in benchmarking are highlighted in orange colour. All analyses are  
 353 considered at the coarsest CMIP6 GCM (i.e., NESM3, ~ 216km).

354 Overall, most CMIP6 GCMs reproduce the phase well but tend to overestimate precipitation intensity, notably for  
355 the observed precipitation peaks during boreal summer (Fig. s3). The INM- and IPSL-family simulations stand  
356 out, consistent with the wettest biases observed in spatial patterns (section 3.1.1).

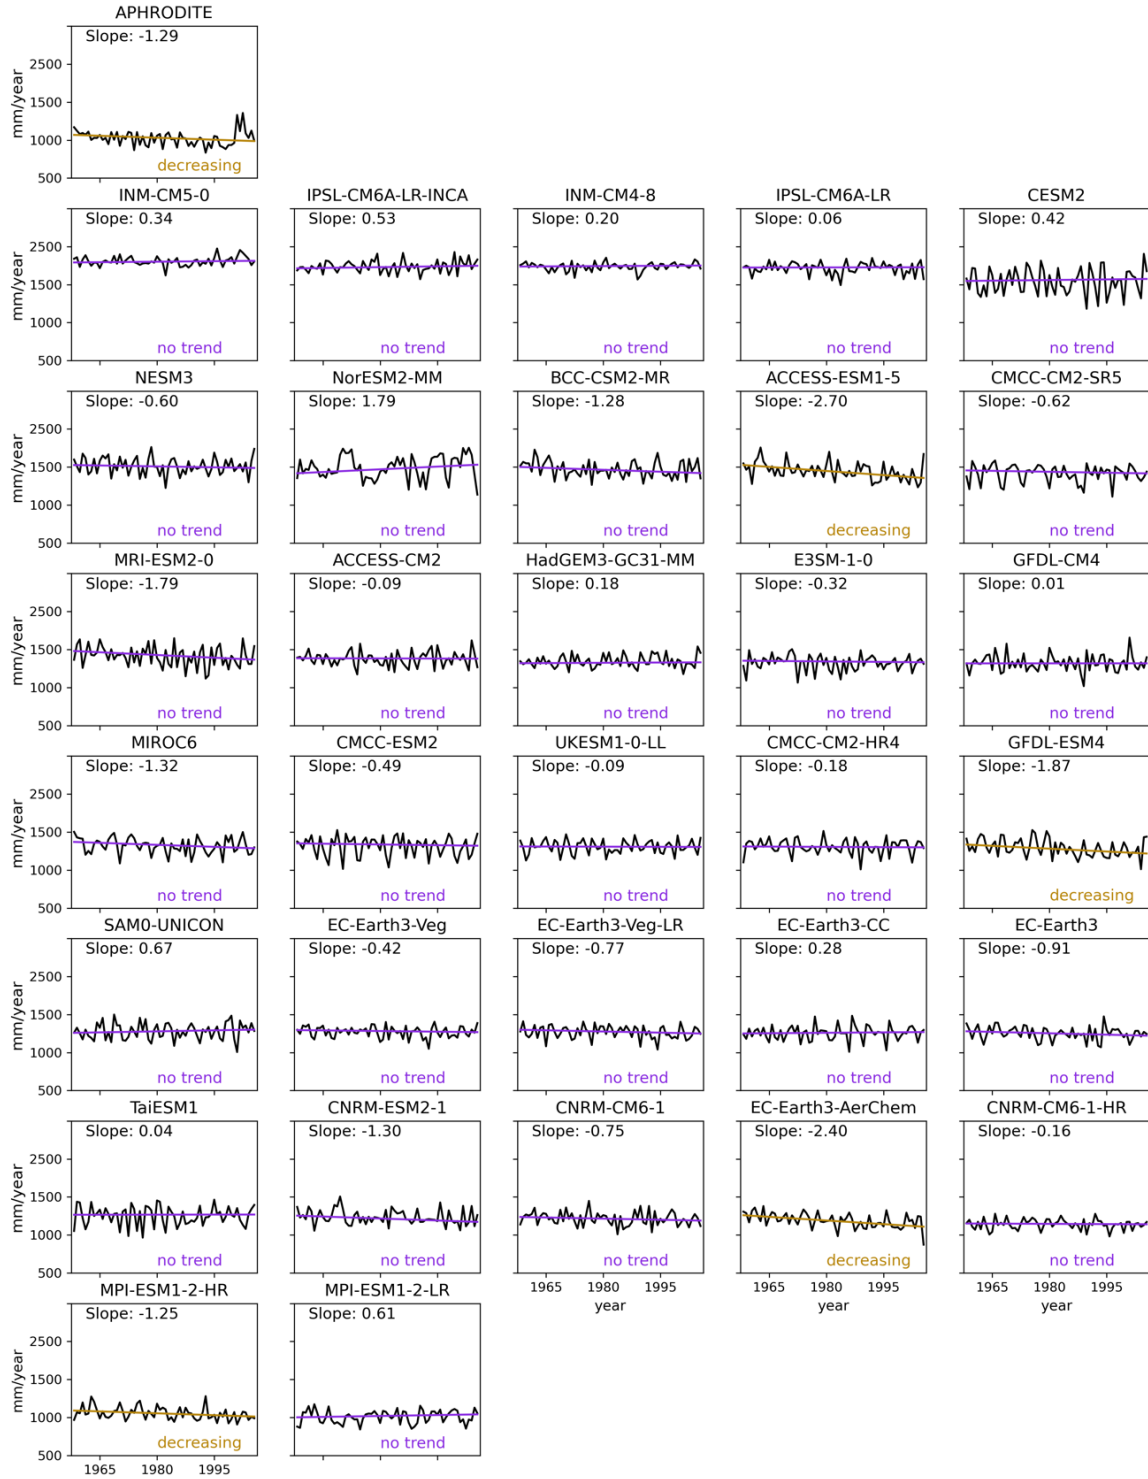

357 According to the benchmarking threshold definitions, all models meet the benchmark for simulating the four  
358 wettest observed months. However, six models do not pass the benchmark for simulating the four driest observed  
359 months, as highlighted in orange in Fig. 4. Specifically, one of the four driest months according to the  
360 APHRODITE dataset (December through March) is ranked as the sixth wettest month (ranked 7th in Fig. 4) by  
361 these models.

### 362 **3.1.3. Significant trend**

363 The final MSM aims to explore how rainfall changes over time (Isphording et al., 2024). In this part, we compare  
364 the signal of statistically significant simulated and observed trends using the wet (Fig. 5) and dry (Fig. 6) seasons  
365 accumulated precipitation. A Theil-Sen trend is calculated over a 65-year period (1951-2014) and tested at a 5%  
366 significance level using a Mann-Kendall significant test (Kendall, 1975).

367 There is a significant decreasing trend in observed total precipitation during the wet season (Figure 5 – top panel)  
368 while the dry season has a significant increasing trend (Figure 6 - top panel). A model fails this benchmark if it  
369 exhibits an opposite significant trend to that of the observations. Using this definition, all models pass this  
370 benchmark during the wet season, but MRI-ESM2-0 and MPI-ESM-1-2-HR fail during the dry season.

371 Note that AR6 [Chapter 8 (Douville et al., 2021)] stated much more confidence in precipitation trends over MC  
372 after 1980. Therefore, we conducted an additional trend calculation (figures not shown) over the 33-year (1982-  
373 2014) period for all considered observational products. Although there are differences in the slope of changes  
374 among observational products, their direction (not shown) remains the same as the 1951-2014 period.

375

376

377

378

379

380

381

382

**Figure 5.** The observed (top row) and modelled seasonal average total precipitation across Southeast Asia land areas during the wet season (May-October, MJJASO) for the period 1951-2014. The direction of the observed Thiel-Sen trend is the benchmark (top row). The Thiel-Sen trend line for each of the simulations is plotted in grey if the models fail the benchmark and in purple if they pass. The magnitude of the trend is noted in the top middle corner and the results of the Mann-Kendall significance test is noted in the bottom right corner. Models are sorted based on the magnitude of the spatial average to match the order of Figure 2. All analyses are considered at the coarsest CMIP6 GCM (i.e., NESM3, ~ 216km). All models pass the benchmark.

383

384

385 **Figure 6.** Same as Figure 5 but for the boreal dry season (November – April, NDJFMA).

386 Table 3 summarizes the MSM benchmarking results for the 32 CMIP6 GCMs tested. There are 19 simulations

387 that pass all MSMs and therefore meet the minimum requirements for the purpose of this study.

388 **Table 3.** Summary of model performance against the MSMs for precipitation. Models pass the benchmarks are highlighted  
 389 in bold.

390 While the BMF was designed for precipitation, we can also apply the MSMs to other climate variables such as  
 391 annual mean near-surface temperature (see Supplementary Fig. s4-7 and Tables s1). For temperature, we use the  
 392 APHRODITE daily temperature datasets [version V1204R1 and V1204XR (Yatagai et al., 2012)] that span 1961–  
 393 2015. In general, CMIP6 GCMs show biases for average temperature, with a greater number of GCMs exhibiting  
 394 cold biases rather than warm biases (Fig. s4). Almost all models succeed in simulating the observed spatial

395 distribution (e.g., Scor greater than 0.75), phases (e.g., no model fails the benchmarking for temperature annual  
396 cycle, Figures s5-6) and historical trends (e.g., increase trend, Fig. s7) of temperature. Overall, models are better  
397 at simulating temperature characteristics (e.g., spatial pattern, annual cycle, and trend) than precipitation over  
398 SEA. Out of four models that fail the MSMs for near-surface temperature, two INM-family simulations do not  
399 meet the expected spatial distribution benchmark ( $\text{Scor} \geq 0.85$ ) while CNRM-CM6-1-HR and NESM3 show the  
400 largest relative errors compared to APHRODITE ( $\text{MAPE} = 0.08$ ). These four models also fail in MSMs for  
401 precipitation, as discussed above.

## 402 **3.2 Versatility metrics – Process-oriented metrics**

403 In addition to the MSMs, our aim is to select a subset of GCMs for dynamical downscaling that simulate  
404 precipitation mechanisms. Therefore, in the next steps we focus on process-oriented metrics which capture the  
405 relationship between precipitation and other variables well.

### 406 **3.2.1. Monsoon wind**

407 We seek to identify models that adequately depict the low-level circulation over SEA during two prominent  
408 seasons: boreal summer (June-September; JJAS) and winter (December-February, DJF), by comparing them to  
409 ERA5 (Fig. 7 and 8 respectively). To measure the agreement between simulated and observed wind patterns in  
410 terms of intensity and direction, we employ three metrics: Scor; MAPE and MD (see section 2.2.3) and we set the  
411 benchmarking threshold for each metric in dealing with limited simulations at this versatility stage. In particular,  
412 we define the threshold for wind intensity as  $\text{MAPE} \leq 0.65$  to seek models that do not overestimate the amplitude  
413 of monsoon wind. In terms of wind structure, we set a stricter benchmarking threshold for Scor as  $\geq 0.70$ , aiming  
414 to retain models that adequately represent the distribution of wind intensity across the whole region. Recognizing  
415 that wind magnitude might be the same at a location, but different directions could substantially impact rainfall  
416 patterns, we consider a threshold for direction MD as  $\leq 20$  degrees. This criterion helps to eliminate models where  
417 high-speed wind direction deviates significantly from observed patterns.

418 During summer, ERA5 shows westerly winds flowing from the Bay of Bengal into Indochina, then deviating  
419 northward to the northern Philippines (along 10N). Concurrently, easterly winds from Australia traverse MC and  
420 Papua (see Fig. 7). Conversely, in winter, the wind patterns are largely reversed (Fig. 8). The easterly and north-  
421 easterly winds from the north pass through the Philippines, reaching the southern coast of Vietnam and the  
422 Malaysian peninsula, while westerly winds predominate between the Indonesian islands towards Papua.

423 Overall, the subset of CMIP6 GCMs capture the circulation structure relatively well (Scor ranging from 0.72 to  
424 0.92 for DJF and from 0.81 to 0.95 for JJAS) but tend to overestimate the wind intensity relative to ERA5,  
425 particularly over high-speed wind areas. For example, the westerly component from the Bay of Bengal during  
426 JJAS or the easterly component over MC during DJF is too strong compared to ERA5. These might link with the  
427 wet biases discussed in section 5.1. Interestingly, all MSM-selected models for precipitation capture the direction  
428 of the main components of JJAS monsoon flow well.

429

430 **Figure 7.** The spatial distribution of the climatology (1979-2014) of low-level wind circulation during the summer (JJAS)  
 431 (vectors) in ERA5 reanalysis (highlighted by red title) and for individual simulations selected using MSM. All analyses are  
 432 considered at the coarsest CMIP6 GCM (i.e., NESM3, ~ 216km). Shading indicates the magnitude of wind (in  $m\ s^{-1}$ ). The  
 433 mean absolute percentage error (MAPE) and spatial correlation (Scor) calculated against ERA5 are plotted in the upper right  
 434 corners respectively. The mean of difference in wind direction (MD) referenced to ERA5 is shown in the lower left corner.  
 435 Values highlighted in purple-coloured boxes indicate that they meet our defined benchmarking thresholds. Models are ranked  
 436 from highest to lowest values of MD.

437

438 **Figure 8.** Same as Figure 7 but for the boreal winter wind (December-February, DJF)

439

440

441

442

Using the definition of benchmark thresholds mentioned above, all models meet our expectations for wind intensity (MAPE) during the summer season but two fail for the winter season (i.e., MAPE of 0.79 for CMCC-CM2-HR4 and 0.69 for MIROC6). Interestingly, only one model fails in benchmarking for wind spatial distribution and direction: CNRM-ESM2-1 (MD is 21.67 during DJF, Fig. 8).

443

### 3.2.3 Rainfall teleconnections with modes of variability

444

447

448

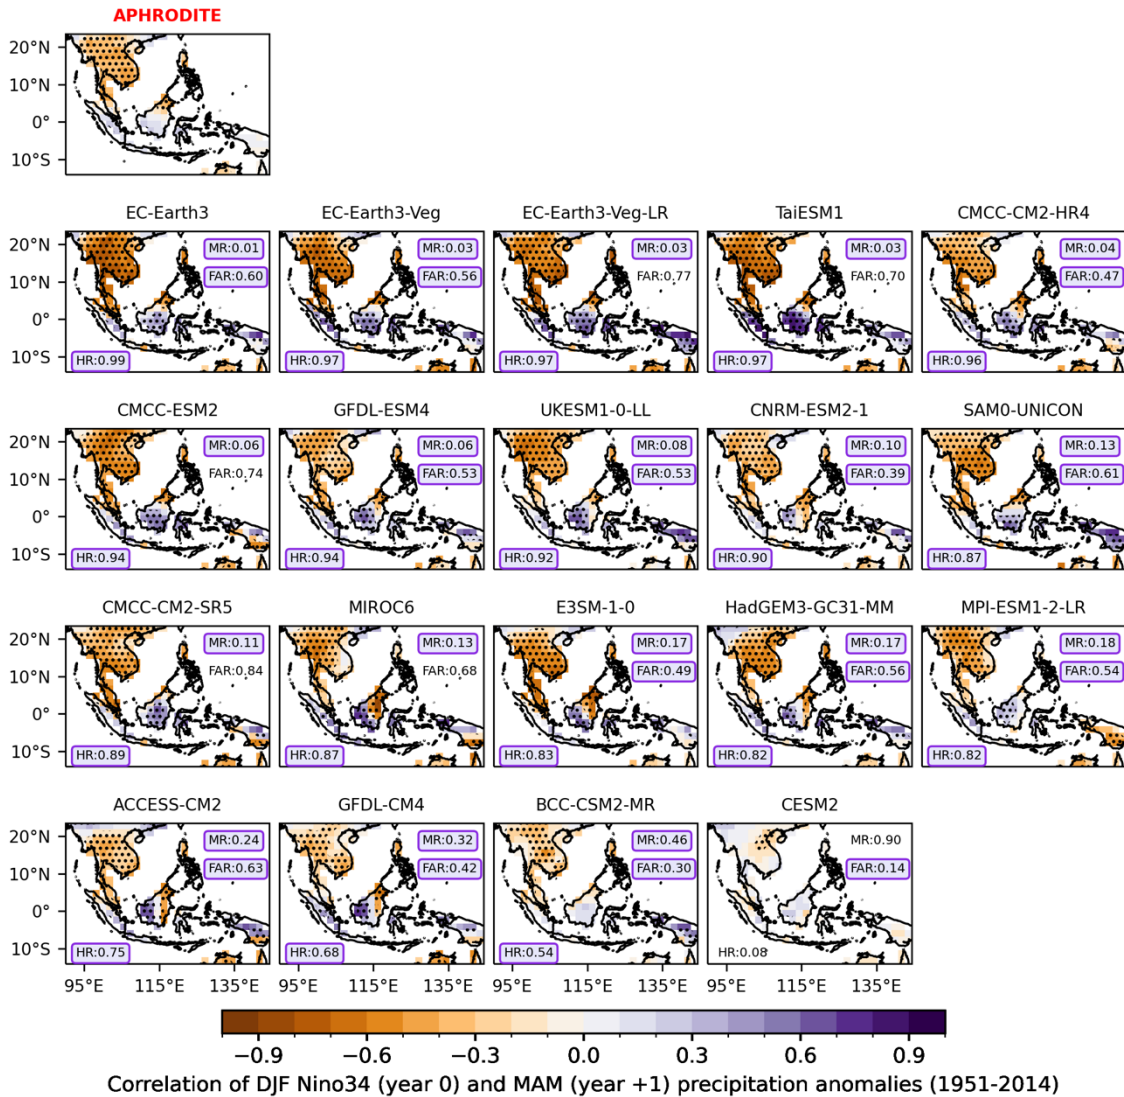

The rainfall teleconnection for DJF ENSO is examined for two different seasons: the extended summer season of the developing year (MJJASO of year 0) the boreal spring of the following year (MAM of year +1) while the precipitation-IOD teleconnection is analysed for boreal autumn (SON). To benchmark CMIP6 GCMs, three metrics (HR, MR and FAR, see section 2.2.3) are calculated for each GCM considering the thresholds  $\geq 0.5$  for HR and  $\leq 0.65$  for MR and FAR, given the limited number of simulations used at this stage.

449

450 **Figure 9.** Lead correlation coefficients of the boreal summer (May-October, MJJASO year 0) rainfall with the mature phase  
 451 of ENSO (December-January-February, DJF year 0 of Niño3.4 indices) for observations from APHRODITE with HadISST;  
 452 individual CMIP6 GCM models during the period 1951-2014. The stippling indicates the grid points where the correlation  
 453 coefficient is statistically significant at 95% confidence level according to the Student t-test. The Hit Rate (HR), Miss Rate  
 454 (MR) and False Alarm Rate (FAR) calculated against APHRODITE are shown in the bottom left and upper right corners  
 455 respectively. All analyses are considered at the coarsest CMIP6 GCM (i.e., NESM3, ~216km). Values highlighted in purple-  
 456 coloured boxes indicate values that meet our defined benchmarking thresholds. Models are ranked from highest to lowest  
 457 values of HR.

458 The results for observations and CMIP6 GCMs selected from MSMs are shown in Fig. 9-11 respectively. The  
 459 observed teleconnections vary widely by region and season. In general, ENSO-induced summer rainfall variability  
 460 is dominant over MC (e.g., Sumatra and Java, Fig. 9), while spring variability is dominant over Indochina,  
 461 northern Borneo and Philippines (Fig. 10), which agrees with the evolution and seasonal circulation migration  
 462 mentioned in previous literature (Juneng and Tangang, 2005; Supari et al., 2018; Wang et al., 2020). On the other  
 463 hand, IOD-induced rainfall variability is more pronounced during the SON season over MC (Fig. 11).

464

465 **Figure 10.** Similar with Figure 9 but for the lag correlation coefficients the mature phase of ENSO (December-January-  
 466 February, DJF year 0 of Niño3.4 indices) with the boreal spring (March-April-May, MAM year +1) rainfall for (a) observations  
 467 from APHRODITE with HadISST; (b)-(k) individual CMIP6 GCM models during the period 1951-2014. Models are ranked  
 468 from highest to lowest values of HR. All analyses are considered at the coarsest CMIP6 GCM (i.e., NESM3, ~ 216km).

469 CMIP6 GCMs (Fig. 10) demonstrate reasonable accuracy in simulating the spatial distribution of the ENSO  
 470 teleconnection, but tend to overestimate its strength, particularly over regions where observed temporal correlation  
 471 coefficients are non-significant. During MJJASO of the developing year, most models successfully reproduce  
 472 significant negative signals over MC (e.g., high HR values ranging from 0.66 to 0.7 and low MR values less than  
 473 0.4). During boreal spring of the following year (MAM of year 1), the ENSO-signals in CMIP6 GCMs match the  
 474 observed pattern better than those during MJJASO of the developing year (Fig. 9), particularly over Indochina.  
 475 Higher values of HR and lower MRs are found in most CMIP6 GCMs. This is consistent with previous literature  
 476 that highlight that GCMs tend to overestimate ENSO variability across much of the equatorial Pacific (Mckenna  
 477 et al., 2020) produce a poor representation of the ENSO life cycle (Taschetto et al., 2014; Mckenna et al., 2020)  
 478 and interaction between ENSO and IOD (Mckenna et al., 2020; Planton et al., 2021). Note that certain models  
 479 consistently perform well across seasons, such as EC-Earth3-Veg, EC-Earth3-CC, GFDL-ESM4 or HadGEM3-  
 480 GM31-MM while others, like BCC-CSM2-MR and CESM-2, exhibit less favourable performance in capturing

481 ENSO teleconnections over the region (Fig. 9 and 10). Eight out of 19 models, including the EC-Earth3 family,  
 482 ACCESS-CM2, E3SM1-0, GFDL-ESM4, HadGEM3-GCM31-MM, MPI-ESM1-2-LR, SAM0-UNICON, UK-  
 483 ESM1-0-LL meet the ENSO teleconnection benchmark. Among models that did not pass the benchmark, many  
 484 indicate an overestimation of observed non-significant ENSO signals (FAR) over the mainland during the  
 485 MJJASO of year 0 (e.g., FAR of CMCM-CM2-HR, TaiESM1 and GFDL-CM4 is 0.76, 0.75 and 0.72 respectively)  
 486 or over MC during MAM of the following year (e.g., FAR of CMCC-CMS-SR5, EC-Earth3-Veg-LR and CMCC-  
 487 ESM2 are 0.84, 0.77 and 0.74 respectively).

488  
 489 **Figure 11.** Correlation coefficient of the boreal autumn (September-October-November, SON) rainfall with IOD (DMI)  
 490 indices for observations from APHRODITE with HadISST and for individual CMIP6 GCMs during the period 1951-2014.  
 491 The stippling indicates the grid points where the correlation coefficient is statistically significant at 95% confidence level  
 492 according to the Student t-test. The Hite Rate (HR), Miss Rate (MR) and False Alarm Rate (FAR) calculated against  
 493 APHRODITE are plotted in the bottom left and upper right corners respectively. Values highlighted in purple-colored boxes  
 494 indicate values that meet our defined benchmarking thresholds. Models are ranked from highest to lowest values of HR. All  
 495 analyses are considered at the coarsest CMIP6 GCM (i.e., NESM3, ~ 216km).

496 Interestingly, the precipitation-IOD teleconnection shows some notable similarities among the 18 CMIP6 GCMs  
 497 considered at the versatility metrics stage (Fig. 11). Most models capture the significant negative correlation over  
 498 Java and southern Borneo, resulting in high HR values (ranging from 0.58 to 0.75). An exception is CESM2,

499 which produces non-significant signals over the entire region (Fig. 11). Interestingly, models that demonstrate  
500 weak performance in simulating ENSO teleconnections (e.g., BCC-CSM2-MR, CESM2 and CNCC-CM2-HR)  
501 also struggle to accurately simulate the IOD teleconnection. Using the same threshold definitions as established  
502 for assessing the ENSO teleconnection, we identify 14 out of 18 models that pass the benchmarking for IOD-  
503 teleconnection.

504 **Table 4.** Summary model performance against the versatility metrics that focused on precipitation drivers and modes of  
505 variability (ENSO and IOD teleconnections). Models that meet or exceed the benchmarks are highlighted in **bold**. All analyses  
506 are considered at the coarsest CMIP6 GCM (i.e., NESM3, ~ 216km).

507 Given the large observational uncertainty, particularly in rainfall estimation over the region (Nguyen et al., 2020;  
508 Nguyen et al., 2022), we apply the BMF using different reference datasets while maintaining a consistent  
509 benchmarking threshold definition. This evaluation identifies a similar list of models meeting the minimum  
510 standards of performance (Table s1). However, exceptions are noted, for instance, MPI-ESM1-2-LR fails to meet  
511 the MSMs when compared with GPDD\_FDD but passes with other references. Similarly, NorESM2-MM exhibits  
512 varying performance across different observational products. However, even if these two models are included in  
513 the subsequent selection steps, they fail to meet one or more versatility metrics. For instance, MPI-ESM1-2-LR  
514 fails the IOD-teleconnection benchmark (Fig. 11 and Table 4) while NorESM2-MM fails on the ENSO-  
515 teleconnection benchmark; Fig. s9).

516 It is acknowledged that different SST products vary in capturing the teleconnection. Figure s8 indicates the notable  
 517 similarities among SST products in capturing the response of precipitation with modes of variability over SEA  
 518 except for the teleconnection between DJF (year 0) ENSO and MJJASO (year 0) precipitation. However, despite  
 519 the diversity in SST products, the final selection of models passing the BMF remains the same.

520 Table 4 summarises the results of benchmarking 19 CMIP6 GCMs selected from the MSM for the versatility  
 521 metrics. At this point of applying the BMF, we find 8 models (ACCESS-CM2, E3SM1-0, EC-Earth3, EC-Earth3-  
 522 Veg, GFDL-CM4, HadGEM3-GC31-MM, SAM0-UNICON, UKESM1-0-LL) meet our expectations in  
 523 simulating precipitation drivers and teleconnections with modes of variability. This could be due to the fact that  
 524 IOD is an ENSO artefact (Dommenget, 2011).

### 525 3.3 Future climate change signals and model dependence

526  
 527 **Figure 12.** CMIP6 GCM climate change signal (2070-2099 relative to 1961-1990) over mainland Southeast Asia during (a)  
 528 the wet (MJJASO) and (b) the dry (NDJFMA) seasons. The analyses are conducted for the GCMs that simulated at least  
 529 monthly near-surface air temperature (tas) and precipitation (pr) for the SSP-3.70 scenario. Note that some models that did not  
 530 simulate tas or pr for SSP-3.70 (e.g., E3SM1-0, HadGEM3-GCM31-MM, SAM0-UNICON) are not plotted.

531 In this section, we examine the climate change signals from CMIP6 GCMs that provide at least mean temperature  
 532 and precipitation data for the SSP3-7.0 scenario across two distinct seasons (see Fig. 12). Note that some models,  
 533 such as CNRM-CM6-1-HR and EC-Earth3-Veg-LR (listed in Table 1), do not offer the sub-daily data (e.g.,  
 534 atmospheric variables in three dimensions at 6-hour intervals) required for dynamical downscaling at the time of  
 535 writing. Nevertheless, we include these models in our analysis to gain insights into the future climate change  
 536 responses of CMIP6 GCMs. Interestingly, while temperature projections show general agreement of an increasing  
 537 trend (ranging from 2.1°C to 5.1°C), precipitation projections exhibit large variation in both signal and magnitude

538 (ranging from -4.3% to 12.9%). Therefore, we cannot see the linear relationship between the change in regional  
 539 total precipitation and temperature. Among the eight models that pass our BMF a priori expectations, there are  
 540 only five models that provide at least data for monthly near-surface temperature (tas) and precipitation (pre), and  
 541 they are distributed across the wide range of temperature and precipitation signals over SEA. They include: the  
 542 wettest models in both seasons with mid-range projected temperatures [e.g. for the MJJASO season: EC-Earth3  
 543 (10 % and 3.6 °C) and EC-Earth3\_Veg (8.9% and 3.4 °C), Fig. 12a]; a model with the largest increase in  
 544 temperature: UKESM1-0-LL (e.g., 5.1 °C during the MJJASO season); a model with larger response in  
 545 precipitation and lower warming: GFDL-ESM4 (e.g., -11.2 % and 2.5 °C during the MJJASO season) and a model  
 546 with a high-range temperature and mid-range precipitation response: ACCESS-CM2 (e.g., 4.9% and 4.2 °C during  
 547 the MJJASO season).

548  
 549 **Figure 13.** Dendrogram with hierarchical clustering applied for a matrix of spatial correlation coefficient between CMIP6  
 550 climate models for the long-term changes (2070-2099 SSP3-7.0 relative to 1961-1990) in total precipitation during the wet  
 551 season (MJJASO). The matrix is plotted for GCMs that simulated at least monthly near-surface air temperature (tas) and  
 552 precipitation (pr) for the SSP-3.70 scenario only. Models are clustered with the Ward's linkage criterion.

553 The dendrogram and matrix of spatial correlation between CMIP6 GCMs are shown for Southeast Asia for  
 554 climatological bias (Fig. s10-11) and long-term changes (Fig. 13-14) in total precipitation. As before we focus on  
 555 the wet (MJJASO) and dry (NDJFMA) seasons. Historical correlations highlight notable similarities between  
 556 models in historical bias maps (mostly significant and greater than 0.5) except UK-ESM1-0-LL which shows  
 557 poorer relationships with other models (e.g., correlation coefficients with other models are less than 0.5) (Fig s10-

558 11). However, there is higher independence in projection maps compared with that in historical maps. This  
 559 interesting feature needs to be further investigated.

560 Clustering analysis indicates three main spatial change clusters for the MJJASO season, as shown in the  
 561 dendrogram (Fig. 13). This indicates similarities in the spatial pattern of the climate change response maps (e.g.,  
 562 correlations greater than 0.5) not only among models from the same families [e.g., among the MetOffice GCM-  
 563 based family (i.e., UKESM1-0-LL, ACCESS's family)] and in model families that share the same model  
 564 components (e.g., UK-ESM1-0-LL and EC-Earth3 families share the same ocean model of NEMO3.6; Table 1)  
 565 but also in less obvious families like CNRM and INM families or EC-Earth-based and GFDL-based simulations.  
 566 An exception is EC-Earth-Veg-LR which appears in different main clusters compared with other EC-Earth-based  
 567 simulations. As indicated in the MJJASO dendrogram, the BMF-passing models that have data available for  
 568 dynamical downscaling are in two main clusters including: EC-Earth3/ EC-Earth-veg/ GFDL-ESM4 and  
 569 UKESM1-0-LL/ ACCESS-CM2.

570  
 571 **Figure 14.** Similar to figure 13 but for the dry season (November – April, NDJFMA).

572 Figure 14 indicates two main spatial change clusters in the dry season. Interestingly, some models from the same  
 573 family (e.g., EC-Earth3 and EC-Earth-Veg) still belong to the same main cluster but span different branches of  
 574 the dendrogram. This might be related to the different role of internal variability in determining the level of  
 575 uncertainty for precipitation during different seasons and needs further investigation. Interestingly, among models  
 576 that pass the BMF, EC-Earth3 and EC-Earth-veg appear on a main cluster while UKESM1-0-LL, ACCESS-CM2

577 and GFDL-ESM4 are in the other main cluster for the NDJFMA dendrogram. This highlights the dependence of  
578 clustering analysis on the season.

579 We acknowledge that a model's good performance in simulating historical climate conditions does not necessarily  
580 guarantee similar accuracy in future climate projections, a well-recognized issue in climate modelling (Herger et  
581 al., 2019). However, there are no arguments in the literature suggesting that models with weaker skill in simulating  
582 historical climatology perform better in future projections. On the contrary, we believe that models demonstrating  
583 good performance in both statistical and process-based metrics are more likely to provide credible future  
584 projections given their proven ability to accurately simulate the physical mechanisms responsible for generating  
585 rainfall in the region.

586 In general, based on our evaluation of model performance, model dependence and future climate change spread,  
587 we identify two independent groups of models to use for dynamical downscaling over SEA, that is, EC-Earth3/  
588 EC-Earth-Veg, ACCESS-CM2/UKESM1-0-LL. Models from these two groups also offer atmospheric variables  
589 in three dimensions at 6-hour intervals required for dynamical downscaling (Table 1). Given the inconsistency of  
590 classification of GFDL-ESM4 during different seasons and metrics, it is suggested to consider GFDL-ESM4 with  
591 caution.

#### 592 **4 Discussion**

593 Our results somewhat differ from traditional model evaluation studies like Desmet and Ngo-Duc (2022), which  
594 ranks models by evaluation metrics and identifies a list of the best models including EC-Earth3, EC-Earth3-Veg,  
595 CNRM-CM6-1-HR, FGOALS-f3-L, HadGEM3-GC31-MM, GISS-E2-1-G, GFDL-ESM4, CIESM-WACCM  
596 and FIO-ESM-2-0. First, rather than ranking models, our aim is to retain models that meet our predefined  
597 expectations (e.g., benchmarking thresholds). Second, the list of examined models is different since we especially  
598 focus on models with a resolution greater than 2 degrees to avoid the impacts of coarser resolutions in GCMs on  
599 dynamical downscaling. Furthermore, while Desmet and Ngo-Duc (2022) combine model performance in  
600 simulating surface climates (e.g., precipitation, near-surface temperature) and climate processes (e.g., low-level  
601 atmospheric circulation), our focus is solely on precipitation, its drivers and teleconnections with modes of  
602 variability.

603 We acknowledge that the list of models passing the BMF might change, depending on how the benchmarking  
604 thresholds are defined. Isphording et al. (2024) notes that the definition of the benchmarking thresholds for the  
605 MSMs and versatility metrics can be subjective, and they should be chosen to fit the purpose of the study while  
606 incorporating strong scientific reasoning. The strategy employed here involves defining the benchmarking  
607 thresholds based on our knowledge of observational uncertainty over the region. In addition, we aim to give each  
608 model the 'benefit of doubt', thus retaining a broad range of plausible future climate change responses. In  
609 particular, in the initial step of the BMF framework, we are generous in defining the benchmark threshold for the  
610 wet season given the lower model performance compared with the dry season. This approach results in 19 out of  
611 32 models passing the MSMs. Subsequently we employ versatility metrics to cover a more process-based  
612 assessment. Given previous studies have highlighted the overestimation of GCMs in simulating precipitation  
613 drivers and its teleconnections and limited possible simulations at this stage, we also set relaxed thresholds for

614 various metrics to maximize the number of models passing the BMF. We feel this is a pragmatic approach to  
615 retain a reasonable sample size and explore plausible futures. However, we acknowledge that dynamical  
616 downscaling experiments often require significant computing resources and only a small subset of GCMs should  
617 be pre-selected. Therefore, we narrow down our selection of 8 GCMs for further assessment using metrics related  
618 to model dependency and future climate change spread.

619 Previous studies suggest the potential impact of smoothing the extreme values when interpolating to coarser  
620 resolutions, which might affect the skill score metrics used to measure percentage errors in a simulation relative  
621 to a reference (i.e., MAPE). Although we observe a higher number of failed models for the same skill when  
622 conducting the BMF at the GCM original resolutions (Table s4), we identify a similar subset of models meeting  
623 all minimum performance requirements (Table s4). This suggests that the coarser resolution of ~210 km used for  
624 benchmarking is not the main reason behind the results of quantifying model skill used in this study. This is in  
625 line with Nguyen et al. (2022), where they demonstrate that model components (e.g., configurations in different  
626 schemes) are the main reason behind the model biases rather than model resolution.

627 The relationship between model structures and model biases is investigated in the model dependency section using  
628 cluster analysis. We acknowledge that grouping of models might change for not only for considered periods and  
629 seasons (as discussed in section 3.3) but also for considered metrics. Interestingly, using mean percentage changes  
630 as distance measure between models, we identify similar main clusters of EC-Earth3/ EC-Earth-Veg and  
631 ACCESS-CM2/ UKESM1-0-LL among models that passing the BMF (Fig. s12-s13). This subset of models is  
632 suitable for dynamical downscaling over Southeast Asia.

633 The customized BMF implemented in this study offers a consistent framework for model evaluation across the  
634 whole CORDEX-SEA domain. The framework can be further developed and applied extensively to sub-regions  
635 of interest, in particular within the upcoming Climatic hazard Assessment to enhance Resilience against climate  
636 Extremes for Southeast Asian megacities (CARE for SEA megacities) Project of CORDEX-SEA. In this project,  
637 each mega city can identify their climate priority and the associated metrics for selecting a fit-for-purpose subset  
638 of models. This framework could also be implemented in impact-related projections over SEA, for particular  
639 sectors: agriculture, forestry, water etc. for credible future projections.

## 640 **5 Conclusion**

641 In this paper, we apply the insight gained from the CMIP6 selection process for dynamical downscaling across  
642 various CORDEX-domains to Southeast Asia by encompassing several critical factors: model performance, model  
643 independence, data availability and the spread of future climate change projections.

644 Rather than exhaustively evaluating all performance aspects of the models in simulating the Southeast Asian  
645 climate, our focus is on selecting models that simulate precipitation well, including its drivers and teleconnections  
646 given the high uncertainty in rainfall projections over the region. In addition, we apply a novel standardised  
647 benchmarking framework – a new approach in identifying a subset of fit-for-purpose models that align with a  
648 user's a priori performance expectations. This framework has two stages of assessment: statistical-based metrics  
649 and process/regime-based metrics, conducted for both wet (MJJASO) and dry (NDJFMA) seasons.

650 From the first step we identify 19 GCMs that meet our minimum criteria for simulating the fundamental  
651 characteristics (e.g., bias, spatial distribution, seasonality, and trends) of seasonal rainfall. GCMs generally exhibit  
652 wet biases, particularly over the complex terrain of the Maritime Continent. These models then undergo a second  
653 evaluation, focusing on their ability to simulate climate processes and teleconnections with modes of variability.  
654 While these models consistently capture atmospheric circulation and teleconnections with modes of variability  
655 over the region, they exhibit a tendency to overestimate their strength. Ultimately, our framework narrows down  
656 the selection to eight GCMs that meet our model performance expectations in simulating fundamental  
657 characteristics of precipitation, key drivers, and teleconnections over Southeast Asia. There are obvious high-  
658 performing GCMs from allied modelling groups, highlighting the dependency of the subset of models identified  
659 from the framework. Consequently, additional tests on model independence, data availability for the SSP 3-7.0,  
660 and the spread of future climate change are conducted. These tests lead to the identification of two independent  
661 groups of models (e.g., EC-Earth3-Veg/EC-Earth3 and ACCESS-CM2/UKESM1-0-LL) that align with our a  
662 priori expectations for dynamical downscaling over CORDEX-SEA. It is recommended that only one model from  
663 each group be chosen to avoid models that are too closely related.

#### 664 **Code availability**

665 Codes for benchmarking the CMIP6 GCMs performance (Isphording, 2024) are available from  
666 <https://doi.org/10.5281/zenodo.8365065>

#### 667 **Data availability**

668 Data used in this study is available through:  
669 CMIP6 GCMS at the Earth System Grid Federation (ESGF):  
670 <https://esgf.nci.org.au/projects/esgf-nci/>.  
671 ERA5 (Hersbach et al. 2020): <https://doi.org/10.24381/cds.bd0915c6>.  
672 OISST version 2.1 (Huang et al. 2021):  
673 <https://www.psl.noaa.gov/data/gridded/data.noaa.oisst.v2.highres.html>.  
674 ERSST version 5 (Huang et al. 2017):  
675 <https://www.ncei.noaa.gov/pub/data/cmb/ersst/v5/netcdf/>.  
676 APHRODITE version V1101R1 and V1101 XR (Yatagai et al., 2012):  
677 <https://www.chikyu.ac.jp/precip/english/index.html>.

#### 678 **Author contributions**

679 RNI built the BMF used in this research. PLN applied and developed the BMF for the region of interest, performed  
680 the analysis and prepared the original manuscript. LVA, MJT, SCHN and JLM supervised the research, reviewed  
681 and edited the manuscript.

682 **Declaration of Competing Interests**

683 The authors declare that they have no known competing financial interests or personal relationships that could  
684 have appeared to influence.
